Dr. Rose is not a mere blind enthusiast for education, unable to see the other factors which have made for the commercial progress of Germany. On the contrary, he gives due weight to the system of protection, the orderly habits inculcated by the universal system of military service, and other matters which contribute in this direction; but after doing this he is still compelled to recognise the great part played by the German technical high schools in the industrial development of the nation.

The object of this article is to compare the condition of technical education in the United Kingdom with the condition in the country with which Dr. Rose deals; unfortunately, the comparison is one calculated to give Englishmen little satisfaction.

In this country we have a fairly large number of technical institutions with many thousands of students; indeed, in numbers only, it is probable that we should compare not unfavourably with our German cousins. But when we look more closely into the statistics we find that in most of these institutions the majority of the students are attending evening classes only, and that of this majority a very large number are engaged in work of an exceedingly elementary character. If one considers the day students and restricts oneself to those who are above the very low minimum age of fifteen, it is found that, counting not merely the technical institutions, but also the universities and university colleges, the total number of day students for the United Kingdom amounted in 1901 to less than 4000. The corresponding total for the German Empire was, in 1902, nearly 15,000.

These figures, as they stand, are sufficient to show how very backward we are in this country in the matter of higher technical education; but, when we bring into the comparison the ages and previous education of the students of the two countries, we see that the above figures by no means adequately show how far we are behind the foreigner in the matter of training. For it must be remembered that, with very few exceptions, all students in German technical high schools commence their studies when they are not less than eighteen years of age, and after passing with credit a nine years' course of instruction in secondary schools. We may estimate that of the 4000 students over fifteen in institutions in the United Kingdom providing technical education in the daytime, at least 1400—probably considerably more—were under eighteen; this reduces us to 2600 students to compare with the 15,000 of Germany.

Nor is this all; for, while the majority of the German students pursue their course of study for at least three years, and in many cases for four, in this country only a very small proportion proceed beyond two years; thus it was found that in 1901 there were about 400 third or fourth year students taking complete day courses in engineering in the *whole United Kingdom*; at the same time there were in the Berlin Technical High School *alone* more third and fourth year students of engineering than in all the universities and colleges of the United Kingdom put together; moreover, none of these German students were under twenty, while our figures could only be obtained by counting every student of this standing over seventeen.

To what must we attribute our great inferiority in this respect? In the first place to the condition of secondary education in this country; secondly, to the fact that German and American manufacturers believe in technical education, while many of their competitors in this country are still blind to its advantages; and thirdly to the fact that, while our Government contributes with liberality to elementary education, it is exceedingly parsimonious in its dealings with higher education.

First, then, let us look at the question of secondary education. Dr. Rose's report gives an adequate idea of the splendid character of the preliminary training which young Germans receive before they enter the technical high schools or other higher institutions in Germany. The secondary schools to which he refers are accessible to children of intelligence all over the Empire; they are carefully graded so as to overlap one another as little as possible, and every inducement is given to parents to allow their children to pursue a complete course of study. The leaving certificates of these schools confer upon children the right of entry to the universities and technical high schools, while they also form a starting point for those who wish to enter the more important branches of the State service, and confer the right to escape part of the compulsory military training. We may hope that in this country the new education authorities will improve our secondary education. Is it too much to expect that the Government may issue a leaving certificate conferring similar privileges to the German one, and taking the place of the medley of university local, Board of Education, Army, Navy, and Civil Service examinations, and many others, which now hang like mill-stones round the necks of the teachers in secondary schools.

The problem how to make British manufacturers believe in technical education is one which is slowly solving itself, and within the recollection of the present writer an improvement in this direction has taken place. That the improvement has not been more rapid is partly due to the fact that in this country the imperfectly trained student has been over-confident in his own powers to an extent only explicable by considering the shortness and imperfection of his training. The half-educated, college-trained youth has thus often become a laughing-stock in the shops; he has given his opinions freely, and they have not infrequently been wrong.

In some of the best technical institutions we are altering all this; our students are made to understand that the preliminary training they receive is only a preliminary training, enabling them to acquire more complete knowledge later, but not entitling them to

[1] "Report on the German Technical High Schools." By Dr F. Rose, H.M. Consul, Stuttgart. (No. 591, Miscellaneous Series of Diplomatic and Consular Reports.)

Since this article was written, Lord Rosebery's letter has appeared, foreshadowing the establishment of a technical high school approximately on the Berlin scale in London. But the writer lets the article stand; for one such institution will scarcely suffice for the ultimate needs of the metropolis alone. It may be hoped, however, that similar developments will occur in our other great centres of population.

become critics. Our manufacturers, on the other hand, are learning to value young men who have had a sound training, and it is becoming less and less difficult each year to find suitable places for students of this kind, even though many of the students are prolonging their training longer than was the case some years ago, though still for a far shorter period in most cases than is the case with the German students.

In estimating the amount of assistance which the State gives to higher technical education in this country we are confronted with a serious difficulty, for the institutions in which such education is given are seldom concerned with this work only. The technical institutions spend much of their energy and financial resources on elementary work in evening classes, while in some cases they also include preparatory day departments, which are simply secondary schools of a modern type. In the university colleges which provide higher technical education, such work represents, as a rule, only a small fraction of their activity.

It is, however, quite certain that comparatively little of the grants made to technical institutions and university colleges can be considered as given specifically for higher technical education. Indeed, in so far as the former are concerned, the present policy of the Board of Education is to give high grants for secondary schools and elementary evening classes with numerous pupils, and but little aid to the day classes for adults, which form the most important part of the work of the best technical colleges.

The Scottish Education Department, on the contrary, has recently altered this for Scotland by selecting the institutions at Glasgow, Edinburgh, and Dundee, and putting them in a position of great liberty to develop their higher work, while promising to give aid, not so much for thousands of students doing elementary work as for the high quality of the advanced work done by a smaller number of persons. May we not hope that in England the authorities will soon adopt a similar policy?

As to Germany, Dr. Rose's report mentions the following facts. The Prussian State gave to the Berlin Technical High School alone, in 1871, an annual subvention of 8511*l.*; this grant has been gradually increased until, in 1899, it amounted to 33,675*l.*, while in the same year the total grant to the three Prussian technical high schools reached the sum of 65,350*l.*, being more than half the total revenues of these institutions. But besides these amounts, sums are independently voted by the Prussian Ministry of Finance towards meeting extraordinary expenses incurred for new buildings, machinery, apparatus, &c. If these sums be taken into consideration, we reach the grand total of 121,348*l.* a year. It must be remembered that these figures relate not to the whole of Germany, but simply to the kingdom of Prussia, with an industrial population many times less than that for which we have to provide leaders in the United Kingdom.

One of the tables in Dr. Rose's report shows in a remarkable way the great progress which has been made in the matter of higher education in Germany since the Franco-Prussian War. For the attendance of students at the German universities, technical, agricultural, and veterinary high schools, &c., has increased from 17,761 in 1870 to 46,520 in 1900; or to state the matter in another way, there were in such institutions in 1870 about nine students for every 10,000 male inhabitants of Germany, while in 1900 there were nearly seventeen students for every 10,000 male inhabitants. The rate of increase has been much more rapid in the technical high schools, though the universities also have made progress; the actual figures given by Dr. Rose are:—for the universities, 13,674 students in 1870, and 32,834 in 1900; for the technical high schools, 2928 in 1870, and 10,412 in 1900, irrespective in each instance of students in agricultural and mining high schools and other higher institutions. We see, then, that the attendance at the technical high schools has increased nearly fourfold during the thirty years, while in the same period the university students have become only about two and a half times as numerous.

An important point in Dr. Rose's report is that in Germany the technical high schools are independent of universities, although in some of the largest towns, such as Berlin and Münich, universities and technical high schools both flourish, existing side by side, and in some cases apparently overlapping, but not really so doing, since the object of the two institutions is not the same. The university students may be supposed to seek knowledge mainly for its own sake, while students in technical high schools propose to put their knowledge to commercial uses.

There is no doubt that this separation of technical work from the control of the university professors has been a good thing for both classes of institutions, which are now recognised as of equal standing in Germany by the action of the Emperor, as King of Prussia, followed shortly after by the King of Württemburg, whereby the technical high schools have the right of conferring the degree of doctor of engineering, thus putting them on a par with the universities in this respect. This action was taken notwithstanding the strong opposition of the Prussian universities, and the Emperor at the same time admitted the principals of the Prussian technical high schools to the Prussian House of Lords, and bestowed upon each of them the title of "His Magnificence."

Perhaps the most important lesson to be learnt from Dr. Rose's report is the need for the strengthening of the best technical institutions in England which provide for the training in day classes of our industrial leaders.

The report shows that in Germany higher technical education is concentrated in a limited number of institutions, and these the State makes thoroughly efficient. The result is the gathering into a single institution of such a large number of students that it is possible to provide for them buildings, equipment, and teaching staff on a scale far in advance of anything found here. Thus the teaching staff of the three Prussian technical high schools numbered in 1899 no less than 554, being one teacher for each nine students in attendance. This liberal staffing enables the German teachers to specialise, greatly to the advantage of the country, the students, and the teachers themselves. In Germany a man is not—as is the rule here—expected to deal with the whole range of such enormously wide subjects as, *e.g.* electrical engineering. One teacher has a thorough knowledge of central station equipment, another of telephony, a third of electro-motors, a fourth of electro-plating, and so on.

It is evident, then, that, if we wish our higher technical training to be as good as that of the Germans, we must concentrate our students. But this has been difficult, because our technical education has been so largely in the hands of local authorities; these bodies are naturally anxious to give the highest form of training for many industries within their own limits, but they are not, as a rule, willing to expend the very large sums needed to make this possible; nor would such an expenditure be wise. We have, therefore, in the United Kingdom a comparatively large number of institutions each attempting—for the most part inefficiently—to do the highest work in many branches of technology.

If imperial patriotism would but outweigh local partiality, the sums already available might go further

than they do at present to provide better training for our industrial leaders. In London one may hope that this may be effected by inducing certain institutions to specialise in given directions. To take a case in point, the buildings, equipment, and numerical size of the staff of the Central Technical College might be equal to dealing satisfactorily with one branch of engineering or of applied chemistry. At present the college undertakes nearly all branches, and does it remarkably well, considering the difficulties under which it labours. If all the teaching staff for higher work in London were amalgamated, it would still be inferior in quantity—and, probably, in quality for *specialised* work—to that at Berlin; but it would not be, as is at present the case in the more or less isolated institutions, far too small for the work it is trying to do.

In the provinces the problem is more difficult, but not insoluble, if we are all more anxious for the good of the nation than for the glory of our own town or institution. Elementary technical education is needed in all the towns, but technical colleges are wanted in a few great cities only; and even in these populous centres every important branch of technology cannot be taught with efficiency, because, for a long time, there will be too few students to warrant adequate expenditure. Why should Sheffield and Leeds, *e.g.* both attempt the highest work in metallurgy and mining? Might not Sheffield send, say, its mining teachers and students to Leeds for higher work, and Leeds return the compliment by helping to develop the highest possible training in, say, metallurgy at Sheffield?

The case mentioned is only one instance of a principle which the Government ought to seek to establish generally, and to induce local authorities to adopt by offers of suitable grants in aid of what is really a pressing national need, viz. the development and improvement of our higher technical training. Each of the great cities might be made a centre for the highest training for one or more of our national industries, and the neighbouring cities should be willing to act as feeders to it in respect of this higher work.

Unless some such policy be adopted, there seems but little chance that we shall ever be able to offer a training equal to that available in Germany. For it would require enormous and wholly unnecessary expenditure to develop into a first-class technical high school dealing with many branches of technology, every technical institution and university college which is at present attempting to give some form of higher technical training.

Above all, let us note that both in Germany and America the flourishing technical colleges are not, as a rule, under the control of the universities, but exist side by side with them as co-equal organisations with different aims. To subordinate higher technical education to ordinary academic control would be to make a mistake which our German and American cousins have carefully avoided. Technical institutions might, however, very well become constituent parts of a university, provided, as has, *e.g.* been arranged at Sheffield, that they retain a sufficient measure of self-government. The scheme of Prof. Riedler, which Dr. Rose quotes with approval, would be a very good basis upon which to make a division between the work of our technical institutions and university colleges which exist in the same area, and, to some extent, overlap one another.

The university college might embrace, as Riedler proposes for the universities of Germany, the faculties of law, theology, medicine, philosophy, languages, history, State science, art, mathematics, and natural science; while the technical institutions would on his plan embrace the faculties of engineering, mining, forestry, agriculture, military science, and applied chemistry.

Finally, it may be well to quote the words in which Dr. Rose summarises the results of his extensive inquiries:—"The technical high schools cannot boast of the proud traditions of the old universities, nor are their buildings and institutions regarded with those feelings of gratitude and reverence which a long and honourable career in the service of humanity naturally inspires; but in default of this they can point to an almost perfect organisation and equipment for modern requirements, and to a development within the last forty years almost unparalleled in the annals of educational history." May a similar statement be possible ere long in regard to our own higher technical institutions!

J. WERTHEIMER.

THE TENTH "EROS" CIRCULAR.[1]

"AS an example of needless duplication, fifty observatories agreed to observe the planet Eros during its opposition in 1900, but so far as known, only two or three have made the reductions needed to render their observations of any value." So wrote Prof. E. C. Pickering in April, in his "Plan for the Endowment of Astronomical Research"; and he is not alone in asking, directly or indirectly, when we may expect to have the result of all the work done at the opposition of 1900-1. The tenth Eros circular, dated June 1, appears at the right moment as a provisional reply. It gives the results of equatorial observations at twelve observatories, all compared with the ephemeris; and two splendid series of photographic observations made at Bordeaux and Paris, completely reduced so as to show not only the comparison of the planet's place with the ephemeris, but a series of places for individual stars such as has never been given before. If these two observatories had done nothing else in the two years elapsed since the plates were taken, they might be congratulated on a fine piece of work. Other results will doubtless follow now that these are in print to act as an incentive, and we need have no fears for the ultimate result.

It is, however, well to remember that the opposition of Eros came upon us at a time when our hands were already more than full with the ordinary work of the astrographic catalogue. It was an embarrassing choice whether to put aside the catalogue measures for a time, to finish them before undertaking the Eros work, or to try to do both simultaneously. The various observatories have selected one or other of these alternatives according to the stage which the catalogue work had reached. At Bordeaux and Paris a leisurely programme has been adopted for this work; the French Government has supplied ample means, but the vote has been spread over twenty-five years, and the work will be extended over the same period. It would have been ridiculous to defer the measurement of the Eros plates for any period of this kind, and we imagine the catalogue work has been put aside in order to measure the Eros plates. At Oxford, to take a different case, the catalogue work has been pushed forward rapidly so as to make the best use of the small sum available, and is on the point of completion. The Eros work can then be taken up without undue delay. At other observatories some compromise has doubtless been adopted between these extreme courses. So long as the work goes forward on the lines of least resistance there is no particular need to be anxious; and we welcome the appearance of the tenth circular as an outward and visible sign of the vitality of this research, which some were beginning to accuse of hibernation.

[1] Conférence Astrophotographique Internationale de Juillet, 1900. Circulaire No. 10. Pp. 318 Paris, 1903.)

The results already published tempt one sorely to estimate a provisional parallax. Indeed there is no need to resist the temptation if one keeps the results to oneself, and avoids multiplying provisional results in print which only make confusion. An excellent example of reticence has already been set. This much may be said from experience; if anyone indulges himself by studying the results in the tenth circular, he will find no reason to be dissatisfied with the accuracy of the work.

The circular concludes with 100 pages of tables for facilitating the photographic reductions. Such tables may be thrown into an endless variety of forms according to individual taste; and the differences between any two particular arrangements are not of much importance compared with the great advantage of having the tables published. The thanks of everyone who measures photographs are due to M. Lœwy for his tables in the tenth circular. H. H. TURNER.

NOTES.

WHEN it was announced, a few months ago, that Prof. von Neumayer, the distinguished meteorologist, was about to retire, on account of advanced age and ill-health, from his post of director of the German Naval Observatory at Hamburg, which was under his control for a considerable number of years, the rumour quickly gained currency in usually well-informed circles that his successor would not be a man of science but a naval officer. This rumour was discredited at the time by many people, but it proves to have been quite correct, for during the Kaiser's recent visit to Hamburg for the purpose of unveiling a statue to the Emperor William I., he summoned Captain Herz, of the Imperial Navy, to his presence, and informed him that he had been appointed to the vacant post with the rank of a Rear-Admiral. As the work of the observatory is necessarily so largely scientific, it may at first sight seem strange that a man, who, no matter how able he may be, is not a man of science, should be placed at its head. A similar arrangement, however, has been made in several other cases in recent years—as, for instance, in the construction department of the Navy, which until quite recently was under the supervision of scientific engineers, but is now in the hands of naval officers—and the explanation given is that a man of science in such a position is so overburdened with administrative work—for which, very possibly, he is not well fitted—that he has little or no time for scientific investigation. The naval authorities have, therefore, decided to utilise their investigators wholly for scientific purposes, and to place the work of organisation and administration into the hands of a naval officer who is a man of practical affairs.

A BUST of the late Sir William Flower, F.R.S., will be formally presented to the trustees of the British Museum by the "Flower Memorial Committee" on Saturday next, July 25. The ceremony will take place in the central hall of the Natural History Museum at 1.15 p.m. The bust will be unveiled by the Archbishop of Canterbury as the representative of the trustees of the museum.

PROF. W. J. MCGEE has been elected chairman, and Dr. J. H. McCormick secretary, of the committee of arrangements for the eighth International Geographical Congress to be held at Washington, D.C., in September of next year.

A FEW weeks ago we recorded the unveiling of a monument of Pasteur at Chartres. We learn from the *British Medical Journal* that on July 12 another monument was unveiled in the commune of Marnes-la-Coquette in the presence of many well-known men of science. It was in the district of Marnes-la-Coquette that Pasteur established his laboratory for the study of hydrophobia, and it was there that he died.

THE seventy-first annual meeting of the British Medical Association will be held at Swansea on July 28–31, under the presidency of Dr. T. D. Griffiths. After the delivery of the presidential address on July 28, the Stewart prize will be presented to Dr. F. W. Mott, F.R.S. Dr. F. T. Roberts will deliver an address in medicine, and Prof. A. W. Mayo Robson an address in surgery. The scientific work of the meeting will be conducted in eleven sections—medicine, surgery, obstetrics and gynæcology, State medicine, psychology, pathology, ophthalmology, diseases of children, laryngology, tropical diseases; Navy, Army, and ambulance.

THE Wilts Archæological Society held a meeting at Stonehenge on Friday last, and the Rev. E. H. Goddard gave an account of the raising of the leaning stone. Mr. Story Maskelyne, in thanking Sir Edmund Antrobus for his invitation to visit Stonehenge, said that, by raising the leaning stone, the biggest stone of its kind in England, one of the most important pieces of archæological work he had known had been accomplished. People might quarrel about barbed-wire fences and rights of way, but in his opinion the greatest public right in Stonehenge was the preservation of the monument, and that the present owner was doing to the best of his abilities.

THE long excursion of the Geologists' Association will be made from July 28 to August 4. The head-quarters will be at Berwick-on-Tweed, and in the course of the week the coast at Scremerston, Burnmouth, Eyemouth, and St. Abb's Head, and the country inland along the Whiteadder, the Eildon Hills and Melrose, and a portion of the Cheviot Hills will be visited. Silurian, Old Red Sandstone, Lower Carboniferous, various igneous rocks and glacial drifts will be examined under the direction of Mr. J. G. Goodchild, with Mr. R. S. Herries as excursion secretary.

THE death is announced of Mr. J. Peter Lesley, who from 1872 to 1878 was professor of geology and Dean of the Faculty of Science in the University of Pennsylvania, and was recognised in America as one of the most competent experts on coal and iron mining. From an obituary notice in *Science* (July 3) we learn that he was born in Philadelphia on September 17, 1819, and after graduating at the university in 1838, served on the first geological survey of the State, when he paid especial attention to the coal-deposits. On the abrupt termination of the survey in 1841 he passed through a course of theology, was licensed to preach in 1844, and was for some years pastor of a Congregational church at Milton, Mass. His views, however, underwent some changes, and returning to Philadelphia he again took up geological work, making elaborate surveys of several coal and iron fields in different States. For twenty-seven years he was secretary and librarian of the American Philosophical Society, part of the time holding the geological professorship in Pennsylvania, and in 1874 taking charge also of the second geological survey of the State. This last post he retained until 1893, when he retired to Milton. He died on June 1.

A SEVERE earthquake was felt throughout the island of St. Vincent on the morning of July 21.

WE have received the official *Protokoll* of the third meeting of the International "Commission" for Scientific Aëronautics, which was held in Berlin on May 20–25, 1902.

The meeting was attended not only by the members of the "commission," but also by a large number of delegates from various countries interested in aëronautical investigation. A report of the proceedings has already appeared in this Journal (vol. lxvii. p. 137, December 11, 1902). The opening address by Prof. Hergesell, president of the commission, gives a very lucid summary of the work already attempted in the investigation of the upper atmosphere by international cooperation, and of the general results achieved.

THE scientific balloon ascents on June 4 were made in broad northerly air-current, which covered nearly the whole of Europe. At Itteville (Paris) the balloon rose to 12,840 metres; the temperature at 10,490 metres was $-52^{\circ}.6$ C.; at starting $9^{\circ}.3$. At Zürich, an altitude of 15,750 metres was reached, minimum temperature, $-66^{\circ}.5$; at starting, $10^{\circ}.2$. At Berlin, a temperature of $-53^{\circ}.0$ was recorded at 11,500 metres; at starting, $10^{\circ}.2$. At Vienna, $-43^{\circ}.7$ was registered at 9500 metres; temperature at starting, $15^{\circ}.8$. At Pavlovsk, a kite rose to 4430 metres in the afternoon of June 3, temperature $-11^{\circ}.6$; on the ground, $23^{\circ}.0$. A balloon sent up from Bath rose to about 14,000 metres; it descended in the sea, and the record is not published.

DURING the past week thunderstorms have been prevalent in various parts of the United Kingdom. In the early morning of Saturday last, a sharp storm occurred in the neighbourhood of London, and rainfall exceeding one inch and a half was measured; another storm occurred in the afternoon of that day, and further heavy rainfall occurred in parts of the metropolis. On Sunday severe storms were experienced in the southern counties; in parts of those districts the roads were under water for some time, and much damage was done to crops. The barometer readings were, for several days, generally low and uniform over the whole country, and although the weather has seemed to be "close," the thermometer has been low for the season, the day readings being at times as much as 10° below the average.

DR. D. K. MORRIS, writing in the June number of the *University of Birmingham Engineering Journal*, gives an interesting description of the power transmission installation from St. Maurice to Lausanne. The installation is for the transmission of 5000 h.p. over a distance of 35 miles, and the chief interest in the scheme lies in the fact that high tension direct currents are used in place of alternating or three-phase currents. The choice of this system has enabled a much greater simplicity in switching gear to be attained without any loss in efficiency, which is stated to be as high as 94 per cent. The system is a constant current one, 150 amperes at all loads, the voltage varying with the power transmitted, and reaching a maximum of 22,300 volts. The generators at the St. Maurice power station are designed to generate 150 amperes at about 2000 volts, and are connected in series, more machines being put in circuit as the load rises. The high voltage involves very special precautions in the insulation not only of the machine windings, but also of the machines themselves. The windings are very carefully insulated in the ordinary way, and, in addition, all the active parts of the armature are separated from the support by micanite insulation; the machines are insulated from earth by heavy porcelain insulators in which the lower ends of the foundation bolts rest. The journal contains several other interesting contributions from the pens of students and others, and affords ample evidence of the flourishing condition of the engineering school at the university.

AN interesting and rare case of infection of the mouth and subcutaneous tissues by a parasitic nematode worm is recorded by Mr. Whittles (*Lancet*, May 23). The patient had never been out of England, and the source of infection was surmised to be a pet Pomeranian dog. In a tropical disease affecting the skin, known as "craw-craw," a nematode has been described by Mr. O'Neil (possibly *Filaria perstans*), and the *bilharzia* may cause papillomatous growths.

AN interesting and exhaustive report has been issued by the Worcestershire County Council upon the bacterial treatment of sewage by different methods, the analytical details being supplied by the county analyst, Mr. Cecil Duncan. The conclusion arrived at is that the best method for the treatment of domestic sewage is a closed septic tank with bacterial beds filled with coke, which was found to be better than coal, brick or stone, two bacterial beds being provided to be used alternately to avoid ponding. As regards fish-tests of effluents, it is remarked that the Salmonidæ require a larger quantity of oxygen than the Cyprinidæ. Mr. Duncan gives details of the methods of analysis used, and suggests several modifications of those usually employed. For preparing ammonia-free water for analytical processes he has found that boiling ordinary distilled water with bromine-water (1200c.c. and three drops) for a few minutes is a rapid and trustworthy expedient.

THE first edition of the Kew hand-list of the Coniferæ has been exhausted for some time, and the authorities have published a new edition, which brings up to date the catalogue of species now in cultivation in the gardens. The revision has been undertaken by Dr. Masters, who was also responsible for the first edition. There is a considerable increase in the number of varieties, but only a very slight addition of fresh species.

THE necessity for adopting a uniform system of nomenclature in botany is sufficiently obvious, but at present this desirable condition has not been attained. In the presidential address delivered before the Linnean Society of New South Wales, Mr. J. H. Maiden presents a good summary of the codes which have been drawn up with this object, and enumerates the chief difficulties which confront the systematist.

INSTANCES of the disappearance of uncommon or interesting plants in the neighbourhood of towns are unfortunately only too frequent, so that the gift of a small but particularly rich piece of land, presented by Mr. Willett to the Ashmolean Natural History Society of Oxfordshire, will appeal to all naturalists. The donor desired to perpetuate the name of his famous fellow-collegian, and suggested that the area should be known as the "Ruskin Plot." The unique character of the vegetation is due to the presence of oolite overlying the clay, and these provide the situation required by a number of orchids and sedges. Mr. G. C. Druce, who selected the spot, describes in a small pamphlet the interesting plants which are collected together.

WRITING in the Lombardy *Rendiconti*, Prof. A. Martinazzoli urges the desirability of initiating anthropological observations in the Italian elementary and other schools. In view of the fact that hitherto nothing had been done in that direction, it is to be regarded as an indication of progress that during the last year about six anthropometric laboratories were fitted up in Italy, but it will be a long time before, from this small beginning, results are reached comparable with those achieved in the United States.

The June number of *Biometrika* contains an interesting contribution to the discussion on Mendel's theory of inheritance by Prof. Weldon, in which further difficulties are put forward against the acceptance of the laws as interpreted and amended by Mr. Bateson. Mr. Darbishire gives, in the same number, his third record of the hybrids between waltzing mice and albinos, and Mr. Woods an account of his experiments in breeding rabbits as bearing upon the principles of the same theory. Among other interesting papers there will be found what appear to be preliminary attempts on the part of Mr. Geoffrey Smith to determine the mass relations of nucleus and cytoplasm in Actinosphærium, and of Dr. Warren to determine the relationship between the size of the cell and the size of the body in Daphnia. Further work in this very interesting but difficult field of research is much needed.

The North American representatives of the widely spread group of diminutive ants, known as Leptothorax, are revised by Mr. W. M. Wheeler in the *Proceedings* of the Philadelphia Academy (pp. 215 *et seq*). The small size and concealed position of the colonies of these ants (which in general contain only from 25 to 50 individuals) account to a great extent for our imperfect knowledge of the group.

In the June number of the *American Naturalist* Prof. B. Dean records partial and complete albinism, as well as polychromatism, in the hag-fishes. Since one species of the group is thus proved to possess a definite type of coloration, it is inferred that myxinoids, as a whole, can scarcely differ in this respect from true fishes, in which deep-sea forms are uniformly coloured, while shallow water types are variegated. Hence follows the further inference that the few existing forms are survivors of a once numerous tribe. Later on in the same issue Mr. C. J. Herrick discusses the sense-organs in the skin of fishes, and concludes that those species which possess terminal nerve-buds in the lateral line system of the outer skin detect and taste their food by means of these organs, while those which lack these structures in the skin have the sense of taste confined to the mouth.

An extremely suggestive and interesting paper by Dr. Lewkowitsch, dealing with problems in the fat industry, appears in the *Journal* of the Society of Chemical Industry, vol. xxii. No. 10. The author is of the opinion that a fresh wave of inventive activity is approaching in the various branches of the fat industry, and in his paper points out a series of problems which await solution at the present moment. Industries having for their object the refining of fats and oils, industries in which the glycerides undergo a chemical change but are not saponified, and those industries based on the saponification of fats and oils, are all dealt with in the paper.

The additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*), a Black Hornbill (*Sphagolobus atratus*) from West Africa, presented by Mr. T. Wright; two Arabian Gazelles (*Gazella arabica*) from Sheik Osman, Arabia, presented by Messrs. Wheatley and Glossop, R.N.; a Brazilian Tapir (*Tapirus americanus*) from South America, an Amazonian Manatee (*Manatus inunguis*) from the River Amazon, presented by Mr. Charles Booth; a Grey Squirrel (*Sciurus cinereus*) from North America, presented by the Lady Kintore; a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, a White Stork (*Ciconia alba*), European, deposited.

OUR ASTRONOMICAL COLUMN.

Bright Spots on Saturn.—Mr. W. F. Denning sends us the following approximate times of transit of two bright spots across the central meridian of Saturn, and the times of rising and southing of the planet during the next fortnight:—

1903	Spot "A" h. m.	Spot "B" h. m.	Saturn Rises h. m.	Saturn Souths h. m.
July 25	10 37	—	8 5	12 25
,, 26	—	14 18	8 1	12 21
,, 27	13 47	10 43	7 57	12 17
,, 28	10 12	—	7 53	12 13
,, 29	—	13 53	7 49	12 8
,, 30	13 22	10 18	7 45	12 4
,, 31	9 47	—	7 41	12 0
Aug. 1	—	13 28	7 36	11 56

,, 10	—	12 13	7 0	11 18

The spots are separated by about three hours (=108°) of longitude, and are conspicuous objects when the planet is well defined.

Spectroscopic Observations of Nova Geminorum.—Photographs obtained in April by Prof. Perrine, using the Crossley reflector, show that, despite its reddish colour, the light from Nova Geminorum was rich in actinic rays. They do not show any trace of nebulosity around the star such as was obtained in the case of Nova Persei.

Spectrograms obtained with the small slitless spectroscope attached to the Crossley reflector, show that in the region photographed—$H\beta$ to λ 335—the spectrum somewhat resembles that obtained by Messrs. Wright and Campbell for Nova Persei in April, 1901, and consists of bright lines and bands superposed on a continuous spectrum; these lines are almost all accounted for by the hydrogen lines in that region. $H\epsilon$ and $H\zeta$, as well as the lines at λ 339 and λ 346, were the strongest lines in Nova Persei, but they are very weak in the recent Nova, whereas $H\beta$ and $H\delta$ are strong in the latter but very weak in the former spectrum; the chief nebular line, λ 501, which was conspicuous in the spectrum of Nova Persei, is not shown in these spectrograms of Nova Geminorum. These differences may be due to the different stages of development of the two stars.

A comparison of two spectrograms obtained on April 2 and 8 respectively, show a considerable alteration in the six days interval, particularly in the ultra-violet region, where the continuous spectrum became weaker and the bands at $\lambda\lambda$ 350, 374 and 384 consequently appeared stronger; λ 339 and λ 346 also appeared to have developed. $H\beta$ appeared weaker, and there was a faint condensation in the region of λ 501. This condensation appeared as a fairly well-marked line on a later photograph obtained on May 11. Visual observations showed a strong $H\alpha$ line and a condensation in the region about D_1 and D_2.

An ordinary photograph exposed on April 22, 23 and 24 for 6h. 29m. showed no trace of nebulosity around the Nova.

Reproductions of these region photographs and spectrograms, and a detailed account of the visual and photographic observations of Profs. Reese and Curtis accompany Prof. Aitken's article in Lick *Bulletin*, No. 37.

Measurement of the Intensity of Feeble Illuminations.—M. Touchet, of Paris, has devised an apparatus for measuring the intensities of such feeble illuminations as the Zodiacal Light and the Gegenschein. It is similar in appearance to a theodolite, but has a flame of constant illuminating power so arranged as to illuminate the field through a variable slit. This slit may be opened and closed, like the slit of an ordinary spectroscope, by a screw having a divided head, so that the intensity of the field illumination may be instantly made equal to that of the light it is desired to measure, and readings, which are reducible to a standard, thus obtained (*Bulletin de la Société Astronomique de France*, July).

THE GERMAN ROYAL NAVAL OBSERVATORY.—The twenty-fifth annual volume (1902) of the publications of this observatory, entitled "Aus dem Archiv der Deutschen Seewarte," contains descriptive papers on "The Regulation of Marine Compasses," "A New Free-horizon Astronomical Base Line," "The Definitive Determination of the Path of the Comet Swift (1899.I)," and "The Results of Sextant Tests made at the Observatory.

In addition to the introduction, Dr. Neumayer, the director, contributes an article on "A New Method of Forecasting the Meteorological Conditions of the North Atlantic Ocean," and a novel chart, indicating all the meteorological conditions obtaining in the North Atlantic area during March, 1902, accompanies the volume.

RECENT ADVANCES IN STEREOCHEMISTRY.[1]

IN the year 1803, just a century ago, John Dalton delivered a series of scientific lectures in the Royal Institution during the course of which he doubtless laid before his audience a theory which he had recently devised for the purpose of connecting together the vast number of isolated chemical facts known at the commencement of the nineteenth century. This theory, of which the centenary is being celebrated during the present month by the Manchester Literary and Philosophical Society, is known as the atomic theory, and was destined to form the foundation upon which the whole superstructure of modern chemistry has been built. For our present purpose Dalton's theory may be briefly stated in the form of the following two principles:—(1) Every element is made up of homogeneous atoms of which the mass is constant; (2) chemical compounds are formed by the union of atoms of the various elements in simple numerical proportions. In accordance with Dalton's hypothesis, chemical substances may be mentally pictured by imagining the atoms as small spheres which have the power of aggregating themselves together under suitable conditions to form complexes or "molecules"; thus, taking two similar spheres representing hydrogen atoms, in conjunction with a sphere of a different kind, representative of an atom of oxygen, a chemical representation can be given of the compound water, the molecule of which is composed of two atoms of hydrogen and one of oxygen. The original atomic theory offers no explanation of the observed fact that the atoms combine together in different proportions; this deficiency was remedied by the doctrine of valency enunciated by the late Sir Edward Frankland in 1852. Frankland supposed that the atoms of certain elements, such as hydrogen and chlorine, are unable to combine with more than one atom of any other element; these elements are termed monovalent. Other atoms, such as those of barium and zinc, can become directly attached to at most two other atoms; these are the divalent elements. Tri-, tetra-, penta-, hexa-, hepta- and octa-valent elements can be similarly distinguished, the valency of hydrogen being taken as unity, in order to measure and define the saturation-capacity or the atom-fixing power of the atoms of the other elements. It will be clear that for rough diagrammatic purposes we may provide the spheres representing the atoms with as many wooden pegs as the element itself exhibits units of valency; compound molecules can then be represented by fitting the atoms together by means of the pegs representing the number of valency-units possessed by the various constituent atoms. By so doing a great advance is made upon the atomic theory of Dalton's time, and a mental picture is obtained of the way in which the atoms are connected together within the molecule itself.

During the early part of the nineteenth century it became evident, principally from the work of Liebig and Wöhler in Germany, and of Faraday at the Royal Institution, that substances exist which possess totally different properties, but nevertheless have the same molecular composition; as this became slowly realised, the atomic theory was naturally called upon to furnish some adequate explanation. In view of the proven identity of molecular composition, the required explanation could only be sought for in differences in the atomic arrangement within the molecules of the several substances. That such differences can be successfully illustrated by the aid of the atomic models will be seen on considering some specific case. Ordinary ethyl alcohol and methyl ether differ greatly from each other—the first is a liquid, whilst the second is a gas at ordinary temperatures—but possess the same molecular composition, the molecule in each case consisting of two atoms of carbon, six of hydrogen and one of oxygen. These two substances have to be represented on the assumption that hydrogen is monovalent, carbon tetravalent, and oxygen divalent. By joining wooden spheres together in the order shown in the figures—in which the valencies of the component atoms are carefully respected—diagrammatic representations are obtained which illustrate to the chemist the differences existing between ethyl alcohol and methyl ether.

$$\begin{array}{ccccc} & H & H & \\ & | & | & \\ H- & C & - C & -OH \\ & | & | & \\ & H & H & \end{array} \qquad \begin{array}{ccccc} & H & & H & \\ & | & & | & \\ H- & C & -O- & C & -H \\ & | & & | & \\ & H & & H & \end{array}$$

Ethyl Alcohol. Methyl Ether.

Substances related to each other in this way are said to be isomeric; they have the same molecular composition, but different molecular constitutions. The step in advance which is involved in thus writing molecular constitutions or in constructing molecular models was taken by Kekulé in 1858.

Two great stages in the development of chemical theory have now been indicated. First, that contributed by Dalton, who regarded constancy of molecular composition as characteristic of a chemical substance; secondly, that further stage, attained as a result of the labours of Liebig, Wöhler, Faraday, Frankland and Kekulé, which involved the introduction of the idea that the chemical individuality of a substance is dependent upon its molecular constitution as well as upon its molecular composition. A third great development in the atomic theory had yet to take place.

Whilst the theoretical views which culminated in Kekulé's constitutional formulæ were at first found sufficient to explain numerous observed cases of isomerism, instances soon began to accumulate of substances which exist in so many isomeric forms that the Kekulé method of representation is incapable of accounting for them all. At an early date Pasteur showed clearly that substances exist which have the same molecular composition and the same molecular constitution, but which nevertheless differ in important respects. A crisis was ultimately reached when, in 1870, Wislicenus demonstrated the existence of three isomeric lactic acids, all having the molecular composition $C_3H_6O_3$ and the molecular constitution

$$\begin{array}{ccc} & OH & \\ & | & \\ CH_3- & C & -COOH \\ & | & \\ & H & \end{array}$$

and contended that he had amply proved the insufficiency of Kekulé's method of writing constitutional formulæ.

The step needed to rid the atomic theory of these apparent anomalies was indicated by van 't Hoff and Le Bel in 1874; they pointed out that the weakness of the Kekulé method lies in the tacit assumption that the molecule is spread out upon a plane surface, and that by throwing this assumption aside and taking a rational view of the way in which the molecule is extended in space, all difficulties immediately vanish. The considerations put forward by van 't Hoff and Le Bel form the basis of the subject now known as stereochemistry, the branch of science which deals with the manner in which the atoms are distributed within the molecule in three-dimensional space; they deal, in the first place, with the arrangement of the constituent atoms in the simple organic compound, methane, the molecule of which has the composition CH_4, or consists of one carbon atom and four hydrogen atoms. The Kekulé constitutional formula pictures the component atoms of the methane molecule as if joined together in one plane (Fig. 1), whilst according to the new view, the four hydrogen atoms are imagined situated at the four apices of a regular tetra-

[1] A discourse delivered at the Royal Institution on May 1 by Prof. William J. Pope, F.R.S.

hedron of which the carbon atom occupies the centre (Fig. 2). This is conveniently illustrated with the aid of a few cardboard models.

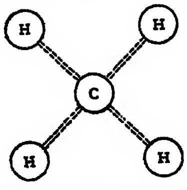

FIG. 1.

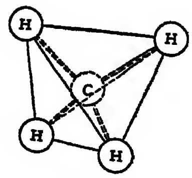

FIG. 2.

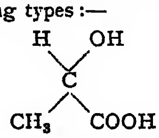
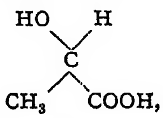
Consider now the result of replacing three of the four hydrogen atoms present in the methane molecule by three different groups of atoms, the three groups CH_3, OH, and CO_2H for example. One of the most striking results which has accrued from the chemical investigation of the past century has been the demonstration of the remarkable rigidity with which the atoms are held together in the molecule; it might therefore be anticipated that by actually making all the isomerides having the constitution indicated above, some means would be afforded of judging whether the van 't Hoff-Le Bel or the Kekulé view forms the closest approximation to truth. Kekulé's constitutional formulæ indicate the existence of two isomeric compounds of the following types:—



and



whilst on the van 't Hoff-Le Bel view, two isomerides of the nature illustrated by Figs. 3 and 4 are indicated; although in each case two isomerides would be obtainable, the examination of the two kinds of figure reveals very essential differences. The solid-figure isomerides differ only in that the one is the image in a mirror of the other—they are related in the same kind of way as a right and a left hand glove. The differences observable between two molecules thus related should consequently not be differences of an ordinary chemical nature, but differences involving merely a kind of chemical, physical and mechanical right- and left-handedness. The two Kekulé constitutional formulæ, on the other hand, would indicate—if they indicate anything—that the substances to which they refer differ in the more gross way in which ordinary chemical isomerides differ in chemical, physical and mechanical respect. That carbon atom which was present in the original methane molecule is, in these new compounds, now attached to four different atomic groups, and such a carbon atom is termed an "asymmetric" carbon atom. It is in the case of substances containing an asymmetric carbon atom that a lack of agreement is observed between the facts and the kind of isomerism indicated by the Kekulé

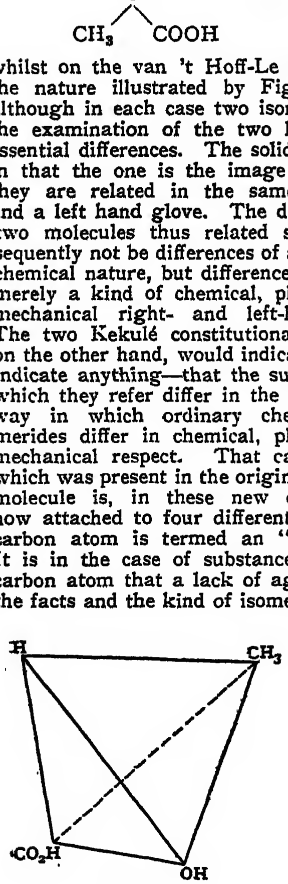


FIG. 3.

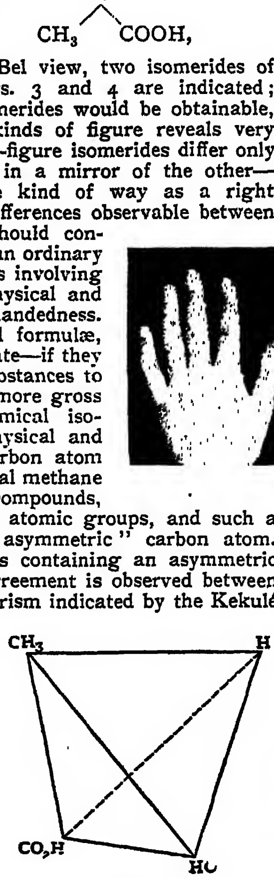

FIG. 4.

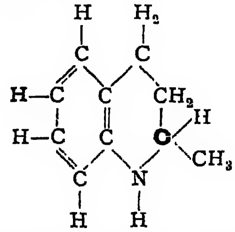
formulæ, and in these cases, also, the species of isomerism indicated by the solid models exhibited is found to correspond closely with the facts.

To illustrate this we may refer to a somewhat complicated substance, termed tetrahydroquinaldine, which has the following constitution:—



and the molecule of which contains an asymmetric carbon atom, that, namely, which is printed in heavy type. Three

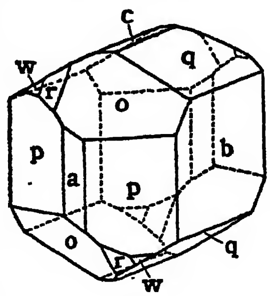


FIG. 5.

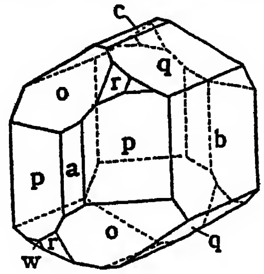

FIG. 6.

different isomeric forms of this substance exist, and are quite indistinguishable by any of the ordinary methods of chemical or physical identification; one of these is a loose kind of compound of the other two, and may therefore be disregarded for the moment. The remaining two have the same melting point, the same boiling point, and correspond exactly in all ordinary properties; they yield, however, series of derivatives which differ in the same sort of way that a right-hand and a left-hand glove differ. Here, for instance, is a diagram showing the shapes of the crystals

FIG. 7.

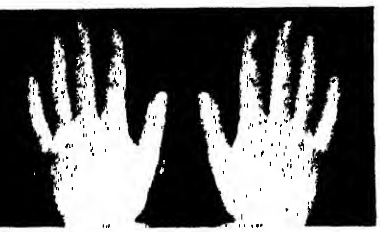

FIG. 8.

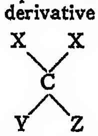
of the salts which these two substances form with hydrochloric acid (Figs. 5 and 6); the crystals obtained from the one base are the mirror-images of those prepared from the other. Any figure which possesses handedness of the kind exhibited by these two crystal figures is termed "enantiomorphous," and two figures which are related to each other as these figures are related are said to be "enantiomorphously related." A hand is thus enantiomorphous, and a right and a left hand are enantiomorphously related, the one being the mirror-image of the other. Here, for example, is a photograph showing a right hand and a left hand side by side (Fig. 7); the pair of hands is exactly reproduced in the next photograph (Fig. 8), which shows a right hand side by side with the photograph of its reflection in a mirror. Just the same enantiomorphous relationship as that existing between the right and the left hand, exists between the molecular pictures of the two lactic acids discovered by Wislicenus, and shown in Figs. 3 and 4.

Reference may now be made to the existence of other differences of an enantiomorphous character between substances which possess enantiomorphously related structures. Early in the last century the French physicists Arago and Biot showed that a number of substances have the power of deflecting the plane of polarisation of a plane-polarised

beam of light thrown through their solutions. Such substances are said to be optically active, and since the deflection of the plane of polarisation may be either towards the right or towards the left, the exhibition of optical activity constitutes an enantiomorphous property; optically active substances are conveniently classified as dextro- and lævorotatory. Van 't Hoff and Le Bel declared that the molecules of all naturally occurring substances which exhibit optical activity when in the fluid state contain asymmetric carbon atoms. All substances the molecules of which contain an asymmetric carbon atom must possess enantiomorphous molecular configurations—similar to those assigned to the two lactic acids—because they exhibit properties of an enantiomorphous character. A very beautiful experiment which the late Sir George Gabriel Stokes devised may be so modified as to serve for the demonstration of optical activity. Stokes's experiment consists in passing a plane polarised beam of light through a tall cylinder containing water which has been rendered very slightly turbid by the addition of a little alcoholic solution of resin; a spectrum is then seen spread out in the column of liquid, and spread out in a way which is not enantiomorphous, the water possessing no optical activity. The modification of Stokes's experiment consists in replacing the non-enantiomorphous water by some enantiomorphous liquid—conveniently by a 70 per cent. aqueous solution of the dextrorotatory cane-sugar, or by a 50 per cent. solution of the lævorotatory fruit-sugar; on making this change it is seen that instead of the spectrum lying in the cylinder vertically, and therefore non-enantiomorphously, it winds spirally or corkscrew-wise round and round the column of the enantiomorphous liquid. The two spirals or helices are clearly enantiomorphous, and the two liquids of opposite optical activity give rise in this experiment to oppositely wound spirals—to spirals which are related to each other like the right- and left-handed corkscrews shown in the lantern slide. The opposite sign of the rotatory power exhibited by the cane-sugar and fruit-sugar solutions is more clearly shown by turning the polarising prism in its mount, when the two spirals turn in opposite directions.

Although cases of optical activity are very frequently met with among chemical substances of animal or vegetable origin, it must be noted that no purely laboratory product or substance prepared without the use of enantiomorphous operations or materials is, in the ordinary way, optically active. The reason of this needs but little seeking, if the solid tetrahedron models are once more consulted. Starting with a non-enantiomorphous substance is equivalent to starting with a methane derivative of the constitution



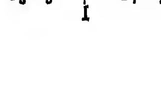
and replacing one of the two X groups by a fourth group Q so as to obtain a compound containing an asymmetric carbon atom. Obviously, unless some power of selection of an enantiomorphous nature is exercised in replacing X by Q, the doctrine of chance will ensure the one X group being replaced the same number of times as the other in an enormous number of tiny molecules. Thus there will result just the same amount of the right-handed optically active substance as of its left-handed isomeride. When an optically active substance is prepared in the laboratory, it is therefore obtained as a mixture of two enantiomorphously related isomerides; such a mixture is said to be compensated, because the right-handedness of the one component is just counterbalanced by the left-handedness of the isomeric constituent. These compensated substances are represented by the third lactic acid and by the third tetrahydroquinaldine previously referred to, but not further discussed.

Since one of the great problems with which chemistry is grappling involves the synthetic preparation of naturally occurring optically active substances, it is of the utmost importance that the chemist should be in possession of working methods for resolving these compensated mixtures into their optically active components. All the kinds of methods applicable to such resolutions necessarily involve the introduction of enantiomorphism—either of method or of material. Three types of methods were introduced by Pasteur, namely, (1) spontaneous resolution by crystallisation; (2) resolution by combination with optically active substances; and (3) resolution by the action of living organisms.

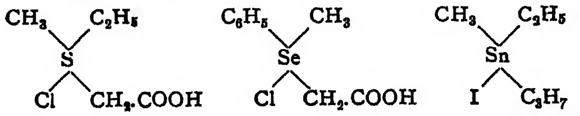
The first method depends upon the fact that on crystallising a compensated substance it sometimes deposits crystals of the dextro- and of the lævo-isomeride side by side, and of such size that they can be mechanically sorted. The enantiomorphous factor determining the separation in this kind of method is obviously the enantiomorphous intelligence which has the power of discriminating between right- and left-handedness. This sort of method is unfortunately but rarely applicable, owing to the fact that two enantiomorphously related substances usually crystallise together in the form of a loose chemical compound.

The second kind of Pasteur method is applicable to the resolution of compensated acids and bases, and depends upon the following considerations. On combining a compensated basic substance, viz. a mixture of *d*-B and *l*-B with an optically active acid—say with *d*-A—a mixture of two salts, namely *d*-B, *d*-A and *l*-B, *d*-A, will be obtained. These salts, however, are not enantiomorphously related, as will be realised on substituting for illustrative purposes a hand for the base and a glove for the acid; the combination *d*-B, *d*-A will then be represented by a right-hand in a right-handed glove, whilst the combination *l*-B, *d*-A will correspond to a left hand in a right-handed glove. The struggles of the left hand with the right-handed glove will not be a factor in determining the behaviour of the appropriately assorted right hand and right-handed glove. So, also, the properties of the substance *d*-B, *d*-A—its solubility, melting point, &c.—will be conditioned by an enantiomorphous relationship of quite a different order from that determining the corresponding properties of the salt *l*-B, *d*-A; the solubilities, being determined by different factors, will naturally also differ, and the two salts will therefore be separable by crystallisation. The first resolution of a compensated base was effected in 1885 by Ladenburg, and consisted in resolving the synthetic alkaloid coniine into its optically active components—one of which proved to be identical with the alkaloid contained in the juice of the hemlock—by crystallising it with dextrotartaric acid. Since this time the methods of resolving compensated bases have been materially improved by the application of optically active acids derived from camphor for use in place of the dextro-tartaric acid, and an experiment in illustration can now be shown on the lecture table.

On adding a solution of ammonium dextrobromocamphor-sulphonate to a solution of compensated tetrahydro-β-naphthylamine hydrochloride, a white crystalline precipitate of dextrotetrahydro-β-naphthylamine dextrobromocamphor-sulphonate—the salt *d*-B, *d*-A—is thrown down, whilst the lævotetrahydro-β-naphthylamine remains in solution as its hydrochloride. The resolution in this, and in many other cases, can be very rapidly effected, and by still further applying the optically active sulphonic acids derived from camphor a considerable extension of the original van 't Hoff-Le Bel theory has become possible. These workers traced all cases of optical activity to the presence of an asymmetric carbon atom, and deduced from their work the conclusion that the environment of the carbon atom in methane is a tetrahedral one. It is true that all the optically active substances which have yet been obtained from natural sources owe their optical activity to the presence of an asymmetric carbon atom, but it is important to note that by applying the second Pasteur method to the investigation of synthetic materials, substances owing their optical activity to the presence of asymmetric atoms of elements other than those of carbon can be prepared. Thus, ammonium iodide has the molecular composition NH_4I, and, like methane, contains in its molecule four hydrogen atoms which are replaceable by other atoms or groups of atoms; on replacing these hydrogen atoms by the four groups of atoms or radicles, methyl, allyl, benzyl and phenyl, a substance is obtained which is conveniently named methylallylbenzylphenyl-ammonium iodide, and has the following constitution:—



On replacing the iodine atom in this molecule by an optically active group of atoms, viz. by the dextrobromocamphorsulphonic residue, two salts are obtained, each of which contains an optically active basic part and an optically active acidic part; these are salts of the kinds *d*-B, *d*-A and *l*-B, *d*-A, and can be separated by crystallisation from a convenient solvent, and, after separation has been effected, each salt may be reconverted into the iodide. These regenerated iodides are found to be optically active in solution, and the conclusion is consequently drawn that optical activity is an attribute of the asymmetric pentavalent nitrogen atom as well as of the asymmetric tetravalent carbon atom. The optical activity of this substituted ammonium compound indicates that its molecule has an enantiomorphous configuration, and is extended in three-dimensional space; the exact nature of this configuration is not yet known, inasmuch as a space arrangement of five groups is concerned, but the environment of the nitrogen atom in ammonium salts is clearly not a simple tetrahedral one. Just as enantiomorphism has been proved to be an attribute of the asymmetric nitrogen atom, we have also demonstrated that asymmetric tetravalent atoms of sulphur, selenium and tin give rise to optical activity; optically active substances having the constitutions shown below have been prepared, and we are thus well on the way towards obtaining a complete stereochemical scheme embracing all the elements:—



It has been mentioned that optically active substances occur as such, rather than in the compensated form, in many animal and vegetable products, and also that when a substance containing an asymmetric carbon atom is prepared synthetically in the laboratory, it is of necessity obtained in the compensated form, or as a mixture in equal proportion of the dextro- and the lævo-isomerides. Taken together, these two facts have a very interesting bearing upon our speculations as to the origin of animal and vegetable life. Optically active substances have been isolated as products of the vital activity of all forms of animal or vegetable life which have been properly examined, but in spite of this they are never obtained directly as laboratory products; some enantiomorphous influence has always to be employed in their synthetic preparation, just as Pasteur applied enantiomorphism, either of method or of material, to the resolution of compensated substances. It was very strenuously argued by Prof. Japp, in his presidential address to the Chemical Section of the British Association in 1898, that no matter how successful we may be in reducing the problems relating to vital processes to mere questions of physics and chemistry, a residuum will always evade explanation by such means; this residuum will involve the discussion of the way in which the first enantiomorphous substance was resolved into its optically active components. This question involves the introduction of an enantiomorphous agency at some period during the evolutionary development of living matter. In attributing difficulty to the solution of this residuary problem, Dr. Japp implies that the enantiomorphous agency, the cooperation of which is essential, must be an intelligent agency. Let us ask ourselves whether the enantiomorphous agency premised is necessarily other than one acting fortuitously. The assumption of a fortuitously enantiomorphous agency is certainly all that need be made to explain the building up of many enantiomorphous systems. The dead universe itself, as we know it, is enantiomorphous, but this fact has never been regarded as a valid argument against the current hypothesis as to the cosmic origin of our planet. Some degree of obscurity is, however, introduced into the discussion of the primitive origin of the optically active substances now produced by animals and plants by the probability that ages of evolution have transformed the primeval optically active substance into multitudes of other and more complex products—have, in fact, accentuated the enantiomorphism to such an extent that physiological chemistry is now almost entirely the chemistry of enantiomorphous substances. If in any particular case, however, we can show that an optically active substance can be locally accumulated by the aid of some enantiomorphous agency acting purely fortuitously, it will be clear that the formation of the first optically active substance was not necessarily the work of an intelligent enantiomorphous agency. Such a species of separation of an optically active substance from a compensated one can be readily brought about in the laboratory. Pasteur showed that on crystallising the sodium ammonium salt of compensated tartaric acid (racemic acid) at ordinary temperature, large crystals separate, each of which consists of the salt of one or other of the *d*- and *l*-tartaric acids, the separation being brought about by the first of the Pasteur methods. If one of these crystals be selected casually, without the exercise of any selective intelligence, and used as a nucleus for inducing the crystallisation of further large quantities of the original solution, it will cause the separation of salt of its own kind, and ultimately a large quantity of salt of one of the optically active tartaric acids can be accumulated as a result of the introduction of an enantiomorphous agency such as might act fortuitously in a non-living universe. The probability of such a fortuitous agency arising would naturally be far greater in a living universe.

Again, suppose that at its origin life were carried on non-enantiomorphously, and that it involved the consumption and the production only of non-enantiomorphous substances and of compensated mixtures; it may well be foreseen that a stage in development might arise when each individual, in view of the increasing complexity of his vital processes, would have to decide to use only the one enantiomorphous component of his compensated food, and so evade an otherwise necessary duplication of his digestive apparatus. Acting unintelligently or fortuitously, one-half of the individuals would become dextro-beings, whilst the other half would become lævo-individuals; the succeeding generations would thus be of two enantiomorphously related configurations. It is, however, very difficult to believe that the natural selective operations which have been instrumental in conducting living organisms to their present stage of development would allow the perpetuation of this state of affairs for any considerable period; some fortuitous enantiomorphous occurrence would temporarily give the one configuration the advantage over the other, an advantage which would be quickly accentuated and would involve the permanent disappearance of the weaker configuration.

The kind of difficulties involved in the existence, side by side, of dextro- and lævo-individuals such as these may be shown by a simple illustration. There is no reason connected with human enantiomorphism why vehicular traffic should be forced to keep to one side of the road rather than to the other; as, however, the conditions of civilised life have gradually become more complex, economic reasons have arisen causing us to make an enantiomorphous selection, and in this country we arbitrarily force the traffic to keep to the left; other countries also make an arbitrary and sometimes a different selection. Even if, when legislation on this matter first became necessary, the population had been equally and obstinately divided upon the question of the rule of the road, we cannot doubt that by this time the question would have been satisfactorily and finally settled by the extermination of one or other of the enantiomorphously inclined parties without the cooperation of any intelligent enantiomorphous agency.

I mentioned that Pasteur gave a third method for the resolution of compensated substances, a method depending upon the selection exercised by living organisms upon the enantiomorphously related components of the mixture. He found, for instance, on allowing the mould *Penicillium glaucum* to grow in a solution containing compensated tartaric acid, that the mould used the *d*-tartaric acid as a food-stuff, and rejected the lævo-isomeride, which latter could ultimately be separated from the solution. The kind of method thus indicated has been applied with success in a great number of cases, and is, in the end, merely a special application of Pasteur's second method. During recent years a considerable change has taken place in our views upon the action of the lower organisms upon their food-stuffs. It was formerly supposed, for example, that the fermentation of sugar by an ordinary beer yeast is a part

of the vital process of the organism itself—that the sugar taken in as food by the organism is finally thrown out in the form of carbon dioxide and alcohol; it is now clear, however, that the formation of these two products is in no way a vital process. By triturating yeast with powdered quartz, so as to shatter the cell walls, and expressing the pulp thus produced, Buchner has succeeded in obtaining a solution which, when mixed with sugar solution, converts the sugar into carbon dioxide and alcohol. The fermentation is therefore not a vital phenomenon, but is a chemical action induced by some non-living substance contained in the expressed juice of the yeast cells. This substance—zymase—has been isolated in the solid state, and belongs to the class of substances known as unorganised ferments or enzymes. Although many enzymes are known, each active in inducing the occurrence of some particular chemical change or changes, nothing is as yet known as to their molecular constitutions; ages of evolution have given such complexity to these substances that a century or less of chemical investigation has contributed practically nothing towards elucidating their nature.

During the investigation of cases of animal and vegetable vital activity, great numbers of instances of the action of enzymes have been found, the function of the enzyme being to bring about the molecular degradation and, in certain cases, the molecular complication, of more or less complex materials used or produced in the organism. As an example of molecular degradation due primarily to enzymic action, the action of zymase on grape-sugar—*d*-glucose—may be quoted. In aqueous solution, one molecule of grape-sugar becomes directly converted into two molecules of alcohol and two molecules of carbon dioxide, in accordance with the equation

$$C_6H_{12}O_6 = 2C_2H_6O + 2CO_2,$$

by the enzyme zymase. The enzyme itself suffers no permanent change as a result of exercising the power of causing this chemical reaction to take place, so that a comparatively minute quantity of the enzyme, acting for a more or less prolonged period, is able to convert an unlimited quantity of grape-sugar into alcohol and carbon dioxide. The power which the enzyme possesses of inducing the occurrence of some chemical reaction which otherwise does not take place is not peculiar to enzymes; many substances, which are all classed together as the so-called catalytic agents, are known to exercise the same sort of influence in assisting a chemical reaction to occur. Thus the action of finely divided platinum in causing certain inflammable gases to ignite in air at the ordinary temperature is a catalytic action. The particular function exercised by enzymes in animal or vegetable life consists in bringing about chemical change, quietly and continuously, without necessitating the application of any violent chemical effects such as we are in the habit of using in the laboratory. Although they proceed so quietly, the chemical changes thus effected are, in certain cases, changes which we have not yet succeeded in carrying out without the assistance of an enzyme; in the conversion of sugar into alcohol and carbon dioxide, zymase is performing a reaction which has never yet been brought about by the use of the ordinary laboratory methods.

Without quoting more specific instances, it may be generally stated that most of the cases of enzymic action hitherto investigated are cases in which a large molecular complex is degraded or broken down into substances of lower molecular weight. But it is important to note that the organism is also the seat of processes which result in the building up of very complex molecules from simpler ones, such, for instance, as the formation of starch from carbon dioxide and water. A specific case in which enzymic action leads to the production of a complex substance from simpler ones has been recently worked out by Fischer and Armstrong, who show that the enzyme, lactase, converts the sugar galactose, $C_6H_{12}O_6$, into a new sugar, isolactose, $C_{12}H_{22}O_{11}$, of nearly twice the molecular weight of the former.

All the enzymes with which we are acquainted appear to be enantiomorphous bodies; they are, perhaps, substances to which no definite molecular composition can ever be assigned, inasmuch as they may be systems consisting of a number of different true chemical compounds, the system being one which becomes endowed with extraordinary chemical activity when placed in a suitable environment. The enantiomorphism of the enzyme has been repeatedly demonstrated during the course of Emil Fischer's remarkable synthetic work on the sugars. Fischer succeeded in preparing fruit-sugar or fructose by purely synthetical methods as a mixture of the dextro- and the lævo-isomerides; in order to isolate the previously unknown *l*-fructose, he applied the third Pasteur method in that he cultivated a yeast in the solution of the compensated fructose. The yeast enzyme—presumably zymase—has arrived at its present stage of development by passing through countless generations, all of which have been fed upon sugars of the dextro-configuration, these being the only ones occurring in Nature. In Fischer's experiment the enzyme therefore readily devoured the *d*-fructose, but refused to touch the *l*-fructose, which had never before been presented to it. The *l*-fructose was, of course, subsequently isolated from the solution. The need for compatibility between the enzyme and the material upon which it has to act is very clearly illustrated by considering the effect of yeast upon a number of optically active and isomeric sugars. In the table (Fig. 9) are given the constitutions of a number of sugars of the composition $C_6H_{12}O_6$, the configurations of the three or four asymmetric carbon atoms present in the molecule being indicated by writing the hydrogen atoms on the right or the left of the figure, as the case may be; the right or left hands indicate which asymmetric carbon atoms are of similar, and which of opposed, configurations.

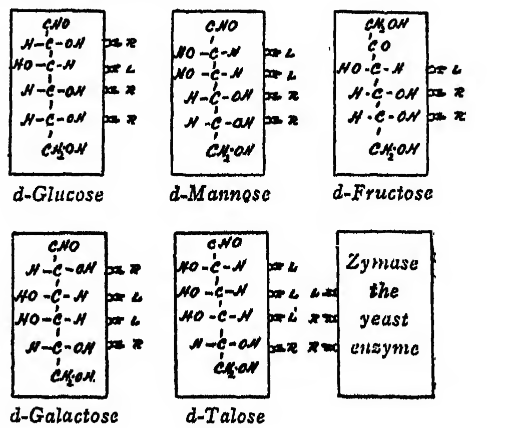


Fig. 9.

The beer yeast ferments *d*-glucose, *d*-mannose and *d*-fructose, each of which contains in the molecule a set of three asymmetric carbon atoms of similar configuration, with about equal readiness; *d*-galactose is, however, only fermented with difficulty—in the set of three asymmetric carbon atoms referred to, it contains one differing in configuration from the corresponding one in the three easily fermentable sugars. *d*-Talose, in which two of the three asymmetric carbon atoms differ in configuration from the corresponding carbon atoms in *d*-fructose, is quite unaffected by the yeast. It is just as if the enzyme were provided with three hands, in the order right, right, left, to enable it to grip the sugar molecule and commence tearing it to pieces; with these three hands it grips the corresponding hands—also of the configuration and order, right, right, left, of the first three sugars. The enzyme can, however, only grip the *d*-galactose molecule by two hands, and so obtains a less firm hold. Owing to the greater incompatibility between the zymase and the *d*-talose, the former obtains too feeble a hold on the latter to enable it to make a successful assault, and the sugar therefore remains unfermented.

The fact that the chemical reactions of animal and vegetable physiology consist, in the main, of the production or destruction of optically active substances through the agency of enantiomorphous enzymes is one of enormous importance. The complex substances concerned, such as starches, albumins and food-stuffs generally, occur in Nature in but

one of the enantiomorphously related configurations; all the albumins are lævo-rotatory, all the starches and sugars are derived from dextro-glucose. Since Fischer's work teaches us that none of the sugars derived from lævo-glucose are fermentable by yeast, it would seem to follow as a legitimate conclusion that, whilst *d*-glucose is a valuable food-stuff, we should be incapable of digesting its enantiomorphously related isomeride, *l*-glucose. Humanity is therefore composed of dextro-men and dextro-women. And just as we ourselves would probably starve if provided with nothing but food enantiomorphously related to that to which we are accustomed, so, if our enantiomorphously related isomerides, the lævo-men, were to come among us now, at a time when we have not yet succeeded in preparing synthetically the more important food-stuffs, we should be unable to provide them with the food necessary to keep them alive.

CHLORINE SMELTING, WITH ELECTROLYSIS.

A PAPER on chlorine smelting with electrolysis was read by Mr. Swinburne at the first meeting of the Faraday Society; as the process described in the paper is of considerable interest, and may one day be of great importance, we give a brief abstract of the paper below.

The process is one for the treatment of complex sulphide ores, such, for example, as the Broken Hill slimes, and is divided into three stages as follows:—(1) the treatment of the ores with hot chlorine, whereby the metals are all obtained as chlorides; (2) the treatment of the mixed chlorides by substitution until finally all the chlorine is combined with zinc; and (3) the electrolysis of the zinc chloride to extract the zinc and recover the chlorine. The first stage of the process is carried out by blowing hot chlorine into the crushed ore in a "transformer"; the essential feature is to avoid the formation of chloride of sulphur.

This involves a careful regulation of temperature and of the rate of feed of the ore; the temperature can be easily regulated by the rate of feed of the ore and chlorine as the reaction evolves a great deal of heat, and the transformer is entirely self-heating. Advantage can be taken of the composition of the ore, as some of the metals have a greater heat of reaction than others; if necessary, a mixture of ores of different compositions can be made so as to give a satisfactory working material. The sulphur is set free and condensed. At the end of a charge the ore feed is stopped, and the excess of sulphides converted to chlorides, after which the fused chlorides are drawn off and dissolved; the gangue having been separated by filtration, the second part of the process begins. This naturally depends on the composition of the ore; lead, silver, and gold are separated with the gangue, and after drying are fused first with lead, which extracts the silver and gold, and then with zinc, which gives lead and zinc chloride, the former practically pure. The filtrate is treated with spongy copper to separate lead and silver, and then with zinc to take out the copper. Iron, manganese, and zinc chlorides are left; the iron is chlorinated up to the ferric state, and precipitated as ferric hydrate by zinc oxide, and further chlorination in presence of the zinc oxide throws down the manganese as peroxide. There is thus left only zinc chloride in solution, and this is evaporated down and fused. To it is added the fused chloride from the lead substitution, and the whole is electrolysed in vats made of iron lined with fire-brick. The heating is internal; the current and the chloride soaking into and solidifying in the fire-brick gives really a vat with zinc chloride walls. Vats taking 3000 amperes have been in use, but these are small, and 10,000 ampere vats are to be tried; the pressure required is less than four volts. The result of the process is pure zinc and chlorine ready for chlorination of fresh ore.

It will be seen that the chief merits of the process are its comprehensiveness, its cyclical nature, and the fact that it turns out pure metals. Obviously it is suited, with only slight modifications, for the treatment of a great variety of ores. The chlorine simply goes round and round; apart from leakage, which, as Mr. Swinburne says, if it would show on the balance sheet would make the works uninhabitable, chlorine can only be lost as chloride of sulphur (a source of loss the inventors claim to have overcome), and as oxychlorides formed in the iron separation and in evaporation of the zinc chloride, neither of great importance if care be taken. The works therefore simply take in ore and electrical energy and turn out metals, sulphur, and gangue. Mr. Swinburne enters at some length into the question of cost, but space does not permit of our following him here; we have said enough to indicate the interesting character of the paper, to which those more specially interested may be referred for further details.

M. S.

THE ROYAL INSTITUTE OF PUBLIC HEALTH.

THE annual congress of the Royal Institute of Public Health was held at Liverpool, July 15–21, under the presidency of the Earl of Derby. The sections met in the various departments of the University College, and were thus closely associated and readily accessible. The proceedings were opened by an interesting address from the Earl of Derby, in which he directed attention to the considerable progress in sanitation that had been made by many ancient civilisations. The Harben medals for 1901 and 1902 were then presented to Sir Charles Cameron and Prof. W. R. Smith.

A combined conference of the preventive medicine and municipal hygiene sections discussed the subject of tuberculosis, and Dr. Nathan Raw read a paper upon "The Prevention of Consumption in Large Cities," in which he expressed the opinion that consumption is frequently conveyed to children by milk from tuberculous cows, though patients in the advanced stage are the greater source of danger to the community. He suggested as means for controlling the disease (1) the establishment of a central office where consumptives might seek advice; (2) the erection of a municipal sanatorium which, for Liverpool, should contain 100 beds, and be within the reach of any needy citizen; and (3) the foundation of a hospital for the poor for at least 100 incurable cases. Several other papers dealing with tuberculosis were also contributed; one, by Mr. McLauchlan Young, who summarised the experiments performed by Prof. Hamilton and himself upon the communicability of bovine tuberculosis to man, and expressed the opinion that there could be little doubt that human tubercle can be readily inoculated upon bovines; another, by Drs. Dean and Todd, upon the communicability of human tuberculosis to the pig, in which the six animals experimented upon were all infected with the human bacillus. Thus there is already an accumulation of evidence against the view expressed by Koch at the Tuberculosis Congress of 1901, that bovine tuberculosis is probably not communicable to man.

In the section of bacteriology and comparative pathology, the president, Prof. Boyce, F.R.S., in his opening address directed attention to the connection between abstract research and the good of the community, instancing the value of bacteriological research to practical medicine, to the farmer, to the water engineer, and to the oyster merchant. A paper by Dr. Savage upon "A Uniform Method of Procedure for the Bacterioscopic Examination of Water," evoked an interesting discussion. He considered the subject under four headings:—(1) the methods of collection and transmission of the samples; (2) the data which it is desirable to ascertain; (3) the processes and procedures of the examination; and (4) the significance to be attached to the results obtained. It was ultimately resolved to form a committee to consider whether it might not be possible to systematise the methods, &c., to be used for the bacteriological examination of water.

Another important discussion, upon "the nature and significance of the pseudo-diphtheria bacillus," was opened by Dr. Cobbett, who expressed the opinion that this organism has nothing whatever to do with the true diphtheria bacillus. Prof. Hewlett stated that he was not yet convinced that the two organisms had no connection, and directed attention to several points of similarity between the two. Several medical officers of health held that, whether the two organisms had any connection or no, the pseudo-bacillus sometimes produced a diphtheritic condition. It is im-

possible to summarise the number of important papers that were read upon the housing question, child-study, port sanitation, and other subjects. Dr. Hope, the local secretary, is to be congratulated upon the arrangements made, and it is hardly necessary to add that Liverpool extended a hearty welcome to the delegates and members of the congress. R. T. HEWLETT.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A REPORT on the scheme for the establishment, in London, of an institute for advanced technological instruction and research, recently put forward by Lord Rosebery, was presented to the London County Council on Tuesday. It will be remembered that the offer was made of land, buildings, and equipment required for such an institution to the value of 500,000*l.*, with the promise to secure other funds for both capital outlay and maintenance, provided that the council would express, in general terms, its willingness to contribute, when the buildings were equipped and ready to be opened, a sum of 20,000*l.* a year towards the maintenance of the educational work. In referring to these proposals in our issue of July 2 (p. 203), we pointed out the importance of coordinating the work of such an institute with that of the University of London, and expressed the opinion that the development of both was a national concern, and ought not to depend upon the contributions of the County Council. We are glad to see that the committee of the council appointed to consider the scheme regard substantial assistance from the State as an essential condition of support, and think the council should not lend any encouragement to the idea that the whole of the cost of maintenance could be provided from London sources. The following recommendations of the committee were adopted by the council at Tuesday's meeting:—(*a*) That the council expresses its high appreciation of the important proposal contained in Lord Rosebery's letter, and would cordially welcome the establishment of further provision in London for advanced technological teaching and research. (*b*) That the council, in response to the request contained in Lord Rosebery's letter, places on record its opinion that, when the land, buildings, and equipment for the proposed additional technological teaching and research are provided to a value of not less than 500,000*l.*, the council will be well advised to contribute, out of the moneys annually placed at its disposal under the Local Taxation (Customs and Excise) Act of 1890, a sum not exceeding 20,000*l.* per annum towards such part of the work as falls within the statutory definition of technical education, subject to the following conditions:—(1) That a scheme be prepared to the satisfaction of the council for the constitution of the governing body and the adequate representation of the council thereon; (2) that financial arrangements adequate to the whole maintenance of the proposed work are made to the satisfaction of the council; (3) that, in view of the national scope and utility of the proposed work, substantial contributions towards maintenance be made from funds of a national character; (4) that due provision be made in the scheme to prevent overlapping and secure coordination of the work already carried on by the university colleges, polytechnics, and other science and technological institutions, and the proper connection of the whole with the university; (5) that a sufficient number of scholarships, including free places, be placed at the disposal of the council; (6) that it be considered whether other counties and boroughs should not be invited to contribute towards the maintenance, receiving in return the right to send their picked scholars for instruction under the proposed scheme.

THE Board of Education have issued new regulations for the instruction and training of pupil teachers and students in training colleges. In a preface by Mr. Morant it is stated that the "regulations are intended to secure for the pupil teacher a more complete and continuous education, and to make the period of service in an elementary school a time of probation and training rather than of too early practice in teaching." Pupil teachers admitted on and after August 1, 1904, must not be under sixteen years of age, except in rural districts, where the limit will be fifteen. After August 1, 1905, pupil teachers will not be permitted to serve in a public elementary school more than half the time the school is open, and they will be required to receive half-time instruction in an approved pupil teacher centre throughout their engagement. The Board of Education desires to encourage plans for educating pupil teachers with other scholars, and urges local educational authorities to arrange, by means of an adequate scholarship system or otherwise, that all the best candidates for pupil teacherships, whether boys or girls, should receive a sound general education in a secondary school, with schoolfellows intended for other careers, before they commence service in any capacity in an elementary school. There is already in existence a number of well-equipped and well-staffed pupil teacher centres, the best of which have more than fulfilled the purpose for which they were originally recognised by the Board. The new regulations should assist in developing corporate school life in such centres, and also in improving other less satisfactory central classes; they mark a very decided step in advance, and show an exact appreciation of the shortcomings of the pupil teacher system as it has existed until now.

A SCHEME whereby pupils in schools in different parts of the Empire may be put in communication with one another, with the view of exchanging observations, specimens and ideas, has been drawn up by the League of the Empire, and promises to be of great educational value. The committee recommends that linked-schools and members should first exchange maps of their respective districts, and where possible, photographs or drawings of their houses, of the school house, grounds and surroundings. It is suggested that nature calendars should be kept, essays written on common trees or other plants, and notes made on the habits of birds or other animals, or on industrial processes or natural products in the neighbourhood of the schools—all with the view of exchanging them with schools in other parts. Personal observations are to be insisted upon, so that the descriptions will be twice blessed—those who make the observations by exercising the best of their faculties, and those who receive the results by gaining knowledge of natural conditions beyond their individual view. Specimens are also to be exchanged for school museums. Already there are nearly two thousand members in correspondence all over the Empire exchanging specimens and letters, and the number will doubtless be greatly increased. Particulars of the scheme may be obtained from Mrs. Ord Marshall, hon. secretary of the central committee, 11 Dartmouth Street, Victoria Street, London, S.W.

To prevent misunderstanding, Mr. C. McDermid, secretary of the Bessemer Memorial Fund, has issued a letter in which the relationship between the scheme for the Bessemer memorial and that put forward by Lord Rosebery is described. The persons responsible in each case have been in close consultation throughout, but the two schemes will continue for the present to be directed separately, though they will be controlled by joint trustees. For the purposes of the advanced metallurgical training and specialised research works which are to form the Bessemer memorial, it is proposed that London shall be regarded as the centre for the metallurgy of copper, silver, gold, &c., Sheffield as the centre for steel, and Birmingham as the centre for cast and wrought iron and alloys. It is intended that the post-graduate scholarships shall, in part, be international. It is hoped that the committee will be able to submit the complete scheme in October.

DR. W. SCHLICH, principal professor of forestry in the Royal Indian Engineering College, Coopers Hill, has been appointed honorary professor of forestry at the Royal Agricultural College, Cirencester. Mr. McClellan, jun., who was recently appointed professor of forestry and estates management at the college, has, during the past four months, been gaining experience of continental forestry, and with Dr. Schlich has made a six weeks' tour through specially interesting forest districts in Germany.

MR. H. W. RICHARDS has been appointed principal of the Brixton Technical Institute of the London Technical Education Board. The Board has made the following appointments in connection with the Paddington Technical

Institute:—Head of the chemical department, Dr. H. Reynolds; head of the physical department, Mr. J. H. Vincent.

THE following research fellowships and scholarships have been awarded by the executive committee of the Carnegie Trust for the universities of Scotland. *Research Fellowships.*—Chemical: Dr. C. E. Fawaitt, Dr. J. C. Irvine, Mr. W. Maitland. Biological: Dr. J. Cameron. Historical: Dr. D. Mackenzie. *Research Scholarships.*—Physical: Mr. J. H. MacLagan Wedderburn, Mr. H. W. Malcolm, Mr. J. R. Milne, Mr. T. B. Morley. Chemical: Mr. J. Knox, Mr. J. Johnston, Mr. F. J. Wilson. Biological: Mr. S. F. Ashby, Dr. R. T. Leiper, Mr. H. J. Watt.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 28.—"Researches on Tetanus." By Prof. Hans **Meyer** and Dr. F. **Ransom.**

The experiments were in the first place made with the object of finding an explanation for local tetanus. One of the earliest and most striking symptoms of tetanus in man is, as its popular name implies, stiffness of the masseter muscles (lockjaw); this is the case wherever the infected wound may be situated. In certain animals, however, as cats, dogs, and rabbits, when tetanus toxin is injected subcutaneously into a limb, the first symptom is a rigidity of the muscles of the injected member; this is known as local tetanus. Afterwards, if enough toxin has been given, the rigidity becomes general. An experimental explanation of this condition has hitherto been wanting.

The authors believe that their experiments prove conclusively that the course of events in experimental tetanus is as follows:—The toxin is taken up from the point of injection by the motor nerves (probably their naked endings). Passing along these it reaches first the corresponding motor centres in the spinal cord and excites there an over-irritability, so that the discharges which normally give rise to muscular tone become abnormally strong, and produce in the muscles of the injected limb the condition known as tetanic rigidity. The toxin also passes from the point of injection into the lymphatics and thence into the blood.[1] From the blood-lymph stream, if enough has been given, other motor nerve ends take up toxin, and general muscular rigidity ensues.

The authors show experimentally that the toxin only reaches the nervous centres by way of the motor nerves, and further, that the movement of the toxin in the nervous system does not take place in the lymphatics, but in the protoplasm of the nerves. Tetanus toxin never reaches the spinal centres along the sensory nerves, but, if it is injected into a posterior root, sensory disturbance is the result.

The greater part of what is known as the period of incubation, that is, the interval which elapses between the injection of toxin and the first symptom of intoxication, is the expression of the time occupied in the conveyance of the toxine from the periphery along the motor nerves to the susceptible centres.

Relying upon the results of their experiments, the authors are of opinion that the tetanus of warm-blooded animals consists of two processes, separated from each other both in time and space. Of these the one is primary, a motor intoxication, local muscular rigidity; the other, secondary, is a local sensory intoxication, a diffused reflex tetanus starting from the intoxicated neuron.

Repeated experiments showed that, when tetanus toxin was introduced direct into a motor nerve, antitoxin, though present in large quantities in the blood, was unable to prevent the outbreak of the disease, or even to hinder a fatal result. This was the case both when large doses of antitoxin were given before and after the toxin, as well as when an actively immunised animal was employed. The experimenters therefore conclude that injected antitoxin does not reach the substance of the nerve fibrils and centres, and that even with highly immunised animals the neurons remain free from antitoxin. As regards the serum treatment of tetanus, it is clear that in these circumstances any toxin which is already in the motor nerves, though not yet in spinal centres, will not be neutralised by antitoxin, whether injected under the skin or direct into the blood. An attack corresponding to the amount of toxin absorbed by the nerves will break out and run its course in spite of antitoxin. On the other hand, any toxin in the blood or lymph will be rendered harmless by an injection of antitoxin, and so a further intoxication will be prevented.

The authors have further made successful attempts to prevent the access of tetanus toxin along the motor nerve to the susceptible centres by injecting antitoxin into the nerve substance (ischiadicus), so, as it were, blocking the passage of the toxin.

Just before this paper was read, a case occurred at Marburg of a man who received an injury of the hand from the breaking of a flask of tetanus toxin. Antitoxin in large quantity was injected under the skin a quarter of an hour after the injury; nevertheless, after eight days, a local tetanus of the arm broke out. This was treated by injection of antitoxin into the nerve trunks of the affected limb, and the patient recovered. The occurrence of a local tetanus in spite of the large quantities of antitoxin, and the satisfactory result which followed, and perhaps was due to the injection of antitoxin into the motor nerves of the affected limb, show that the conveyance of the poison from periphery to centre takes place in men, as in animals, along the motor nerve, and affords, further, a valuable hint for the treatment of tetanus.

The full report of these experiments appears in *Archiv für experimentelle Pathologie und Pharmakologie*, Band xlix.

June 11.—"Observations on the Physiology of the Cerebral Cortex of the Anthropoid Apes." By Dr. A. S. F. **Grünbaum** and Prof. C. S. **Sherrington,** F.R.S.

June 18.—"Cyanogenesis in Plants. Part iii. Phaseolunatin; the Cyanogenetic Glucoside of *Phaseolus lunatus.*" By Wyndham R. **Dunstan,** M.A., F.R.S., Director of the Imperial Institute, South Kensington, and T. A. **Henry,** D.Sc. Lond.

The poisonous seeds produced by partial cultivation in Mauritius of the plant *Phaseolus lunatus* have been examined and found to contain a cyanogenetic glucoside of the formula $C_{10}H_{17}O_6N$, to which the name *Phaseolunatin* has been given. The glucoside crystallises in colourless needles, and when acted upon by the enzyme emulsin, which is also present in the seeds, or by warm dilute acids, it is hydrolysed into *dextrose, acetone,* and *hydrocyanic acid.*

$$C_{10}H_{17}O_6N+H_2O=C_6H_{12}O_6+CH_3.CO.CH_3+HCN.$$

Alkalis convert the glucoside into *phaseolunatinic acid* ($C_{10}H_{18}O_8$), and this, by the further action of hot dilute acids, is hydrolysed into *dextrose* and *a-hydroxyisobutyric acid.* Phaseolunatin is therefore the *dextrose ether of acetonecyanhydrin* $(CH_3)_2:C(CN).O.C_6H_{11}O_5$.

The seeds produced by *Phaseolus lunatus* vary in toxicity and in the colour of their seed-coats, depending upon the care bestowed on the cultivation of the plant. In Mauritius, where the plant is grown for use as a green manure, the seeds furnish, when moistened with water, from 0·041 to 0·088 per cent. of prussic acid, and possess dark brown or purple seed-coats; in India the seeds, which are imported into this country under the name of "Rangoon" or "Paigya" beans, and are used for the manufacture of cattle foods, are pink with purple spots, and yield only 0·004 per cent. of this acid, whilst the large, white Lima or duffin beans, produced by long-continued cultivation of the plant, yield no prussic acid, although they still contain the enzyme emulsin.

It is suggested that if hydrocyanic acid or its precursors —the cyanogenetic glucosides—in plants, may be regarded as formative materials utilised for the synthesis of proteids, then the absence of such glucosides from the cultivated seeds of *Phaseolus lunatus*, and from those of the cultivated almond, may be the result of more active metabolism induced by improved conditions of growth, so that no supplies of the glucoside are available for storage as reserve material in the seeds.

[1] Ransom, Hoppe Seyler's *Zeitschrift f physiol. Chemie,* Band xxix and xxxi.

Faraday Society, June 30.—Mr. J. Swinburne, vice-president, in the chair.—Mr. W. C. Dampier **Whetham**, F.R.S., gave an abstract of his paper on the present position of the theory of electrolysis. The fact that the products of electrolysis appear at the electrodes only led to the Grotthus chain hypothesis. Faraday's laws suggest opposite convective streams of anions and cations. Hittorf's observations on the unequal concentration of the solution lead to the conception either of complex ions, dragging along salt or solvent, or else unequal velocities of the ions the ratio of which can be measured. Kohlrausch's measurements of the resistance of electrolytes enable the absolute velocities to be measured. The fact that electric conduction in solutions obeys Ohm's law shows that the E.M.F. is merely directive, and that the ions have migratory freedom. The fact that ionic mobilities only vary slowly with dilution, while the conductivity of a dilute solution is proportional to the first power and not the cube of the concentration, shows that the ions must be free of the solute molecules—not necessarily of those of the solvent. The osmotic properties of electrolytes lead to the same conclusion. A short consideration of conduction in non-aqueous solution and in fused salts completes the paper.—Mr. **Swinburne** gave a short account of his paper on chlorine smelting, with electrolysis, an abstract of which we print elsewhere (p. 285).—A paper by Dr. R. A. **Lehfeldt**, on the total and free energy of the lead accumulator, was taken as read, and the discussion adjourned until the next meeting.—Dr. **Perkin** exhibited and explained several novel pieces of electrolytic apparatus devised by him for laboratory work.

PARIS.

Academy of Sciences, July 13.—M. Mascart in the chair —On the stability of a particular mode of flow of a sheet of water of infiltration, by M. J. **Boussinesq**.—On the torsional movements of the eye during the rotation of the head, by M. Yves **Delage**.—Remarks by M. Alfred **Picard** on the third volume of his "Rapport général sur l'Exposition universelle de 1900."—On the deformation of surfaces, by M. M. **Servant**.—On the measurement of coefficients of self-induction by means of the telephone, by M. R. **Dongier**. A special telephone invented by M. Mercadier was used in this work. It only reinforces sounds of a determined period, and remains insensible to the harmonics caused by capacity or by magnetic substances in the core of the bobbin. Measurements of self-induction of the order of 10^{-3} Henry were made with an accuracy of one-half per cent.—A combination of ferric sulphate with sulphuric acid, by M. A. **Recoura**. A ferrisulphuric acid has been isolated, possessing an analogous composition to the chromosulphuric acid previously described; unlike the latter, however, it is immediately decomposed by water.—On the action of carbon monoxide upon iron and its oxides, by M. Georges **Charpy**. Ferric oxide, heated in a current of carbon monoxide, is completely reduced to metallic iron, containing carbon, at all temperatures between 200° and 1200°, the velocity of reduction increasing with the temperature. Metallic iron takes up carbon at all temperatures between 560° and 1190° C., the metal remaining free from deposited carbon at temperatures above 750° C.—On the so-called colloidal silver, by M. **Hanriot**. The conclusion is drawn that the albuminoid material in collargol, the oxide of iron in the preparation of C. Lea, and the silica in the silicargol are not to be regarded as impurities, but as integral portions of the molecule, not only because it is impossible to separate them without destroying the colloidal silver, but also because these bodies have then lost their characteristic properties.—The action of hypophosphorous acid on diethylketone and on acetophenone, by M. C. **Marie**. Acids containing phosphorus have been obtained analogous in composition with acids derived from other ketones; the oxidation products are also similar.—On the chloride of phenylpropargylidene, $C_6H_5.C:C.CH.Cl_2$, by MM. Ernest **Charon** and Edgar **Dugoujon**. Phenylpropargylic aldehyde was treated with phosphorus pentachloride, and the chloride separated by fractional distillation. Its stability is greater than that of cinnamylidene chloride. The addition products with chlorine and bromine were isolated, and also proved to be very stable towards air and water.—The preparation of the secondary amides, by M. J. **Tarbouriech**. Two methods were used, the action of the acid on the corresponding nitrite, and the action of the acid chloride upon the primary amide; the latter gave better yields. The properties of dibutyramide, diisobutyramide, divaleramide, and diisovaleramide are described.—The action of ammonium persulphate upon metallic oxides, by MM. A. **Seyewetz** and P. **Trawitz**.—The action of bromine upon pinene in the presence of water, by MM. P. **Genvresse** and P. **Faivre**.—The influence of the nervous system on the ontogenesis of the limbs, by M. P. **Wintrebert**. A MODERN PHYSICIST.

Scientific Papers of Lord Rayleign. Vols. ii., iii. and iv., 1881–1901. Pp. xiv+598; xii+596; xiv+604. (Cambridge: University Press.)

TO review these volumes in an ordinary sense is an impossible task. Fortunately it is quite unnecessary. Lord Rayleigh's work in its many phases is so well known that a brief notification of the fact that his papers have been collected and published by the Cambridge University Press is almost all that is called for. Every physicist will realise that his library is incomplete without these four splendid volumes, the first of which has already been noticed, and that he will find in their pages the details of many of the most striking advances in his subject during the past twenty years.

Lord Rayleigh succeeded Maxwell as professor of physics at Cambridge in 1879. The first volume under notice opens with his classical work in the Cavendish Laboratory on the electric units; the latter pages of vol. iv. deal with his experimental verification of Boyle's law for pressures down to the hundredth of a millimetre. A list of the papers—272 in number in the four volumes—would cover the whole range of physics, and each contains a contribution of real value to natural knowledge.

During his tenure of the Cambridge chair, Lord Rayleigh undertook the determination of the three fundamental units of electrical science, the ohm, the ampere, and the volt.

> "It is generally felt," he writes in the first paper (*Proc.* Roy. Soc., 1881), "that considerable uncertainty still attaches to the real value of the ohm or British Association unit of resistance. The ohm was constructed to represent 10^9 C.G.S. units of resistance, but according to Kohlrausch it is nearly 2 per cent. too great, and according to Rowland nearly 1 per cent. too small."

The ohm, thanks to the work of Lord Rayleigh and those who have followed in his steps, is now known to some few parts in ten thousand.

It is much the same with the ampere and the volt; more recent work has shown that possibly some small change is required in the numbers given by Lord Rayleigh to represent the electrochemical equivalent of silver and the electromotive force of a Clark cell, but the change will be very small. His work made the Clark cell a practical standard, and every electrician now knows its value. The H form of cell is first described on p. 315 of the second volume of the papers.

But this series of papers did not exhaust his experimental work at Cambridge; the researches on the value of the ohm would have been incomplete without the determination of the specific resistance of mercury (Article 81) by Mrs. Sidgwick and himself. The experiments on the rotation of the plane of polarisation of light in a magnetic field were planned at first in the hope of utilising the results in the measurement of an electric current, and though this hope was not realised, they remain as the standard determination of Verdet's constant. A second paper on the Clark cell is dated 1886.

A short paper (No. 92) from the *Philosophical Magazine*, vol. xiv., 1882, will serve as an example of Lord Rayleigh's work as a critic. It is a comparison of the methods for the determination of resistances in absolute measure, and affords a most valuable *résumé* of the methods employed.

Resistance being on the electromagnetic system of the dimensions of a velocity, the measurement of a length and a time are necessary; the principal length involved is nearly always the mean radius of a coil, and the presumption is in favour of the method which involves only a single linear measurement.

The paper exhibits in a marked degree Lord Rayleigh's great capacity for seeing distinctly the essential point of an experiment or a measurement, and keeping that clearly in view throughout. This, indeed, is the distinguishing feature of his experimental work, a main factor in his success. Those who knew the Cavendish Laboratory when the electrical measurements were going on, or have since visited the laboratory at Terling, from which no less important work is continually being published, have sometimes been surprised at the makeshift character of much of the apparatus. Contrivances of wood and wire and wax do duty where most men would use apparatus elaborated with a quite unnecessary care; but in Lord Rayleigh's case, while the essential instrument on which the accuracy of the result really depends is as perfect as the skill of the workman can make it, and, in addition, has been thought out in all its details so as to fit it best for the purpose immediately in view, for the rest the arrangement which comes first to hand is utilised without regard to appearances.

In addition to the fundamental measurements already referred to, the Cambridge years were marked by a series of optical papers of great value. Among these may be mentioned the article on optics for the ninth edition of the "Encyclopædia Britannica," in which the theory of the resolving power of an optical instrument is given in a simple manner.

The papers already mentioned are contained in vol. ii. of the collected works. Those in vol. iii., written after Lord Rayleigh had resigned the Cambridge chair, differ somewhat in character, but are no less interesting. The article on the wave theory of light from the "Encyclopædia Britannica," and the papers on the relative densities of hydrogen and oxygen, and the composition of water, Articles 146, 153, 187, are perhaps the most important.

Attention may also be directed to a series of papers on capillary questions, while Article 191, on the physics of media that are composed of free and perfectly elastic molecules in a state of motion, has a special interest. Waterston had communicated to the Royal Society in 1845 a paper with the above title, which remained unpublished until 1892, when Lord Rayleigh's attention was directed to it, and the paper was printed in the *Phil. Trans.* with an introduction by himself. Waterston was the first to introduce into the kinetic theory the notion that heat and temperature are to be measured by the kinetic energy of the moving particles. From

this he deduces the law of Dalton and Gay Lussac, and he further establishes, though in an incomplete manner, the law that in mixed gases the mean kinetic energy is the same for the different sets of molecules present, from which Avogadro's law and Graham's law of diffusion follow at once. The memoir also contains the first calculation of molecular velocity, and points out the relation of this velocity to the velocity of sound.

The papers on the relative densities of hydrogen and oxygen find a fitting sequel in some of the earlier papers of the fourth volume, the first of which is on the density of nitrogen, Article 197. This begins:—

"I am much puzzled by some recent results as to the density of nitrogen, and shall be obliged if any of your chemical readers"—the article is a letter to this Journal, NATURE, vol. xlvi. pp. 512, 513, 1892—"can offer suggestions as to the cause. According to two methods of preparation I obtain quite distinct values. The relative difference, amounting to about 1/1000 part[1] is small in itself, but it lies entirely outside the errors of experiment, and can only be attributed to a variation in the character of the gas."

And the paper concludes:—

"Is it possible that the difference is independent of impurity, the nitrogen being to some extent in a different (dissociated) state?"

The matter is again referred to in the Royal Society paper, No. 201, on the density of the principal gases, published in the *Proceedings* of 1893, and in detail in Article 210. On an anomaly encountered in determinations of the density of nitrogen gas (*Proc.* Roy. Soc., 1894), when it appeared that while the weight of nitrogen derived from the air required to fill a certain globe under standard conditions was 2·3102 grammes, when the nitrogen was obtained as a chemical product from other sources than the air the weight was 2·2990 grammes, a difference of 11 milligrammes, or one-half per cent. The question was answered satisfactorily by the paper which appears as No. 214, "Argon, a New Constituent of the Atmosphere," by Lord Rayleigh, Sec.R.S., and Prof. William Ramsay, F.R.S. (*Phil. Trans.*, clxxxvi., A, 1895), and an interesting account of the discovery is contained in the Royal Institution lecture on argon, which forms Article 215.

The *Phil. Trans.* paper contains the account of the means used to separate from the nitrogen of the air the new dense gas the presence of which Lord Rayleigh had discovered, as a residual, by the accuracy of his weighings.

A number of further papers dealing with argon and some of the other new gases are contained in this volume. One of the latest is on the verification of Boyle's law for low pressures. There is also much valuable optical work, specially, perhaps, Article 198, on the intensity of light reflected from water and mercury at nearly perpendicular incidence, and many important investigations of a mathematical character on the electromagnetic theory of light. Among these may be noted Article 227, on the passage of waves through apertures in plane screens, and Article 230, on the incidence of aërial and electric waves on small obstacles.

[1] The difference ultimately found was 1/200.

Perhaps enough has been written to convey to readers who are not professed students of physics the width of range and the power of Lord Rayleigh's work, and to unite them with those who look to him as their leader and master in thanking him for collecting his papers in these four volumes, and rendering them accessible to all.

It is almost needless to add that the University Press has done its part admirably, and fully deserves the thanks of students of nature for its share in the work.

Within a few years the Cambridge Press has published the collected works of Adams, Cayley, Maxwell, Stokes, Tait, Kelvin, Reynolds, and Rayleigh, men whose names will ever make the Cambridge school of mathematics and physics of the last half of the nineteenth century famous in the history of science.

MICRO-ORGANISMS IN THE ARTS AND MANUFACTURES.

Technical Mycology: the Utilisation of Micro-organisms in the Arts and Manufactures. By Dr. Lafar. Translated by C. T. C. Salter. Vol. ii. *Eumycetic Fermentation,* Part i. Pp. viii+189. (London: C. Griffin and Co., Ltd., 1903.)

THE first volume of Mr. Salter's translation of Dr. Lafar's "Technical Mycology," which made its appearance some four or five years ago, opened up to the general reader a very wide and interesting field, the utilisation of micro-organisms in the arts and manufactures. This volume dealt with schizomycetic fermentation, and to the uninitiated who had not looked into the scheme of the whole work, it appeared as though almost the last word must have been said on fungi and fermentation.

The first part of the second volume, the advent of which has been eagerly awaited, has now come to hand, and we may say at once that in many ways it is equal to the first volume and that, not only have we the results of the author's own experience and observations, but a *résumé* of the results of others well brought up to date. This volume deals with the eumycetic fermentation and opens with a series of chapters on the rudiments of the general morphology and physiology of the Eumycetes, chapters of as great interest to the general biologist as to the bacteriologist and fungologist. A short description of the structure of the Eumycetes is given, the method of spore formation, the development of the mycelium from the spore, the gemmating mycelium, and the various methods of reproduction—fructification by sporangia, zygospores, conidia, or by the formation of oidia and gemmæ without the intervention of conidiophores. The author refers the reader for more detailed accounts of structure and function to the early text-books provided by Zopf, De Bary, and Brefeld, but supplements these works by carefully written chapters on certain parts of the subject on which much work has been done since the appearance of these text-books. He describes the researches which have been carried out on the celluloses, chitin, hemicelluloses, and other carbohydrates of which these fungi are composed, dis-

cusses the position of their colouring matter and ascribes the waterproof character of certain cell membranes to the deposition of excreted fatty or waxy substances, pointing out that this waterproof character is of importance biologically,

"since it prevents the penetration of toxic substances from the surrounding aqueous medium, and thereby also opposes the attempts of the mycologist to kill such fungi by means of aqueous toxic solutions."

A chapter is devoted to the mineral nutrient matter utilised by the Eumycetes, the author indicating that certain substances which are not absolutely necessary for the nutrition of these organisms may still, as in the case of nickel, cobalt, and manganese, like iron, exert a stimulative action on the growth of fungi. Sulphur, selenium, and silicon may also be found in the protoplasm of these fungi, but phosphorus appears to be a most important element in their composition, and, although arsenic does not take the place of the phosphorus in the Eumycetes, certain of these organisms appear to have the power of converting arsenious acid into volatile compounds having an odour of garlic. These organisms have, therefore, been used for the purpose of indicating the presence of arsenic in cases where, by the ordinary Marsh's tests, only a doubtful reaction has been obtained. The influence of light on the development of the Eumycetes is discussed, and it appears that although strong light interferes with their development, moderate illumination interferes very little with their activity. Chemotropism is discussed somewhat fragmentarily; this remark applies also to the diastatic enzymes and the enzymes capable of decomposing fat; the enzymes of yeast, however, are described more fully in the later part of the work.

The special part of the book consists of two sections, one devoted to the fermentation set up by Zygomycetes, the other to a preliminary consideration of yeast-fermentation. The first of these sections is interesting to the technologist from the fact that it deals with Calmette's *Amylomyces Rouxii* or *Mucor Rouxii*, derived from the Chinese yeast-balls used in the preparation of rice spirit. This produces a powerful diastatic enzyme which first produces glucose, and this, in the absence of oxygen, is converted by yeast ferment into alcohol. For a full account of the Amylomyces process the reader may be referred to the description of the use of the Mucoreæ in the spirit industry.

The latter half of part i. of vol. ii. is devoted entirely to yeasts, especially the forms, structure, and chemical composition of the yeast-cell, and anyone who studies this will be amply repaid by obtaining a knowledge of the principles and mechanism of fermentation such as can be obtained elsewhere only by the study of bulky treatises, though now and again one is a little disappointed that the author has not elaborated his descriptions somewhat more fully, this remark applying specially to the chapter on the chemistry of the yeast-cell. The sketch given is so interesting that one would have welcomed a somewhat more detailed account of this part of the work.

After reading this work one feels the truth of Hansen's statement that none of the text-books and manuals giving a summary of larger or smaller sections of technical microbiology has treated the subject of this extensive field from so comprehensive a point of view as that of Dr. Lafar. In preparing the work, the author has exhibited not only many sided discernment and enthusiasm for his task, but also great courage and endurance. Certainly, this part of the second volume

"will be welcomed not only by those for whom it is primarily intended, viz., technical chemists, chemists dealing with food stuffs, fermentation and agriculture, pharmacists, and agriculturists, but many another worker will derive benefit from its pages for his lectures and researches."

We can cordially recommend this section of Dr. Lafar's work as an excellent supplement to the first volume, which has already been reviewed in our columns.

We are glad to learn that the translators have made arrangements with the German publishers to obtain advance proofs of the German work in order that the concluding sections may appear as soon as possible. This portion of the work fully maintains the interest aroused by the first volume, and the translators are to be congratulated on the fact that they have been able to give so accurately not only the substance, but the spirit of the German work.

G. SIMS WOODHEAD.

VISUAL PURPLE.

Abhandlungen zur Physiologie der Gesichtsempfindungen. By J. von Kries. Heft. i., 1897, pp. vi+198; Heft. ii., 1902, pp. 197. (Leipzig: Johann Ambrosius Barth.)

THIS is a collection of papers reprinted from the *Zeitschrift für Psychologie und Physiologie der Sinnesorgane.* The papers are the work of von Kries and his school, and deal chiefly with visual purple and its functions. They give an account of one of the most important of recent advances in our knowledge of the physiology of sensation.

The discovery of visual purple in 1876 aroused great hopes, which seemed to be frustrated when it was found that the substance was absent from the *fovea,* the place of most distinct vision, and physiologists soon settled down to the view that a substance absent from this situation could have little to do with the production of visual sensations.

In the early days, however, Kühne suggested that the great instability of visual purple made it probable that it was a substance for the perception of feeble light, and Parinaud in France later advanced the same idea. It has been reserved for von Kries to develop fully Kühne's idea.

According to von Kries, visual purple is a substance which supplies the retinal basis for vision at low luminosities, and the accumulation of this substance is accountable for the great increase in sensitiveness of the dark-adapted eye—a thousand-fold increase according to some computations.

The change in the relative brightness of different colours with varying illumination, first pointed out by Purkinje, finds a ready explanation on this view.

Hering had shown that this phenomenon is a function of the condition of dark-adaptation produced by feeble illumination rather than a function of the feeble illumination itself, and von Kries shows that the changes of relative brightness are readily explicable if we suppose that, as the eye becomes more and more dark-adapted, there comes into play a new factor which has no influence, or no appreciable influence, at ordinary luminosities. Speaking roughly, the blue end of the spectrum becomes relatively brighter, and it is this end of the spectrum which has the greater action on visual purple.

In pronounced dark-adaptation the spectrum is seen as a colourless band of light, and the curve of luminosity of the spectrum in this condition shows a close correspondence with the curve representing the degree of action of different parts of the spectrum on visual purple. The spectrum is shortened at the red end; it is brightest in the green, and the diminution of brightness towards each end is much more gradual on the blue than on the red side of the maximum.

Visual purple also furnishes an explanation of an anomaly of colour vision which has long puzzled physiologists. A colour-equation which is good for one luminosity is not good for all luminosities, and von Kries shows that the mixed light which becomes relatively brighter at low luminosities is that which has the greater action on visual purple.

The absence of visual purple from the *fovea centralis* provides a ready method of putting the theory to the test. If dark-adaptation with its influence on colour-brightness and colour-equations be due to visual purple, the *fovea* should not share in the increased sensitiveness of the dark-adapted eye, nor should this region show any change in colour-brightness or in colour matches in different conditions of adaptation.

There seems to be no doubt that the *fovea* responds in favour of the theory. There is some difference of opinion as to whether this region fails entirely to show alteration of sensitiveness, but it is generally agreed that any increase which occurs is insignificant compared with that of the surrounding region of the retina. Very careful observations by Nagel and others seem also to show conclusively that Purkinje's phenomenon and the alteration of colour-matches are absent if the stimulation of the retina be strictly limited to the foveal region. The features of colour vision which are believed to depend on visual purple are absent just when, according to the theory, they should be absent.

One of the most interesting developments of the theory is that in which the condition of total colour-blindness is regarded as vision dependent chiefly, or exclusively, on the visual purple of the rods. Hering was the first to show that the curve of luminosity of the spectrum in most cases of total colour-blindness corresponds with great exactness to the curve of luminosity of the normal dark-adapted eye, and von Kries shows that there are other points of close resemblance between the two conditions.

If visual purple be the basis of monochromatic vision, there ought to be a central blind spot, and in several cases which have been examined from this point of view by quite independent observers, this has been found to be the case. Again, the behaviour of the *fovea* is in favour of the theory. The evidence here, however, is not unanimous. Hess has failed to demonstrate the existence of a central scotoma in several cases, but our knowledge of the exact distribution of rods and cones in the human *fovea* is based on very few examinations, and it is possible that there are wide individual variations, and that in some people an area devoid of rods may be absent, or so small that it is impossible to demonstrate its presence. The diffusion of visual purple into the rod-free area is also possible in some cases, but it seems more probable, from a study of the evidence as a whole, that there are two kinds of total colour-blindness, and that in only one of these is it probable that visual purple is the only sensitive substance in the retina.

Several of the papers in the "Abhandlungen" deal with the recurrent image, or "ghost" of Bidwell, which is believed by von Kries to be a "visual purple" phenomenon. This part of von Kries's work has been much attacked, and recent work seems to show that the recurrent image is a much more complex phenomenon than has usually been supposed. It is probable that visual purple is only the basis of one of the elements of the complex.

The comparative evidence is in favour of the theory, visual purple being abundant in nearly all vertebrates the habits of which are nocturnal or which live underground.

It has only been possible here to give the briefest sketch of the views of von Kries and his co-workers. The "Abhandlungen" should be consulted for the elaborate investigations and detailed arguments in support of their views.

W. H. R. RIVERS.

OUR BOOK SHELF.

Botanische Forschungen des Alexanderzuges. By Dr. H. Bretzl. Pp. xii+412. (Leipzig: Teubner, 1903.) Price 12 marks.

THE criticism passed by Sachs in his "History of Botany" on the writings of the ancient classical writers, including Theophrastus, seems to have been unnecessarily severe where he passes over their "corrupt texts" with a brief mention. At that time the study of geographical and ecological botany had not received the stimulus which was mainly induced by the appearance of Schimper's master work, "Die Pflanzengeographie." It would hardly be going too far to say that it required the development of this branch of the subject to admit of the full appreciation of Theophrastus's work. For the essential feature of Theophrastus's "Plant Geography," and this book is the main source of information concerning Alexander's expedition, is the painting of a series of word pictures, illustrations of types of vegetation, in which, while correct morphological ideas could hardly be looked for, the descriptions, in their accuracy of observation and power of expression, are not often excelled by those due to present-day writers. As might be expected, some of the accounts are difficult of explanation, and discrepancies arise which have demanded considerable skill and enthusiasm on the part of Dr. Bretzl to clear up. Others are more obvious; thus the paragraph which begins:—

"*ὑποβέβρωται δὲ ταῦτα τὰ δένδρα πάντα κατὰ μέσον ὑπὸ τῆς θαλάττης καὶ ἕστηκεν ὑπὸ τῶν ῥιζῶν ὥσπερ πολύπους*" calls up very definitely the picture of a mangrove swamp.

Even more striking is the description of a mimosa which grew near Memphis:—"ὅταν δέ τις ἅψηται τῶν κλωνίων ὥσπερ ἀφαναινόμενα τὰ φύλλα συμπίπτειν φασίν, εἶτα μετά τινα χρόνον ἀναβιώσκεσθαι πάλιν καὶ θάλλειν."

Here the difficulty arises with regard to the species which is denoted, but special investigation by Dr. Schweinfurth elicited the information that in the vicinity there grows *Mimosa asperata*, a plant the sensitivity of which is almost unknown to botanists. Another graphic description is that of the banyan, συκῆ 'Ινδική, with the allusion to the roots developed from the branches, which are roots because they are lighter in colour and *leafless*. But the book contains many similar points of interest, and Dr. Bretzl has furnished abundant proof of the accuracy of perception and faculty of discernment possessed by some of the ancient Greeks.

The sources of information are to be traced to the memoirs of certain of Alexander's retinue. These manuscripts, which were deposited in Babylon, have unfortunately been lost; but they were apparently available to Theophrastus, who has worked up the material with truly remarkable intuition. Between the writings of Theophrastus and those of other authors, notably Pliny, Dr. Bretzl draws a sharp line of distinction, the distinction, in fact, between the original thinker and the annotator.

Practical Plane and Solid Geometry for Elementary Students. By Joseph Harrison. Pp. xiii + 250. (London: Macmillan and Co., Ltd., 1903.) Price 2*s*. 6*d*.

THIS little book will be found very useful for the teaching of the fundamental principles of geometry to young students. The most important properties of triangles and other plane figures are illustrated by means of accurate drawing and numerical calculation, and thus appeal more readily to the understanding and memory than if the beginner were made acquainted with them by means of the severe and tedious logic of Euclid. The great advantage of such a book as this is that it prepares the mind of the beginner for methods of accurate logical demonstration at a later stage in his studies. The very large number of numerical exercises requiring calculation and the use of instruments should suffice to give the student a very firm knowledge of all the important part of elementary geometry; and for this reason the book can be confidently recommended to teachers.

The first ten chapters are of this useful kind; then follow some chapters on the nature of vectors and their addition, including some properties of uniplanar forces acting on a particle the necessity for which may, perhaps, be doubted. In these chapters we meet with a little careless writing which, doubtless, will be corrected in the next edition. Thus, the first sentence (or what should be a sentence) on p. 118 reminds us of Mr. Skae's item in "The Jumping Frog": a verb is missing and no assertion is made. The use of the expression "in *tandem*, or *follow-my-leader*" to indicate cyclic order in the sides of a triangle is of doubtful propriety; but such trifles constitute, of course, no serious objection.

The notation l_{θ} for the magnitude and direction of a vector (p. 130) is distinctly useful in the composition of vectors. Chapter xiii., on concurrent forces, will, of course, be omitted by the beginner whose aim is to acquire only a knowledge of the elements of geometry; and it scarcely belongs to the subject.

The remaining five chapters deal with geometrical drawing in three dimensions, and they constitute a very good introduction to the subject, the figures being very numerous, and accompanied by a large number of numerical examples.

Die Aluminium-Industrie. By Dr. F. Wintelen. Pp. xi + 108. (Braunschweig: Friedrich Vieweg und Sohn, 1903.) Price 6 marks.

THIS very interesting monograph upon the aluminium industry commences with a short historical introduction, in which we learn that Davy, so far back as 1808, after he had discovered sodium and potassium, endeavoured to prepare aluminium by electrolysing alumina. In this he was not successful, and it fell to the lot of Wöhler in 1827 first to prepare the metal by purely chemical methods. Bunsen, however, was able in 1854 to obtain it by electrolysing its chloride. In a table on p. 5 the variation in the price of the metal is traced since 1854, when it was merely a chemical curiosity. Its value in that year was 120*l*. per kilo, and even in 1889 it cost 2*l*.; but with the improvements of the electrical methods, the price rapidly dropped, until in 1901 it ranged from 2*s*. to 2*s*. 6*d*. per kilo. Following the historical portion of the work, a very full account of the physical and chemical properties of the metal is given. It is not until we reach p. 22 that the present methods of obtaining the metal are gone into, but here the thoroughness of the treatment leaves nothing to be desired. In the first place a careful account of the preparation of the outgoing materials used in the manufacture is given. This part of the work is of very considerable value. Everyone is aware that bauxite and cryolite are the substances used for preparing aluminium, and those who have studied the subject know that these substances cannot, as a rule, be employed without being first purified. In this book the methods of purification are described in detail, and methods of analysis are also set forth. Page 54 is headed "carbon electrodes"; these are employed both for the anode and kathode, in consequence of impurities introduced into the bath when other electrodes are used. The author gives details of the manufacture of these carbon electrodes—ten pages are devoted to this. Some useful diagrams illustrating the way in which the electrodes become corroded during the electrolysis are also given.

The last few pages of the monograph are devoted to the "working up of the metal"; one of the most interesting points being the method for welding the metal which is employed by Heräus, of Hanau. It consists in heating aluminium sheets with a hydrogen flame to a temperature of about 400°. The edges are then pressed together, and after being worked for some time with the hammer, they weld together in such a manner that tubes made in this way can hardly be distinguished from seamless ones.

This monograph is one of the most interesting and useful which we have had the pleasure of reading for a long time. The facts are well arranged, and although there are 108 pages devoted to the single subject of the aluminium industry, we do not consider that the work suffers from prolixity; we wish this could be said of many German monographs which have lately been published.

F. M. P.

Die Konstitution des Kamphers und seiner wichtigsten Derivate. By Ossian Aschan. Pp. xi + 117. (Braunschweig: Friedrich Vieweg und Sohn, 1903.) Price 3.50 marks.

THE chemistry of camphor and its derivatives has occupied the attention of chemists for many years, and has now become so specialised that it is almost impossible for the ordinary chemist to keep up with the immense amount of research published in the journals devoted to chemistry. The monograph by Prof. Aschan is accordingly very welcome, and will be found useful not only by the non-camphor chemist, but also

by the camphor specialist. The treatment of the subject is purely theoretical, and in that respect differs from the valuable paper "On the Constitution of Camphor" read at the British Association in 1900 by Dr. Lapworth.

A short introduction is followed by a chapter giving a *résumé* of the various camphor formulæ arranged in historical order, starting from that proposed by Victor Meyer in 1870 and coming down to that of Schryver in 1898. This history of camphor formulæ is an interesting example of evolution. The formula proposed by Bredt in 1893, and now generally accepted, seems best to explain the constitution of camphor and its numerous derivatives, and is the one adopted by the author.

In the third chapter the practical data on which the constitution of camphor rests are recorded under twelve heads, such as "camphor is a ketone," it "contains the group $.CH_2.CO$," "camphor and camphoric acid are saturated compounds," &c., all of which conditions are fulfilled by the Bredt formula. In this connection, to the researches of Brühl on the refractive index might have been added those of Perkin on the magnetic rotation, as confirming the bridged ring structure of camphor. The inconsistencies of other formulæ with the above-mentioned facts are briefly pointed out in the fourth chapter. The degradation products are next treated, and the monograph finishes with a discussion of the constitution of camphene and bornylene.

The clear manner in which Prof. Aschan indicates how some of the many seemingly inexplicable reactions probably take place is worthy of comment. The difficulty of excluding unimportant details and including all that is important in such a monograph as the one under notice has been overcome by the author with great success. J. E. M.

Theorie der Bewegungsübertragung. By Richard Manno. Pp. iv + 102. (Leipzig: Engelmann, 1903.)

IN laying down the fundamental notions of mechanics there has been divergence of opinion concerning the definition of force. There is the distinction between cause and effect, between statics and dynamics. The older school has regarded force as the cause of motion, modern theorists prefer to define and measure force by the effect only. Herr Manno attempts to construct a system of mechanics by regarding force as neither cause nor effect, but as the phenomenon of motion itself, and further, in order to get rid of the notion of action at a distance, every instance of force is supposed to be due to impact, so that motion is transferred from body to body by a succession of intervening impacts. Accordingly the attempt is made to develop the theory of impulsive forces from the simple cases of direct and oblique impact. Naturally, in this view, some divergence is found from the ordinarily accepted theory. The proportionality of cause and effect as implied in the "second law of motion" obviously fails when the momentum of a striking body is regarded as producing the momentum of a struck body.

It must be confessed that the author's theory, when its meaning is disentangled from the mass of verbiage with which it is swathed, does not seem to smooth the way towards a clear apprehension of the principles of mechanics. His leading idea seems to be that purely theoretical conceptions, such as action at a distance, must be discarded, and that all the terms used must represent observable phenomena. The author probably has in his mind the subject of a discussion recently appearing in NATURE, as is evidenced by sundry physiological allusions, and his objection to the technical meaning of "work" when applied to living organisms. R. W. H. T. H.

LETTERS TO THE EDITOR.

On a Map that will Solve Problems in the Use of the Globes.

IN mapping an extensive region of the earth in separate sheets, there are great advantages in dividing the region into belts by parallels of latitude, and modifying the law of representation in passing from each belt to the next. This plan is illustrated by the accompanying sketch, which represents a region extending from the equator to the North Pole, and covering 80° of longitude.

The map consists of nine sheets, each covering 10° from north to south, and 80° from east to west. The meridians are indicated at every tenth degree, and are straight lines, all of the same length, at right angles to the parallels of latitude, which are arcs of circles. The two parallels which bound each sheet are on the same scale as the meridians, so

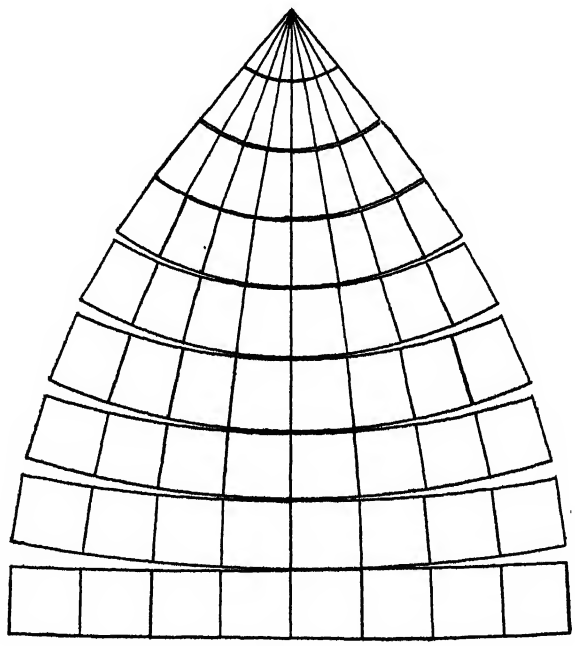

FIG. 1.

that the four sides of each of the seventy-two compartments of the map are precisely equal to the lengths which they represent on a spherical globe; and no difference is made between extreme and central meridians, all longitudes being treated alike. The intermediate meridians and parallels will be at right angles, as well as those shown, and the meridians will be of correct length. The intermediate parallels will be a trifle too short, the defect amounting, in the case of the middle parallel of each sheet, to rather less than 1 part in 250, a difference too small to be detected by the eye.

In examining on the map the borderland of two sheets, the two sheets are to be placed in contact at any point on the parallel common to both, and then, on rolling the edge of one sheet against that of the other, the whole border region from end to end will pass in review. All the successive meridians, when they are brought in turn to the point of contact, will be seen as straight lines crossing the point of contact, and the same will be true for the two portions of any oblique line which crosses the boundary.

If we want to trace a great-circle route from one place to another, we have merely to roll the sheets into such positions that the points of contact lie in a straight line

drawn from one place to the other. This straight line will represent the great-circle route.

I have put this matter to experimental test by constructing (on the scale of a 20-inch globe) eighteen cards, consisting of two sets of duplicates, and the accompanying figure is a reduced copy of one set.

As all meridians are treated alike, one card can be shifted 10°, 20°, 30°, &c., east or west relative to another, and this is necessary when the difference of longitude of the two places exceeds 80°. The second set of cards can either be used for the southern hemisphere or for increasing the range of longitude to 160°. I can thus measure the great-circle distance from London to Shanghai (the route passing 1½ degrees north of St. Petersburg), or from Yokohama to San Francisco, or from Land's End to Cape Horn. For measuring the distances I use a card scale divided into degrees of the same length as the degrees of the meridian.

The process above described also serves for finding the position of the sun in the sky at a given hour of the day, and by obvious modifications of it, most of the problems set forth in books on the use of the globes can be solved. In dealing with a spherical triangle, two of the sides are represented by polar distances, the included angle by difference of longitude, and the third side by the divided scale.

J. D. EVERETT.

Action of Tesla Coil on Radiometer.

THE following phenomena, observed while experimenting with a small Tesla coil, will, I believe, interest some of your readers. Not having access to the necessary literature, I am not in a position to find out whether they are new or already known.

The knobs of the Tesla coil were placed in contact with, or just close to, the bulb of a Crookes's radiometer, and the coil set at work. When the brush discharge fell upon the bulb, the blackened surfaces of the vanes first retreated, as they do under the influence of radiant heat, but soon the direction of rotation changed, and the blackened surfaces moved forward, the motion continuing as long as the brush discharge fell upon the bulb.

At the same time, inside the bulb, were seen diverging from the glass sides close to the knobs two cones of pale blue light; which, falling on the opposite sides of the bulb, caused a yellowish-green fluorescence. On the fluorescent parts the shadows of the rotating cones were clearly visible, the shadow on one side being always more intense than on the other side. When the direction of the current in the charging Ruhmkorff was reversed, the shadows exchanged places, but no change in the direction of rotation of the vanes was noticed.

On examining the fluorescent parts with a screen of potassium platinocyanide, the same effects were noticed as with the X-ray tubes.

Similar effects were obtained on repeating the experiments with two incandescent lamps in the laboratory. The larger of these, an old Swan lamp, fluoresced green, and the smaller new one, supplied with the Tesla coil by the manufacturer, fluoresced blue. But in both cases, though somewhat feeble, the same X-ray effects were observed.

To study further the cause of the motion of the vanes of the radiometer, the experiment was repeated with a Crookes's tube containing a freely suspended wheel with transparent mica waves. In this case it was found possible to alter the direction of rotation of the wheel by adjusting the positions of the knobs of the Tesla coil relatively to the sides of the tube and the wheel inside it.

Tides at Port Darwin.

ALONG the north-west coast of Australia the tidal wave, flowing in from the Indian Ocean, produces at most places a large rise and fall. At Port Darwin the mean spring range is about 24 feet, but the range is sometimes as much as 30 feet. A tide gauge of Lord Kelvin's pattern was set up here by the South Australian Government some few years ago, and good records are available up to 1897, since when it has been dismantled, waiting the building of a new jetty. Captain Inglis, the harbour-master at Port Adelaide, and the writer selected the last good records available for a whole year's tides, the records beginning January 1, 1896, and subjected them to a harmonic analysis, with the results given in the table below. The records show a very marked diurnal inequality, especially at the low waters. In the year examined the greatest difference in height between the two high waters occurred in January and December, and amounted to 4 feet 9 inches. In April, however, there was a difference in height of the two low waters of as much as 10 feet. The analysis shows the existence at Port Darwin of a remarkably large annual tide, the water on this account standing nearly two feet higher at the end of summer than it does at the end of winter. At first sight this seems very remarkable, especially when we find that at Kupang, on the island of Timor, to the north, according to Van der Stok, the solar annual tide has a semi-range of only 2·3 centimetres. The tide appears to be a purely meteorological effect due to the conformation of the harbour and the direction of the prevailing winds. The harbour opens towards the N.W., and, as will be seen from a perusal of the wind charts given in Van der Stok's work, "Wind and Weather, Currents, Tides and Tidal Streams in the East Indian Archipelago," the winds during the summer blow with great persistency from the N.W., tending to pile the water up in the harbour, while in the winter time the prevailing winds are S.E., with, of course, an opposite effect. This is further assisted by the variations of atmospheric pressure. The average barometer readings exhibit a remarkably regular annual fluctuation, as is shown by the following results. The averages are from readings taken at regular intervals of three hours for twenty years, ending 1901:—

	Mean Readings for 20 years.	Mean Readings for 1896.
January	29·765	29·757

The University, Adelaide. R. W. CHAPMAN.

Spirals in Nature and Art.

I HAVE to thank you for a very kind notice of my little essay on spirals, and I venture to trouble you further on the subject, because your last paragraph, criticising my attribution of spiral curves in flight to Leonardo, gives me an opportunity of making a correction to which, I feel sure, your courtesy to a distinguished scientific writer will enable me to give publicity. It appears that, in pp. 153 to 155 of my study of spirals, and in the figures 45 and 46 therein included, I have unconsciously done an injustice to the original researches on flight published by Dr. J. Bell Pettigrew, M.D., LL.D., F.R.S., Chandos professor of medicine and anatomy at the University of St. Andrew's, who, I now find, has been steadily engaged on the problem of flight since 1867, and has apparently published many papers and memoirs on the subject in the *Proceedings* of the Royal Institution of Great Britain, the *Transactions* of the Linnean Society and of the Royal Society of Edinburgh, and elsewhere.

My figure 45, which you acutely ascribe to its right author, is of very little importance to my argument, and only a side-issue in my essay, but it is right to say that it is Dr. Pettigrew's original figure, and should have been acknowledged as such in my pages. Had I known of this, I think I need hardly assure you that this acknowledgment would have been inserted, and that Dr. Pettigrew's own explanation of the figure would have been substituted for what he would justly stigmatise as the incorrect explanation given in my text. I have also to add that Prof. Marey's photograph of a flying pigeon, which I attributed to the only source I knew, was really an illustration of the alternate and opposite rise and fall of the body and the wings of a bird in flight, a principle first described and figured by Dr. Pettigrew in his memoir on "The Physiology of Wings" (*Trans.* Roy. Soc. Edin., 1870), and acknowledged by Prof. Marey as a previous discovery.

THEODORE ANDREA COOK.

Distribution of Calostoma.

IN December, 1891, I found in a pit near Port Katsura, a few miles off this place, a species of Calostoma in abundance, and this year I see the same fungus now and then occurring here. I send you some specimens of it herewith, in the hope that some mycologist of your acquaintance may determine it in my behalf. Of all the species given in Mr. Massee's monograph of the genus in the *Annals of Botany*, vol. ii. 1888, it seems most near *C. Ravenelii*, Mass.

If my memory deceives me not, Mr. Massee, in the same paper, divided the genus Calostoma into two groups, the so-called eastern group, growing in Asia and the adjacent islands, with globose spores, and the western group, the habitats of which are America and Australia, with elliptical spores. Now the Japanese species in question has its spores oblong-elliptical, which fact would seem to necessitate such a naming of the groups as eastern and western to be modified more or less.

KUMAGUSU MINAKATA.

Mount Nachi, Kii, Japan, June 5.

THE specimens of fungi from Japan belong to *Calostoma Ravenelii*, Mass., agreeing in every essential point with the type of that species preserved in the herbarium at Kew.

In the monograph referred to in the letter accompanying the specimens, the form of the spores was not made a basis of classification, but the fact was simply pointed out that eastern species possessed globose spores, whereas in all known western species the spores were elliptical.

The fact of a North American species occurring in Japan, while very interesting, will not cause surprise to botanists, considering the intimate relationship between the phanerogamic flora of the two countries.

GEO. MASSEE.

School Geometry Reform.

IN your issue of June 25, Mr. R. W. H. T. Hudson criticises the fact that, in my "Elementary Geometry," I give three meanings of the word angle, the third being what may be called the "sector of plane space" meaning.

He considers that, even if not wrong, it is undesirable in a school book. It seems to me that the one essential point which requires attention in introducing a new subject to boys and girls is to attach a clear, definite meaning to the terms employed, and that, if there be any terms such as this word "angle," of which many people have confused notions owing to the bringing together and blurring of two or three distinct meanings, then those meanings should be carefully dissected.

Mr. Hudson quotes with approval the French writers who, while stating that an angle is a simple undefinable idea, incidentally give "inclinaison mutuelle" as a synonym; personally, I am adverse to the word "inclination," it seems to mean a "leaning *towards* one another," whereas an angle is a "leaning *away* from one another," if it be a leaning at all. I have endeavoured to express this idea in my second meaning, the "wideness" of the opening between two radii drawn from a point.

That the space-sector meaning is implied in nineteenth century Euclids is indisputable, *e.g.* in iii. 20 we have "Case i., when the *centre is within* the angle"—how could the centre lie within a "mutual inclination" or within "an amount of turning"? Again, "a solid angle is . . . made by . . . plane angles . . . *meeting at one point*"—how can "mutual inclinations" meet? I doubt even if a "mutual inclination" is more capable of being bisected than is any other abstract quality, say, for example, gratitude.

Mr. Hudson speaks of the *axiom*, "whole is greater than its part": surely this is no axiom at all; it is a *definition*, whether of "a part" or of "greater than" I would not venture to say.

Whether my position be right or wrong, it is surely preferable to the attitude which makes geometry the "science of the undefinable."

I am grateful to your reviewer for the suggestion that angles should be quoted in decimals of a degree rather than to the nearest ten minutes, and will adopt the suggestion as soon as possible.

FRANK R. BARRELL.

University College, Bristol, July 6.

The Moon's Phases and Thunderstorms.

IN connection with the note in NATURE (July 9, p. 232), it is interesting to compare the results of Prof. W. H. Pickering with those obtained by Schiaparelli in 1868, from the discussion of observations made in Vigevano (north Italy) for thirty-eight years (1827–1864) by Dr. Siro Serafini.

"Sebbene i numeri della seconda colonna presentino delle grandi irregolarita nel loro andamento, sembra tuttavia indubitato, che nella prima metà della lunazione i temporali debbano in generale essere meno frequenti che nella seconda. Facendo la somma di 5 in 5 per veder meglio la legge di progressione, si vede che il minimum cade verso il 5° giorno della lunazione, il maximum verso il 24°. E la proporzione della frequenza minima alla massima è quella di 101 : 153, ciò è quasi esattamente di 2 : 3."

Translated into English, the quotation reads as follows:—"Although the figures of the second column show great irregularities in their proceeding, it seems nevertheless undoubted that in the first half of a lunation thunderstorms may be, generally speaking, less frequent than in the second. Adding 5 by 5 in order to see better the law of progression, one remarks that the *minimum* falls towards the 5th day of the lunation and the maximum towards the 24th. The ratio of the least frequency to the greatest is that of 101 : 153, or almost exactly of 2 : 3." (Clima di Vigevano: Milano Vallardi, 1868, p. 81.)

The conclusion is thus exactly the reverse of what Prof. W. H. Pickering has found.

OTTAVIO ZANOTTI BIANCO.

THE NEW MAMMOTH AT ST. PETERSBURG.

THE new mammoth just mounted for exhibition in the Zoological Museum at St. Petersburg, is a triumph of the taxidermist's art. The frozen skin has been cleaned, softened, and prepared. The skeleton, and as many of the surrounding soft tissues as possible, have been carefully removed from its interior and preserved separately. The animal has been actually stuffed like a modern quadruped, and placed in the attitude in which it originally died. The skin of the head and the ears are artificial, copied from the famous old specimen obtained a century ago by Adams. A model of the base of the proboscis has also been added. The skin of the trunk and limbs, however, is nearly complete, only embellished in parts by the addition of a little wool and hair from other specimens; and some deficiencies are covered by the surrounding mount, which represents the morass into which the animal slipped. The well-preserved tail is especially noteworthy, and bears a large tassel of long black hair at its tip. The animal is a young male of rather small size.

The hopelessly-struggling aspect of this mammoth is very striking, and reproduces exactly the attitude of the carcase as it lay buried in the Siberian tundra. In fact, the chief value of the specimen depends upon the circumstance that it was scientifically disinterred, photographed at various stages in the excavation, and carefully preserved by the best modern methods. Great credit is due to Dr. Otto Herz, the leader of the expedition organised by the St. Petersburg Imperial Academy of Sciences, who undertook the arduous task of securing the carcase and transporting it to the Russian capital. His are the only photographs hitherto obtained of a mammoth buried in the tundra, and they throw important new light on the question of the conditions under which these large quadrupeds were destroyed and entombed. Some of Dr. Herz's photographs have lately been presented by Dr. Salensky to the British Museum, and two of them are reproduced in the accompanying figures.

FIG. 1.—Front view of Mammoth in frozen earth on the banks of the Beresowka, Jakutsk, showing the bent fore limbs widely spread. From photograph by Dr. O. Herz.

The carcase in question was exposed by a landslip on the bank of the River Beresowka, an affluent of the Kolyma, in the Government of Jakutsk, in latitude 67° 32′ N. The head was entirely uncovered, so that the foxes and other carnivores ate its soft parts, while the inhabitants of a neighbouring village removed a tusk. The Governor of Jakutsk, however, succeeded in keeping the remainder of the specimen undisturbed until the arrival of the expedition from the Academy. It was buried partly in ice, partly in frozen sand and gravel, and there was a sufficient covering of earth to prevent its naturally thawing.

According to the general report published by Dr. Herz,[1] he began to excavate the specimen from the front. In this manner he soon discovered the two fore limbs spread widely apart, and sharply bent at the wrist, as shown in the first photograph (Fig. 1). Proceeding backwards on the left side, he unexpectedly met with the hind foot almost at once, and it gradually became evident that the hind limbs were completely turned forwards beneath the body, as shown in the second photograph (Fig. 2). Dr. Herz then removed the skull, and found the well-preserved tongue hanging out of the mandible. He also noticed that the mouth was filled with grass, which had been cropped, but not chewed and swallowed. Further examination of the carcase showed that the cavity of the chest was filled with clotted blood. It is therefore natural to conclude that the animal was entrapped by falling into a hole, and suddenly died from the bursting of a blood-vessel near the heart while making an effort to extricate itself. As shown by the recent researches

FIG. 2.—Left and partly posterior view of the same specimen, showing the bent left fore limb and the left hind limb turned forwards beneath the body. From photograph by Dr. O. Herz.

[1] "Berichte des Leiters der von der kaiserlichen Akademie der Wissenschaften zur Ausgrabung eines Mammuth-kadavers an die Kolyma-Beresowka ausgesandten Expedition" (St. Petersburg Academy of Sciences, 1902).

of Dr. Tolmatschow,[1] the ice surrounding the carcase was not that of a lake or river, but evidently formed from snow. It is thus quite likely that the mammoth was quietly browsing on grassland which formed the thin covering of a glacier, and fell into a crevasse which was obscured by the loose earth. On this subject, however, much more information may shortly be expected, when Mr. Ssewastianow publishes an account of the geological researches which he made in the neighbourhood of the Beresowka last summer.

The director of the Zoological Museum of St. Petersburg, Dr. W. Salensky, has not only arranged an admirable and unique exhibition of the newly-acquired mammoth, but has also devoted much time to a scientific investigation of the specimen. The results of his researches will be published by the Imperial Academy of Sciences in a series of memoirs, of which the first, dealing with the skeleton, has just appeared. In this work, he not only describes the parts of the new animal, but also refers to the rich collection of remains of the Siberian mammoth already in the museum under his direction. The first instalment, illustrated with twenty-five fine plates of bones and teeth, is unfortunately written only in the Russian language. We venture to express the hope that, when his work is completed, Dr. Salensky will make it more generally accessible by appending a copious abstract in one of the languages with which most naturalists are familiar.

A. S. W.

THE ETHNOLOGY OF THE MALAY PENINSULA.[2]

THE scientific results of the Skeat expedition of 1899 to Siam and the Malay Peninsula have not yet been published, but a secondary result of that expedition was the return of Mr. Nelson Annandale to the same district in 1901. Sir William Turner suggested to Mr. Annandale that he should obtain measurements of the people of the Siamese Malay States, and the Edinburgh University gave him a grant for that purpose from the Moray Fund. Mr. H. C. Robinson joined Mr. Annandale, and together they made a most successful expedition, the results of which are now beginning to appear with praiseworthy promptitude, a result that is rendered possible through private munificence in Liverpool. The association of this expedition with the University of Liverpool augurs well for the spirit of that young institution, and we hope tnat it may continue to foster field work in ethnology.

The present fasciculus contains a general account of the appearance and mode of life of the Semang and Sakai tribes of the Malay Peninsula, of the coast people of Trang, and of the Malays of Perak, and detailed studies of the external physical characteristics of these tribes, together with some valuable osteological observations. So far the authors have presented us with a considerable body of data which are at once available to students for comparative purposes, but they reserve comparisons and discussions until the final part. We look forward with great interest to the fulfilment of this promise, as there are several important ethnological problems connected with the region visited that students at home have no means of solving. When the full results of this expedition are before us, as well as those of the Skeat expedition (which we hope will not long be delayed), we shall be in a better position to reconstruct the anthropological history of a very important district, a knowledge of which is necessary before the ethnological problems of the Indonesian Archipelago can be unravelled.

A general sketch of the main results, from a racial point of view, will be found in the authors' paper in the current number of the *Journal* of the Anthropological Institute, but for the facts on which they are based the student must have recourse to the "Fasciculi Malayenses." Only part i. of this series has yet been published, and as no forecast is given of what is to be expected, one cannot say very much about the accounts of the social life of the jungle tribes, as subsequent parts may render the criticism void. It is safe to say that the physical anthropology is well done, and will prove of permanent value, to which the excellent illustrations of natives materially assist. The characteristic decoration, clothing, implements, habitations, and other details of the several tribes, which an intelligent traveller can readily observe, are carefully noted, and some curious engraved designs and patterns on dart cases, combs, and other objects are figured and partially described. There is an interesting chapter by Mr. Annandale on the beliefs and customs of the Patani fishermen. These Malays have various animal cults, but they certainly do not present any features of true clan totemism. This is followed by the first part of an essay on religion and magic among the Malays of the

FIG. 1.—Semang (Semán) shelter, with kitchen (occupied by married couple); Grit, Upper Perak.

Patani States, in which souls and ghosts are dealt with; a consideration of ghosts and spirits unconnected with material bodies will be published in another part.

The work is admirably printed, and the illustrations are excellent. This first part reflects great credit on the University Press of Liverpool.

ELECTROCHEMISTRY IN AMERICA.

THE third meeting of the American Electrochemical Society took place in New York on April 18. Three meetings may seem rather a small number for a society which has been in existence for more than eighteen months, but the society, which has members from all parts of the United States, only meets once in six months, and the meetings assume the form of a congress, which lasts several days. This style of meeting, which might be compared to the annual meeting of the Society of Chemical Industry, in which members from all parts of the country meet together each year in a different town, partly for work and partly for social intercourse, has certain obvious advantages, in that country as well as town members are able to attend; there is, however, one disadvantage, and that is that papers are only published once in six months. The transactions of the society are also only published once in six months, hence they contain the concentration of six months' work.

The presidential address of Dr. Joseph W. Richards, an abridgment of which is printed below, contains several points of considerable interest. One thing which will strike British electrochemists is that although the Americans have made great progress in the industrial applications of electrochemistry, yet they have to admit that they owe their present position in a large measure to foreign trained electrochemists. Dr. Richards mourns that they are vastly behind the Germans in the number of their chairs and laboratories of electrochemistry. How much more, then, should we in this country mourn—*we have not a single chair devoted to the teaching of electrochemistry*, and there are only two or three laboratories in the whole kingdom.

It is often said that, having very little water power in this country, we can never expect to compete industrially with other countries in electrochemical processes. Dr. Richards remarks that although all countries have not Niagaras, they have gas-engines, and he points out some of the sources of gas supply. Finally his remarks upon the value of literature, *good, sound literature*, are worth consideration. Where is the British electrochemical literature to be found?

To live is to progress, and to progress is to live. A science which does not progress petrifies. The science of electrochemistry has progressed so magnificently in the last decade that a mere catalogue of its achievements would be a monumental compilation. Abler and better-informed pens than mine have given to us recently, in presidential addresses and in careful reviews, the detailed history of this progress. I do not intend to attempt that task anew this evening; my theme is an analysis of the *conditions which make for progress*, and which I hope to make clear in all their bearings on electrochemical science.

I place discovery of new facts in electrochemical science as the corner-stone of progress in our science. Given a freshly-flowing current of new electrochemical facts, and all the other elements of progress have a chance to exist. No less certain than this is the location of the birthplace and the identity of the sponsors of these newly-born facts. The birthplaces are chemical, electrical and physical laboratories; the sponsors are the investigators, the searchers after truth—the professors, students, employees, private investigators, and all who with the insatiable thirst for more knowledge are pushing back the thick curtain of the unknown which hems us in so closely on every side. The elect among these workers, the highly-favoured few, are the professors of electrochemistry provided with well-equipped electrochemical laboratories. They are in the position to do or to direct the most valuable investigations, and are also under the moral obligation to publish freely to the world all that they discover. The giants of the electrochemical fraternity are in this class: Davy, Faraday, Bunsen, Arrhenius, van 't Hoff, Ostwald, Nernst, Moissan. The labours of such workers, given to the world in their publications, form the *body* of electrochemical science, and their thoughts—its *soul*. Such are the heroes of science; men who work for the work's sake, who sacrifice time, money, and often health, to increase the boundaries of our knowledge, and then keep nothing back.

The German-speaking countries count up alone at their universities and technical schools fifteen chairs of electrochemistry and twelve electrochemical laboratories. These, we all know it, have been the source of the greater part of the advance of electrochemical science in the last ten years. The whole industrial electrochemical world is debtor to the European electrochemical laboratories and their workers, and how can that debt be requited? Surely not by selfishly using all the facts and holding fast all the material benefits. Not only common gratitude but also self-interest unite in recommending to the captains of electrochemical industry that more such laboratories be built and more such chairs endowed; money thus spent will be seed which will return many fold its value to the industry. America has boasted that it is "The Electrochemical Centre of the World." It may be so, in the development of electrochemical industries, in the amount of power used and material products turned out; but is it not a fair question to ask "Where are the professors of electrochemistry at our universities and how many electrochemical laboratories are at their command?" Are we not out of comparison with Germany in that respect—but I trust not hopelessly so? Our present flourishing condition industrially is largely due to our foreign-trained electrochemists and our imported literature. Shall we not, through shame at contributing so little ourselves to that literature, soon begin to establish chairs of electrochemistry and build well-equipped laboratories to go with them? Then our boast might begin to be more than the empty boast of a successful money-maker; then we may begin to be an *illuminating* centre radiating knowledge to the rest of the world.

In place of professors and professional laboratories, however, America is blessed with another class of investigators who are no less industrious in acquiring facts, and to whom a large part of our commercial success is directly ascribable; I refer to the small army of patient investigators in the laboratories of our industrial plants, who are searching over ground not yet explored and accumulating facts of value in their special industrial lines. The expense of such work is borne by the corporation for which they labour, and the work itself is in reality an investment made in the hope of yielding financial reward.

By means of facts, correlating, discussing and deducing therefrom, we arrive at a knowledge of the laws of science, the rules governing its various phenomena and according to which its manifestations invariably proceed. Such deductions are the goal of pure science; they contain no element of speculation, hypothesis or theory, and represent man's deepest insight into the phenomena of nature.

The indefatigable Faraday discovered our first fundamental laws. Ohm and Joule added to them, and numerous later investigators have contributed, but we must not make the mistake of thinking that there remains very little more in the nature of generalisations to be discovered; we could not make a greater mistake. If facts are being discovered, the recognition of unforeseen generalisations and the establishing of new laws are bound to follow, and thus the science reaches its highest consummation.

Such discoveries are usually the privileges and the perquisites of the experimenter and investigator, if so be that he is likewise a thinker. He gets the facts at first hand, and has the first chance to deduce new laws. The electro-

chemist not blessed with laboratory facilities has, however, free entrance to this field. He may be only a student, a looker-on at what others are doing, a reader of the newly-discovered and recorded facts, but if he is at the same time a thinker, a compiler, an analyst with the power of collating, dissecting and deducing, he may in the seclusion of his study discover laws which escape the observation of others less studious, and thus render a service of the highest value to the science.

As soon as facts accumulate and laws are discerned, the man of science inevitably begins to reflect on the why and the wherefore. He commences to search for relations, to imagine connections and dependencies, and to make pictures of the mechanism of the phenomena. It was thus that Dalton imagined the atomic theory to account for the fact of chemical combination in simple multiple proportions, that Arrhenius hit upon the dissociation theory to account for the increase of molecular conductivity with increasing dilution, that Nernst worked out the solution-pressure theory to explain the generation of current in the galvanic cell. Thus there are theories and theories, some poor, some good, and some almost perfect in their applicability, since, *granting their premises*, they give an explanation satisfactory to the mind of all observed phenomena.

Such theories are not only allowable, but necessary. We must have them, much as an artisan must have a working drawing of the machine he will construct; the drawing is but paper and ink, which never moves or works, but it guides the workman in putting his ideas into realities. So theories help us to handle mental conceptions as if they were concrete things, and thus to imagine and discover relations and generalisations which would otherwise be beyond our mental grasp.

The danger to the development of a science comes when a theory, by being believed too implicitly and by not being open to constant revision, becomes a strait-jacket for the growing science. Like a "creed outworn," it stifles criticism, warps the judgment, engenders blindness and bias in its adherents and undue hostility and acrimony in its opposers. We should be slow in revising our theories, or in discrediting a theory which has done us good service in its day, just as we are conservative in correcting our "confessions of faith" or indulgent and sympathetic with the weaknesses of a faithful old servant; but, after all, when a theory has come to be considered so firmly fixed as to be above criticism, or so certainly true as to be above the possibility of revision, or so well-established as to thunder its excommunications on those who dare to think or believe otherwise—such a theory had better be placed at once in the museum of scientific petrifactions, where it properly belongs, and where it can do no further harm.

If science is progressing, theories must progress too; they will be outgrown, much light will give way to more light, imperfect pictures of phenomena founded on crude assumptions must be replaced by better pictures corresponding more accurately to the newer and the larger truth, and then progress begins anew.

All theories have been of some use in their day; they have helped men to grasp concretely evanescent immaterial phenomena, they have very often been splendid guides to further experiment and new discoveries, they have at times been so helpful that many have mistakenly thought them infallible, and lastly, they have been stepping-stones to better theories. One great hindrance to scientific progress is the common human weakness of becoming partisans of a theory. Who is not familiar with the well-meaning theoriser whose mental vision is so biased that he refuses or is incompetent to give a fair reception to new facts and theories; or who has not met the egotistical speculator who experiments and makes researches not to discover truth, but to prove his pet theory? Thus the warmest friends of a theory are often its worst enemies, and by their blind partisanship lay obstacles in the path of scientific progress instead of being the leaders which they might be.

To make a specific application of these remarks, who has not felt that the most effective blows dealt the present theory of electrolytic dissociation have come from the excessive zeal of its warmest adherents? There are scientific zealots as well as religious bigots, and the one does as much harm to the progress of true science as the other does to the development of pure religion.

The fundamental conceptions of any and every theory must always be open to correction and revision, and thus progress will be rendered easy. If new facts appear which contradict our theories, let us welcome them, like loyal lovers of the truth should. The theory of electrolytic dissociation is being saved by being modified and revised, it is being transformed into a more perfect mirror of the truth as we now conceive it, and thus only is it retaining its usefulness and aiding in scientific progress.

Power alone is apt to be regarded as the first desideratum for the success of electrochemical processes, but knowledge, thinking power and industry are more primary factors. Given these, crude materials to work with will be found on every hand, and power sufficient will be created if it is not to be found.

A few words, however, about this question of the necessary cheap power. This item in manufacturing cost is of variable importance in electrochemical processes; in some it may form three-quarters of the total cost of the process, in others perhaps only one-quarter. The former are frequently compelled to move to the cheapest power, in order to exist at all, while such as the latter may take into account many other considerations, and find it cheaper for them to locate at more expensive powers. Niagara Falls is the most accessible of our great water powers, and has therefore drawn into its fold the majority of our electrochemical industries. But another source of surplus power is distributed over a large part of our country, in a condition at present as undeveloped as was Niagara power when Columbus touched our shores. I refer to the surplus power from blast-furnaces, obtainable by using gas-engines. Every blast-furnace burns its gases to heat its blast and to raise steam for its power. The two-thirds of its gases used for the latter purpose generate just about the power needed for the blowing-engines, pumps, hoists, &c., an amount equal on an average to 2500 horse-power for a furnace making 500 tons of iron per day. If the gas thus used was used in gas-engines, there would be an average surplus power, over and above all the requirements of the furnace itself, of 10,000 horse-power. The gas-engine plant needed to produce this power does not cost more than 50 dollars per horse-power investment, which compares favourably with the cost of developing water-powers, which vary from 25 dollars to 100 dollars per horse-power. It is thus deducible that there are scattered over the United States, in some of our most flourishing industrial centres, undeveloped powers which aggregate more than 1,000,000 horse-power, which can be developed at no more cost than the average water-power, can be generated just at the spots where they can be most favourably utilised, and without any more drain on our natural resources than the harnessing of a new water-power—for not a pound of coal more would have to be burnt than is used at present.

Other possible sources of power are the waste surplus gases from by-product coking ovens, and the utilisation of gas-producers, using cheap, almost waste, coal, in connection with gas-engines. Power therefore is available in immense quantities in places and in countries not blessed with Niagaras in their midst, and the industrial development of such sources will be one of the most marked industrial movements of the next ten years.

And now, let us inquire, how is this increasing development of power and its increasing application to industrial purposes best promoted by the electrochemists themselves. Undoubtedly, it is by the intimate and cordial cooperation of theoretical with practical electrochemists. This is attained by many agencies, but the most potent are research companies and our Electrochemical Society.

Such organisations as research companies, formed explicitly to combine research with practical application, are novelties in the industrial world which have originated with, and are almost peculiar to, electrochemistry. They invent, investigate and develop electrochemical process, and furnish facilities to would-be experimenters whose ideas might otherwise remain still-born. Such companies deserve the hearty support of all electrochemists, for they are injecting new life into the industry. May we have more such, scattered all over our land to nurse and develop quickly into active being the many electrochemical processes which *are to be*.

The factors which promote increasing applications of

electrochemistry are therefore cheap and accessible power, experimentation on a semi-industrial scale, men with heads full of ideas and inventiveness in applying them to the industrial needs of the country, more research companies and a further cultivation of the beneficent results of our society meetings.

By thus doing, cheap raw materials will be converted by the electrochemist into valuable products with constantly increasing ease and constantly decreasing cost, and thus electrochemistry will achieve its great *raison d'être* by increasingly ministering to the needs, the comforts and the pleasures of life, and thus it will become an increasingly important factor in social progress.

No modern science can progress if it adopts the mediæval practice of the alchemists, and carefully guards its wisdom for the exclusive use of the initiated. Widespread dissemination of the literature of our science, not only among our own fraternity, but among educated people in general, and even down to the rising generation of expectant men of science, is as necessary to our progress as is the recruiting of the human family to the preservation of the race.

The literature of our science consists of transactions, journals, treatises, monographs and text-books. Without these, and without the constant extension, improvement and dissemination of the same, our science would soon be dead indeed.

The transactions of our societies are the standing record of papers and discussions presented at our meetings. The contents represent the labours of many heads and hands, and the opinions of many minds. As such, they form a permanent record of the latest advances and the best thought in electrochemical lines. They are the reservoirs of information from which the other literature of the science, such as treatises and monographs, is largely compiled. They are of particular value to people who cannot personally attend the meetings which they report. Their value is augmented by being quickly printed and distributed, and the publication committees having that task in their charge should receive the cooperation of all authors in their efforts to prevent the transactions from becoming ancient history before they are issued. We may be pardoned referring with a little pride to the fact that the report of our Niagara meeting was distributed seven weeks from the close of the meeting, and that 25 per cent. of the papers presented at this, our most notable New York meeting, were in print before the meeting began.

The increasing membership of our societies, and the placing of such transactions in scientific and public libraries, are potent means towards interesting and instructing the world in electrochemistry, and recruiting the army of electrochemical workers.

Our text-books, intended to give beginners their first ideas of electrochemistry, should be most carefully written. Nothing sticks so permanently in the mind as a correct idea taken in youth from a good text-book—except an incorrect idea taken from a bad one, and I think that the latter often sticks the hardest. It used to be remarked that every professor elected to a chair of mineralogy in Europe felt himself expected to write a treatise on crystallography—and he generally wrote it; it is, of course, an exaggeration to say that every privat-docent elected to lecture on electrochemistry writes a text-book on the elements of the science, but it is an exaggeration with a grain of truth in it. There are entirely too many imperfect or partisan or downright execrable text-books of this kind; one good one, written by a master, is worth more than all of these poor ones put together. Electrochemistry should also be better presented in the elementary text-books of chemistry and electricity. The interrelation of these subjects is so intimate that the fundamentals of either necessarily include some of the fundamentals of the other, and beginners are wonderfully apt at comprehending the essential fundamental facts if they are skilfully presented. I recall to mind a very complete modern text-book of inorganic chemistry, written by a splendidly-informed chemist, in which the electrochemical part was turned over to an assistant, and, as a consequence, abounds in misstatements. We cannot afford to have our students started wrongly, and it is therefore of the highest importance that our text-books, while being as brief as is necessary, should be as accurate as is possible.

NOTES.

THE monument which was unveiled last month at Bonn, in honour of Prof. Kekulé, stands away from the city and just in front of the building of the chemical laboratories of the University of Bonn, the place in which Kekulé laboured and taught for so many years and with such pronounced and conspicuous success. The statue stands on a granite pedestal, and is life-size and of bronze. On each side of the sculptured figure of Kekulé is a sphynx. The character of the man, simple and unpretentious, yet convincing, is well brought out, and some of his greatest scientific achievements are clearly represented in relief on the pedestal. At the unveiling ceremony many universities and scientific bodies, foreign as well as German, were represented, and so also were numerous firms engaged in the chemical industry.

THE third International Mathematical Congress has been arranged to take place in Heidelberg on August 8–13 of next year. The congress will be divided into six sections, dealing respectively with arithmetic and algebra, analysis, geometry, applied mathematics, history of mathematics, and pædagogics. In addition to the business and sectional meetings, there will be conversaziones, a banquet, and an excursion up the Neckar, and illumination of the Castle. The year 1904 is the centenary of the birth of C. G. J. Jacobi, and the occasion will be celebrated in connection with the congress by the publication of a memorial volume on Jacobi under the authorship of Prof. Königsberger. The secretarial work of the congress is in the hands of Prof. A. Krazer, of Carlsruhe.

THE Anthropological Institute announces that Prof. Karl Pearson, F.R.S., has accepted its invitation to deliver the annual Huxley memorial lecture this year. The lecture will be delivered on Friday, October 16, at 8.30 p.m., in the lecture theatre of Burlington House. Prof. Pearson has chosen for his subject, "On the Inheritance in Man of Moral and Mental Characters, and its Relation to the Inheritance of Physical Characters."

A REUTER message from Strassburg states that the second International Seismological Conference, the object of which is to found an association for the study of seismological phenomena in countries interested in the question, was opened there on July 24. Twenty States were represented. The Statthalter of Alsace-Lorraine, who is patron of the conference, welcomed the delegates in the name of the German Empire.

THE Government has appointed Captain Harry Mackay, a Dundee whaling master, to the command of the *Discovery* relief expedition. The relief ship *Terra Nova* will be manned by an entirely civilian crew, chiefly whalemen. The ship is expected to be ready for sea in about a month, and it has been decided, instead of making a long passage round the Cape, to proceed by the Suez Canal. Arrangements will be made to ensure that, after passing Gibraltar, the *Terra Nova* will be towed by fast vessels of the Royal Navy attached to the Mediterranean and East India stations. The relief ship will proceed to Hobart, where she will be joined by the *Morning*.

THE bust of the late Sir William Flower, prepared for the Flower Memorial Committee by Mr. Thomas Brock, was formally presented to the trustees of the British Museum, at the Natural History Museum, on Saturday last. Dr. P. L. Sclater gave an address in the name of, and on behalf of, the 185 subscribers to the fund.

THE Mackinnon research studentships of the Royal Society have been awarded for the year 1903–4 to Mr. F. Horton for physical research, and to Miss A. L. Embleton for biological research.

THE French Association for the Advancement of Science will hold its thirty-second annual meeting this year at Angers from August 4 to 11, under the presidency of M. Levasseur, Administrator of the Collége de France.

GOVERNOR LANHAM, of Texas, has, *Science* announces, issued a proclamation offering a reward of 10,000*l.* from the State to any person who discovers a practical method for eradicating the cotton boll weevil.

AT an extraordinary general meeting of the members of the Jenner Institute of Preventive Medicine on July 22, a resolution to alter the name of the institute to "The Lister Institute of Preventive Medicine," proposed by Sir Henry Roscoe, seconded by Sir Joseph Fayrer, and supported by Prof. W. J. Simpson, was unanimously adopted. A second meeting will be held on August 7, when the resolution will be submitted for confirmation.

THE council of the Society of Arts attended at Marlborough House on Monday, when the Prince of Wales, as president of the society, presented the society's Albert medal to Sir Charles A. Hartley, "in recognition of his services, extending over forty years, as engineer to the International Commission of the Danube, which have resulted in the opening up of the navigation of that river to the ships of all nations."

AN outline programme has been issued for the autumn meeting of the Iron and Steel Institute to be held at Barrow-in-Furness on September 1–4. The president, Mr. Andrew Carnegie, will deliver a short address, and the papers down for reading include the following:—Alloys of iron and tungsten, Mr. R. A. Hadfield; the restoration of dangerously crystalline steel by heat treatment, Mr. J. E. Stead and Mr. A. Windsor Richards; the influence of silicon on iron, Mr. Thomas Baker; the diffusion of sulphides through steel, Prof. E. D. Campbell; the heat treatment of steel, Mr. W. Campbell; the diseases of steel, Mr. C. H. Ridsdale; carbon in iron, Prof. A. Stansfield.

Science announces that the Bufalini prize of the University of Florence will be awarded at the end of October, 1904. This prize is of the value of 240*l.*, and is awarded once every twenty years. The subject is the value of the experimental method in opposition to the speculative method of scientific research.

AN international exhibition is to be opened at Arras, in the north of France, on May 1, 1904, and remain open until the following October. It is under the patronage of the President of the French Republic, the honorary president of the automobile section being the King of the Belgians. Industrial chemistry is dealt with in one of the classes, and another is devoted to alcohol and its production.

IN reply to a question on the position of wireless telegraphy in the Navy, Mr. Arnold-Forster has stated that all battleships, and a very large number of cruisers, are fitted either with the Marconi system of wireless telegraphy or with modifications of that system. The present average expenditure upon wireless telegraphy is about 20,000*l.* per annum, a considerable portion of this amount being paid to the Marconi Company. An agreement with the Marconi Company is now being concluded, and the use of wireless telegraphy throughout the service will be greatly extended in the future.

SOME additional particulars of the International Congress of Science and Arts to be held at St. Louis next year were published in Monday's *Times*. A body of men of learning from all parts of the world will assemble at St. Louis in connection with the congress, and it is hoped their deliberations will stimulate thought, promote science, and thus form a permanent contribution to the world's progress. An administrative board has been entrusted with the arrangements in connection with this new departure, and Prof. Nicholas Murray Butler, of Columbia University, is at the head of it. The main features of a plan proposed by Prof. Münsterberg, of Harvard University, for the conduct of the proceedings of this section have been adopted.

REUTER reports that on July 22, after a period of explosions, there was a flow of lava from Mount Vesuvius.

THE Museum of Practical Geology, Jermyn Street, will be closed to the general public during the painting of the interior from August 1. The business of the Geological Survey will, however, be carried on as usual, and visitors requiring special information will be admitted to the Museum.

THE Rev. G. W. Rawlings, of Ōsaka, Japan, sends us an interesting example of the pertinacity and strength of Japanese sparrows. A pair of sparrows he found flying about his bedroom one morning had begun to build in a corner of the room, and though the beginnings of the nest were cleared away each morning, the sparrows repeated their attempt three or four successive days. A clothes-brush placed in the corner to keep the birds away was found to have been moved by the sparrows, though it was six inches long and two inches wide.

MR. F. W. BRANSON, of Leeds, sends us an account of some experiments made by him with a mixture of radium and barium chlorides in a dry and in a moist state. When the substance was moistened with water and stirred, its radio-activity was only slightly reduced, though the luminosity instantly disappeared, but it was restored by drying for fifteen minutes at 150° C. When placed in benzene the dried salt retained its phosphorescence. Benzene, however, appeared to diminish somewhat the emission of light rays. Exposure of the dried salt for a few hours to a moist atmosphere caused a total cessation of phosphorescence, but not in a dry atmosphere. No action could be observed on a photographic plate exposed to the radiations from the moistened salt for thirty seconds, whereas the dry salt gave a full image in the same time. A much longer exposure of the moist salt gave a faint impression, about equal in amount to that produced by an equivalent amount of the dried salt, when the latter was covered with a thin paper, opaque to light rays.

AT the beginning of this year Mr. A. E. Shipley directed attention in these columns (vol. lxvii. p. 205) to the widely spread belief that a basil plant (*Ocimum viride*) provided a means of protection against mosquitoes. Observations made by Captain H. D. Larymore at Lokoja, Northern Nigeria, seemed to show that the belief was well founded, but Mr. Shipley pointed out that further experiments were needed upon the subject. The article was reprinted in the *British Medical Journal*, and was referred to by many other periodicals; and in consequence requests for seeds of the plant were received at the Royal Gardens, Kew, from many parts of the world. Sir William Thiselton-Dyer has, however, sent to the *Times* of July 27 a report of experiments made on the basil plant in relation to its effect on mosquitoes by Dr. W. T. Prout, at Freetown, Sierra Leone, and he remarks that it "appears to dispose conclusively of the plant's possessing any real protective value." The conclusions arrived at by Dr. Prout as the result of his experi-

ments are:—(1) Growing plants have little or no effect in driving away mosquitoes, and are not to be relied on as a substitute for the mosquito net. (2) Fresh basil leaves have no prejudicial effect on mosquitoes when placed in close contact with them. (3) The fumes of burnt basil leaves have a stupefying, and eventually a destructive, effect on mosquitoes, but to obtain this action a degree of saturation of the air is necessary which renders it impossible for the individual to remain in the room. It is probable, however, that cones made of powdered basil would, when burnt, have the effect of driving mosquitoes away, and to this extent might be found useful.

A REPORT has been issued by the London County Council upon the manufacture of aërated waters in London. It is recommended that, in view of the large consumption of aërated waters, the premises upon which they are manufactured should be registered and periodically inspected in order to ensure a proper standard as regards sanitary conditions.

WE recently noted in these columns the outbreak of ankylostomiasis (infection with a parasitic worm) which has occurred in the Dalcoath mine, Cornwall, reported upon by Drs. Haldane and Boycott. A report has now been issued by the Home Office on an outbreak of the same disease in the Westphalian colliery district in Germany. A case has also been met with in Scotland by Dr. Stockman. In all probability, therefore, this disease is more widespread than was formerly supposed.

DR. TIMBRELL BULSTRODE's report upon alleged oyster-borne illness following the mayoral banquets at Winchester and at Southampton has been issued by the medical officer of the Local Government Board. Dr. Bulstrode summarises the facts as follows. Two mayoral banquets were given on the same day in two towns. After both banquets a certain percentage of guests, all of whom had partaken of oysters, were attacked with illness of analogous nature, in some cases with definite enteric fever, in others with gastro-intestinal disturbance only. The oysters supplied to both banquets were from the same source (Emsworth), and the oysters from this source were at the same time and in other places proving themselves competent causes of enteric fever.

IT is reported that Prof. Kossel, of the Imperial Department of Health, Berlin, supports Prof. Koch's view of the non-transmissibility of bovine tuberculosis to man. He stated at a recent meeting of the Berlin Medical Society that out of all the experiments conducted by the Imperial Board of Health, in two cases only had human tubercle bacilli affected the experimental animals. Prof. Orth, the successor to Virchow in the University of Berlin, on the other hand, states that in his own experiments 10 per cent. of the animals were infected with the tubercle bacillus of human origin. At the recent congress of the Royal Institute of Public Health, Prof. Young, who has collaborated with Prof. Hamilton, of Aberdeen, said that their experiments upon twenty calves left no doubt of the communicability of human tuberculosis to bovines, and Drs. Dean and Todd have proved the same point as regards pigs.

IN a paper entitled "Luftelektrizität und Sonnemtrablung" (Leipzig), Dr. H. Rudolph develops a theory of the origin of atmospheric electricity. We do not think his theory is likely to meet with general acceptance; the reasoning by which he arrives at the laws on which his mathematical investigation is based is, to say the least, by no means convincing. In an appendix the author mentions a method which he has invented for employing a captive balloon to collect from the upper atmosphere the large amount of electrical energy which he believes to be now running to waste, and he complains that the public have not given his scheme the support that it deserves.

THE "spinthariscope" devised by Sir William Crookes to show the scintillations which are produced on a blende screen when a piece of radium nitrate is brought near it, is now made by several scientific instrument makers. Mr. A. C. Cossor, of 54 Farringdon Road, has sent us one of these instruments, which consists of a short brass tube having at one end a blende screen with a speck of radium salt about a millimetre in front of it, and at the other end a simple convex lens. The instrument is very satisfactory, and shows the scintillations wonderfully well; it provides a convenient means of observing the action of radium, and can be recommended as a waistcoat-pocket instrument of scientific value.

WE have received a copy of the observations made at the Batavia Observatory during the year 1901; it contains hourly meteorological values and seismometric records, but the magnetometer was out of action during the year, owing to its removal to Buitenzorg. We are glad to see that the Netherlands Government propose to undertake a magnetic survey of the East Indian Archipelago, extending from longitude 95° to 140°; this will be a valuable addition to the magnetic survey of British India. An appendix to the volume contains a discussion of the anemometric observations for the ten years 1891–1900. This laborious investigation shows that calms largely predominate, especially during the westerly monsoon, from December to April. The direction of the wind during this period is chiefly from the north-western quadrant. From April to November, northerly and north-easterly winds predominate by a large percentage. The greatest horizontal displacement of the air occurs between August and October, during which time easterly trade-winds largely prevail. Another appendix contains valuable electrical and meteorological observations made during the total eclipse of the sun on May 18, 1901, at various stations.

THE *Quarterly Journal* of the Royal Meteorological Society (No. 127, July) contains an important and interesting paper on the prevalence of gales on the coasts of the British Islands during the thirty years 1871–1900, based on the data collected annually in the Meteorological Office for the purpose of testing the accuracy of storm warnings issued. We can only refer here to some of the general results:—the mean annual number of gales experienced on the west coasts is 29·6; of the total number 82 per cent. occur in the winter half-year; on the north coasts the mean number is 25·7, with a percentage of 84 in winter; on the south coasts, mean 19·1, winter percentage 80; on the east coasts, mean 15·6, with 84 per cent. in the winter half year. As regards direction, the mean results show that on the west coasts about 68 per cent. of the gales blew from the Atlantic, or equatorial directions, and about 26 per cent. from the Arctic, or polar directions; on the north coasts about 66 per cent. blew from equatorial, and 30 per cent. from polar quarters; on the south coasts the numbers were respectively 73 and 25 per cent; the results for the east coasts show that less than 53 per cent. blew from equatorial directions, and more than 44 per cent. from polar quarters. The prevalence and direction of gales in each division are plainly illustrated by wind-roses.

AN account of the flora of the north island of Nova Zembla appears in the *Bulletin du jardin impérial botanique* of St. Petersburg. The author, Mr. Palibin, observes that the flowering plants are most closely allied to those found in the Arctic regions of Asiatic Russia, but the algal flora resembles rather that of Spitsbergen.

A SECOND paper by Prof. Vines is published in the *Annals of Botany*, and gives an account of further investigations into the action of proteid-dissolving ferments in plants. Certain divergences appear to exist between the observations of the author and other experimenters; these are traced to the use of different antiseptics, so that it becomes necessary to try several antiseptic substances before formulating any conclusions as to the digestive power of the ferments under consideration.

THE formation of the first tropical experiment station in the British Empire in Ceylon, has already been referred to in these columns. Apart from agricultural experiments and the cultivation of economic products, questions of pure scientific interest will doubtless receive attention. In his report, Mr. Wright, the controller of the station, announces that experimental plots have already been laid out to determine how far the cultivated varieties of cacao plants bearing pure purple or pure white seeds will breed true. Should this be the case, the results produced by crossing will give valuable evidence for testing the Mendelian laws.

AMONG other articles, the *Transactions* of the Manchester Microscopical Society for 1902 contain some interesting observations by Mr. J. Barnes on the microscopic structure of the mountain limestone of Derbyshire. In the first place, it is recorded that the rock contains large numbers of very minute but perfectly formed quartz-crystals, frequently formed round a jaspideous nucleus. Of special interest is the description of a mottled phase of the mountain limestone, in which the dark portions have been produced by the carbonaceous matter contained in foraminifera, with which the rock is crowded.

THE Geological Survey has issued a memoir on the geology of the country around Reading, by the late Mr. J. H. Blake, edited by Mr. H. W. Monckton. The district is a part of the London Basin, with a foundation of Chalk, overlain by Reading Beds, London Clay, Bagshot and Bracklesham Beds, with extensive coverings of plateau and valley drifts. The Reading Beds are of special interest, and many detailed sections of the strata are given, with an analysis, by Dr. W. Pollard, of the mottled clay which is so largely worked for brick- and tile-making. There are also figures of some of the plant-remains which are found in the strata. A list of fossils from the basement-bed of the London Clay is likewise given. Mr. Monckton has contributed many notes relating to the superficial deposits.

SOME interesting facts referring to the cultivation and economic uses of the potato in Germany were recently stated by the American Consul-General in Berlin in connection with a technical exhibition there. In 1901, for every 10,000 inhabitants 160 acres were planted with potatoes, against 98 acres in France, 31 in Great Britain and Ireland, and 34·8 in the United States. The sandy plains of northern and central Germany are well adapted by nature to the cultivation, and elaborate experiments in scientific fertilising and cultivation have increased the production per acre by about 38 per cent. in the last ten years. The result has been that the crop reached the danger point of over-production in 1901, and accordingly there was in that year an enormous increase in potato alcohol, and the market was glutted with raw spirit. In February, 1902, there was an exhibition in Berlin to illustrate and promote the use of denaturised alcohol for technical and industrial purposes, and it has been repeated this year. Besides alcohol, the technical products of the potato are starch, starch syrup, potato flour, dextrin, and starch sugar. The production of these during the last ten years has increased rapidly, as has the export also. Last year the exports of potato flour and starch reached 45,970 tons, or more than double those of 1900, while the export of dextrin was 14,047 tons. The United Kingdom is the largest purchaser of German potato starch, the imports last year being 23,827 tons. The Consul-General adds that the law of 1887 regulating the production and use of untaxed alcohol for technical purposes was one of the wisest and most far-seeing of enactments, for Germany has profited largely by the stimulus thereby given to the cultivation of the potato and to the employment of cheap spirit in the chemistry and the industrial arts.

WE have received a copy of an article published in the Natural History and Scholastic *Abhandlungen* of Leipzig, by Mr. F. Mühlberg, on the object and extent of the instruction in natural science given in the higher middle-schools.

WE have received two further instalments of Messrs. Jordan and Fowler's valuable reviews of Japanese fishes, in course of publication in the *Proceedings* of the U.S. Museum, the one being devoted to the carp group, or cyprinoids, and the other to the cat-fishes, or siluroids. In both groups several new forms are described, some of which have, however, been already referred to in preliminary notices. A new genus of cat-fish receives the name of Fluvidraco, and apparently includes the well-known "yellow dragon" of the rivers of China. In another fasciculus of the same publication Mr. T. Gill discusses the affinities of the opah, or king-fish, and finds that he is not able to accept in their entirety the views on this subject recently published by Mr. G. A. Boulenger. He has some interesting observations on the origin of the name "opah," which appears to have been imported from the west coast of Africa, but does not seem to be the proper native title of the fish to which it is now applied.

THREE other papers from the *Proceedings* of the U.S. Museum are also to hand. In one of these Mr. D. W. Prentiss describes as new an imperfect mink skull from the shell-mounds of Maine. In the second Mr. A. N. Caudell discusses the orthopterous insects of various States, with descriptions of new species; and in the third Mr. J. E. Benedict revises the crustaceans of the genus Lepidopa.

AN issue of the *Circulars and Agricultural Journal* of the Royal Botanic Gardens at Ceylon contains an account, by Mr. E. E. Green, of a recent abnormal and remarkable increase in one district of the numbers of the so-called lobster-caterpillar (*Stauropus alternus*), which affects tea-plants. Until quite recently this caterpillar was so uncommon that good specimens were regarded as prizes by collectors; but latterly it has made its appearance in enormous numbers on certain plantations in the Kalutara district, where it has become a perfect "tea-pest." The reason for this sudden increase has not been ascertained.

ALL that Mr. E. Thompson-Seton writes with regard to the habits and ways of animals is well worth reading, and we are therefore glad to welcome an article from his pen in the Smithsonian Report for 1901 entitled "The National Zoo at Washington, a Study of its Animals in Relation to their Natural Environment." The author describes in some detail the history of the formation of this great and important undertaking, and the prime object which the founders had before them, namely, the preservation of as many of the larger North American animals as possible under conditions assimilating, so far as practicable, to their natural surroundings. In the case of many species, such as the wapiti, the bison, and the pronghorn, the experiment

has, up to the present, been a decided success. There are, however, a number of mammals, inclusive of the bighorn sheep, the true blacktail deer, the mule-deer, the moose, the white goat, and the grizzly bear—all more or less in danger of extermination—which have not yet been established in refuges of their own. This, it is said, is largely due to lack of funds; and the author points out that if the Alaskan brown bear—the largest living member of its kind—be not soon established in the gardens, it will be too late. Many interesting traits in the habits of American mammals are recorded, notably the fact that the prongbuck expands the hairs of its white rump-patch in a disc-like manner when alarmed, after the fashion of the Japanese and Peking deer, the white patch, when thus expanded, forming a conspicuous "recognition mark."

MESSRS. WATTS AND CO. have issued for the Rationalist Press Association, Ltd., a sixpenny edition of a selection of Tyndall's lectures and essays from "Fragments of Science." The famous British Association address at Belfast in 1874 is included, and also the biographical sketch of Tyndall in the "Dictionary of National Biography."

SINCE its publication in 1881, Mr. W. Robinson's delightful book on "The Wild Garden" has been the means of introducing many lovers of plants to new and beautiful aspects of vegetation obtained by placing hardy exotic plants under conditions where they will thrive without further care. The fifth edition has just been issued by Mr. John Murray, and will appeal to a larger circle of readers than that which derived ideas from the original work. The illustrations are all woodcuts by Mr. Alfred Parsons.

THE first part of the fifteenth volume of the *Proceedings* of the Royal Physical Society of Edinburgh, a copy of which has been received, deals with the work of the session 1901–1902. In addition to the opening address by Dr. David Hepburn, vice-president of the society, on some morphological evidences of the evolution of man, the volume contains, amongst others, papers by Mr. Goodchild on the origin of rock-salt and on observations upon the bathymetrical distribution of reef-building corals, and one by Dr. Munro on the prehistoric horses of Europe and their supposed domestication in Palæolithic times.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mrs. Watkins; a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mr. H. P. Jaques; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Captain C. P. Harvey; two Kinkajous (*Cercoleptes caudivolvulus*) from South America, presented by Miss C. Wallace Dunlop; a Himalayan Whistling Thrush (*Myiophoneus temmincki*), a Blue-winged Siva (*Siva cyanouroptera*), a Lesser Blue-winged Pitta (*Pitta cyanoptera*) from the Himalayas, presented by Mr. E. W. Harper; a Cardinal Grosbeak (*Cardinalis virginianus*) from North America, presented by Mrs. F. S. Stevenson; a Greek Tortoise (*Testudo graeca*), European, presented by Mrs. F. Bailey; two Wanderoo Monkeys (*Macacus silenus*) from Malabar, a Common Crowned Pigeon (*Goura coronata*), a Sclater's Crowned Pigeon (*Goura sclateri*) from New Guinea, a White-throated Ground Thrush (*Geocichla cyanonotus*), a Bengal Pitta (*Pitta bengalensis*), two Indian Rollers (*Coracias indica*), three Pond Herons (*Ardeola grayi*), five Scarlet-backed Flower-peckers (*Dicaeum cruentatum*), two Two-banded Monitors (*Varanus salvator*) from India, deposited.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN AUGUST:—

August	2.	8h. 1m. to 11h. 5m. Transit of Jupiter's Sat. III. (Ganymede).
	8.	13h. 10m. to 15h. 56m. Transit of Jupiter's Sat. IV. (Callisto).
	9.	11h. 27m. to 14h. 32m. Transit of Jupiter's Sat. III. (Ganymede).
	10–13.	Epoch of the great Perseid meteoric shower (Radiant point $45° + 57°$).
	12.	11h. Venus at maximum brilliancy.
	13.	10h. 54m. Minimum of Algol (β Persei).
	15.	Venus. Illuminated portion of disc $=0{\cdot}236$; of Mars $= 0{\cdot}877$.
	16.	14h. 50m. to 17h. 54m. Transit of Jupiter's Sat. IV. (Callisto).
	19.	13h. 16m. to 13h. 46m. Moon occults λ Geminorum (Mag. 3·6).
	28.	Perihelion Passage of Borrelly's comet (1903 *c*).
	29.	Mars $1\frac{1}{2}°$ south of α Libræ (mag. 2·9).

PHOTOGRAPHS OF COMET 1902 *b*.—Prof. R. H. Curtiss reproduces on their original scale, and minutely describes, some excellent photographs of Perrine's comet (1902 *b*) in the Lick Observatory *Bulletin*, No. 42.

The photographs were secured with the Pierson camera, which has a Dallmeyer objective of 15cm. aperture and 82.6cm. focal length, the Floyd telescope of 12cm. aperture and 200cm. focus serving as a guiding telescope. The nine photographs reproduced show very clearly the remarkable changes which took place in the size and form of the comet's tail.

THE NEW OBSERVATORY FOR BULUWAYO.—The *Buluwayo Observer* for March 21 gives an interesting account of the new observatory which is being founded in that city by the Jesuit mission.

Father Goetz, who obtained brilliant successes at the Paris University, and for eighteen months has been working at the Georgetown (U.S.A.) Observatory, has been appointed director, and has taken with him a fairly complete outfit of instruments for magnetic and meteorological observations. It is proposed that, as the work progresses, other instruments for astronomical work shall be added, and part of the programme for the new observatory is to undertake the mapping and cataloguing of variable stars in the southern hemisphere on similar lines to those followed at Georgetown for the northern variables. For this purpose the mission negotiated for the loan of an equatorial telescope from the Carnegie Institution, but the negotiations have not yet been successful.

The Chartered Company has given two blocks of land for the observatory site, and the Government has granted assistance in the erection of the necessary buildings (*Zambesi Mission Record*, July).

THE SYSTEM OF ϵ HYDRÆ.—In No. 36 of the Lick Observatory *Bulletin* Prof. Aitken gives the details of, and discusses, his observations of the binary system ϵ Hydræ, which, since its discovery by Schiaparelli in 1888, has been observed to possess a rapid motion. The various observations, except those made at Greenwich, are satisfactorily represented by an ellipse having the following approximate elements:—

$$T=1901{\cdot}1,\ P=15{\cdot}7 \text{ years},\ e=0{\cdot}685,\ a=0''{\cdot}24.$$
$$\Omega=109°{\cdot}5,\ i=35{\cdot}5,\ \lambda=264{\cdot}7,\ n=+22{\cdot}293.$$

The components differ fully two magnitudes in brightness, and their maximum separation is only $0''{\cdot}25$.

There is a third star at a distance of $3''$ forming, with the close double, the double star Σ 1273, and the observations show that together they form a ternary system, whilst the spectrograms obtained with the Mills spectrograph, and measured by Dr. H. D. Curtis, show that this third star has a line of sight velocity varying from $+45{\cdot}2$ on November 28·02, 1899 (G.M.T.), to $+29{\cdot}1$ on November 7·06, 1901, and that the visual and spectrographic binary systems are identical. If this is correct the spectrum observations should show a slow increase in the velocity of recession for the next year or two, and then a nearly uniform velocity until 1912.

WAVE-LENGTHS OF SILICON LINES.—Supplementing his recent work on the wave-length of the magnesium line at λ 4481, Prof. Hartmann has now redetermined the wave-lengths of the two silicon lines at λ 4128 and λ 4131, and has published his results in No. 1, vol. xviii. of the *Astrophysical Journal.*

These two lines, which are of great importance in the discussion of stellar spectra, generally appear broad and hazy in laboratory spectra, but, by photographing the spectrum of Geissler tubes containing silicon tetra-fluoride at low pressure, Prof. Hartmann has obtained them as sharply defined lines, from measurements of which he has obtained 4128·204 and 4131·040 as their respective wave-lengths, these values being based on Kayser's wave-lengths for three iron lines, viz. λ 4118·709, λ 4132·217 and λ 4144·033.

By similar means he has redetermined the wave-length of the carbon line at λ 4267, and gives 4267·301 as its exact value.

THE ECLIPSE OF THE MOON, APRIL 11–12.—In the July number of the *Bulletin de la Société Astronomique de France* a large number of photographs of this eclipse, obtained by various correspondents of the society, are reproduced. The photographs were obtained with many various instruments, and they, together with the remarks accompanying them, emphasise the exceptional density of the earth's shadow during this eclipse.

A METHOD OF APPLYING THE RAYS FROM RADIUM AND THORIUM TO THE TREATMENT OF CONSUMPTION.[1]

THE successful results reported in the treatment of rodent cancer by the rays from radium, and the general germicidal action of the rays, make the discoveries and investigations by Prof. Rutherford of the radio-active emanations of radium and thorium of great possible importance to medical men. The present article deals with the manner in which these emanations can be inhaled into the lungs and be made the means of applying the rays from radium and thorium to the treatment of consumption, in the hope that medical men will be induced to undertake research in this field. The rays from radium and thorium are very similar in kind, but differ greatly in relative degree. Five minutes' application of radium would be about equivalent to ten years' application of the same weight of thorium. Both elements continually and spontaneously produce radio-active emanations, or gases in infinitesimal quantity, beyond the present means of chemical or spectroscopic detection, but endowed with very considerable powers of giving out rays on their own account of exactly similar kind to the rays from radium and thorium themselves. The best condition for the free escape of these emanations, so that they can mingle with the air the patient breathes, occurs with both radium and thorium compounds when they are dissolved in water. In the solid state the emanations are often stored up by the salt and do not escape. Three-quarters of the normal activity of a dry solid radium compound is due to the stored up emanation. This escapes into the air instantly when it is dissolved in water.

If the air containing the emanation is removed and stored in a gas-holder away from the radium, the quantity slowly diminishes, and the radium solution grows a fresh crop as fast as the old disappears. In four days one-half of the emanation removed has disappeared, and one-half has reappeared in the vessel containing the radium solution, provided, of course, that it has been closed air-tight in the interval. After about three weeks the amount of the old emanation remaining is negligibly small; the amount re-formed is a practical maximum, the same as was originally obtained on dissolving the solid salt. In the case of thorium one-half of the emanation disappears or is reproduced, as the case may be, in one minute. In five minutes the old emanation has practically all disappeared, and the thorium solution, if kept in a closed bottle, again contains as much as it ever did or can contain. In three weeks for radium, and in five minutes for thorium, an equilibrium in the amount of emanation present is reached, as much disappearing as is reproduced, in the same way as the population of a country remains constant when the number of births in any given time equals the number of deaths.

These considerations regulate the "dosage." The longer a patient breathes through a thorium solution the greater the dose of emanation. With radium, however, once the emanation has all been inhaled, no further effect is produced, and the solution must be left tightly closed to recover its emanation before it can again be advantageously used. Further, in dealing with the thorium emanation, it is essential that the air should reach the patient's lungs within the shortest possible time, say half a minute, after leaving the thorium solution.

The property of the emanations of leaving behind a film of radio-active matter wherever they come into contact, which causes the phenomenon of "excited" or "induced" radio-activity, is important in the present connection, because this excited activity will remain in the air-cells of the lungs after the emanations themselves have been exhaled. This excited activity gradually disappears in the course of time, becoming negligible with thorium after two days, and with radium after three or four hours. The practical effect of this in both cases will be to cause a feebler continued action of the rays on the lungs after the more powerfully radio-active emanations have all been exhaled.

Which emanation will prove the more suited for the present purpose is, of course, a matter for trial, but thorium possesses many compensating advantages which make up for its very feeble radio-activity. It is cheap, and can be procured in any quantity. Unlike radium, the effect of its emanation is proportional to the time of inhalation. Moreover, in dealing with the emanation there is practically no limit to the quantity effectively employable. The radiation from a solid salt, owing to absorption of the rays by the salt itself, is practically confined to a thin surface layer, but with the emanation no such absorption occurs. The emanation from a kilogram or more of thorium salt could be effectively employed on the lungs of a single patient. Thorium nitrate, a very soluble salt, is the most suitable compound to employ, but the free nitric acid present should be neutralised after the salt has been dissolved in water by cautious addition of ammonia with stirring, until precipitation is about to take place. A gas washing bottle, with outlet and inlet tubes ground in, could be used as the inhaler, and this should be filled as full as possible with the moderately concentrated solution. There is not much fear that an hour's daily inhalation of the emanation from 100 grams of dissolved thorium nitrate would produce any ill effect, and both the quantity employed and the time of inhalation could, after due trial, be increased indefinitely. For use with the radium emanation the inlet and outlet tubes should be provided with taps. A few milligrams of the salt, radium bromide, for example, should be placed in the dry bottle, and water drawn in to dissolve it, the taps being then closed. For the first trials, a few bubbles only of the total gas contained in a fairly large bottle should be drawn into the lungs with a deep breath of air, and retained as long as possible before being exhaled. The dose should be only very gradually increased, and the effect on the system very carefully watched, for the radium emanation is an exceedingly powerful agent. Mixed with air it glows brightly in a dark room, and exerts a very rapid oxidising action on carbonaceous matter, and even on mercury. The maximum possible dose for any one quantity of radium solution would be obtained by inhaling the whole gaseous contents of the bottle, a few bubbles at every breath, once every twenty-four hours.

The immunity of these processes from external interference, the simple nature of the treatment proposed, the infinitesimal quantity of the active agents employed, the manner in which the emanations may be inhaled to do their work at the very seat of the disease, leaving behind in their place the excited activity to continue the work in a gentle manner after they have been exhaled, make out a strong case why the attention of medical men should be directed to these new weapons which physics and chemistry have placed at their disposal. Indeed, if nature had designed these phenomena for the purpose proposed, it is difficult to see in what way they could be improved upon.

FREDERICK SODDY.

[1] Abridged from the *British Medical Journal*, July 25.

THE CHEMISTRY OF THE ALBUMINS.

THE composition and constitution of the albumins have hitherto been studied almost exclusively from the analytical point of view, and particularly by the examination of the products of hydrolysis effected by either acids, alkalies, enzymes, or putrefactive bacteria.

Improved methods for the separation of these products, due to Kossel, E. Fischer, and others, have led to the conception of the complex albumin molecule as composed of a large number of simple molecules, consisting to a great extent of monamino- and diamino-acids and related compounds (compare NATURE, vol. lxv. p. 90), united together by some form of condensation, which involves an amino-group, and is probably similar in nature to that which occurs in the formation of the acid amides.

The various members of the vast group of albuminous substances may differ from one another in many ways, but two of the chief points of difference appear to be the variety of these component groups, and the numbers of them contained in a single molecule. Thus a comparatively simple albuminoid substance, such as silk when it is completely hydrolysed, yields, among other products, the monamino-acids, tyrosine, phenylalanine, leucine, alanine (amino-propionic acid), and glycine (aminoacetic acid). Gelatin, on the other hand, which is also comparatively simple in composition, differs markedly from silk by the absence of tyrosine, whilst oxyhæmoglobin, to take another instance, yields tyrosine, but no glycine.

By the incomplete hydrolysis of the fibroin of silk, moreover, Prof. E. Fischer has obtained a substance which appears to be a compound of aminoacetic and amino-propionic acids. The formation of this substance is of great interest, since it probably represents an intermediate stage of the decomposition, and affords strong confirmation of the view of the constitution of the proteid molecule which has just been stated.

Most of the final products of hydrolysis of the albumins are familiar compounds which can readily be prepared by synthetic methods, but very little has hitherto been known of the more complex substances to be obtained by the linking together of several of these molecules. It is in this direction that Prof. Emil Fischer has been working for some time past, and he has contributed to the current number of the *Berichte* an account of the highly important results which have already been attained. The plan of attack consists in endeavouring to build up complex substances from the simple amino-acids by first introducing a second molecule of the same or another acid, and then repeating the process as frequently as possible with each successive product.

The first step was taken some time ago by the production of glycylglycine, $NH_2.CH_2.CO.NH.CH_2.CO_2H$, from glycine anhydride. This substance contains two molecules of glycine united in the typical manner, and is the simplest of the *polypeptides*, as these bodies have been named, because of their assumed similarity to the peptones in structure. To add a third link to the chain is, however, a matter of difficulty, owing to the ease with which the amino-group undergoes change. Two methods have, however, been found by means of which this can be accomplished.

The first of these consists in building up the new amino-acetic molecule by first introducing into the amino-group the chloracetyl radical, $Cl.CH_2.CO.$ (by the action of chloracetyl chloride), and then introducing the amino-group by the action of ammonia, the final product being a crystalline substance having the formula of a diglycylglycine, $NH_2.CH_2.CO.NH.CH_2.CO.NH.CH_2.CO_2H$. A description of the properties and reactions of this substance has, unfortunately, not yet been published.

The other method consists in first of all introducing the group $.CO_2C_2H_5$ into the amino-group of glycylglycine. The resulting compound can then be converted into an acid chloride, which readily reacts with the ester of glycine to form the desired compound containing three glycine molecules. A repetition of this process leads to the addition of a fourth glycine molecule to the chain, the final product which has hitherto been obtained being of the respectable complexity shown by the formula

$$CO_2C_2H_5.NH.CH_2.CO.NH.CH_2.CO.NH.CH_2.CO.NH.CH_2.CO_2C_2H_5$$

(carboxethyl-triglycylglycine ester). This substance is crystalline and is converted by ammonia into a crystalline amide, which gives, with an alkali and a copper salt, the well-known biuret reaction, which is given by all the amides of this series, as well as by the albumins. The group $.CO_2C_2H_5$ combined with the amino-group cannot, so far, be removed from the molecule, so that, until some means of doing this is discovered, this method can scarcely be expected to yield derivatives so closely related to the actual proteids as those obtained by the method first described.

Both methods obviously lend themselves to the production of a great variety of compounds containing different amino-acid groups, and substances of this kind, derived from glycine and leucine, and from glycine and alanine, have already been prepared. It seems probable that by their extended use compounds of the order of complexity of the peptones or albumoses may soon be prepared. The application of both methods is, indeed, still in its infancy, but we can have little doubt that the genius which laid bare the innermost secrets of the sugars will succeed in solving many of the problems which surround the chemistry of the albumins.

ARTHUR HARDEN.

THE ANTARCTIC EXPEDITIONS.

THE report of Captain Scott to the presidents of the Royal and Royal Geographical Societies, which is printed in the July number of the *Geographical Journal*, adds a number of points of geographical interest to those previously published, especially with regard to the great southern ice-barrier, and the nature of the lands discovered by the British expedition; while the map published at the same time, which has had the advantage of revision by Lieut. Shackleton since that officer's arrival, permits the details of the narrative to be followed with much clearness, although it is still to be considered merely provisional.

The voyage down the east coast of Victoria Land brought to light some new features in the configuration of the country. Thus, in about lat. 75° 30′, an enormous floe of the inland-ice was seen to descend into the sea and extend for many miles to seaward, closely resembling the Great Barrier and the barrier formation which entirely fills Lady Newnes Bay. Near the entrance to MacMurdo Strait (between Erebus and Terror Island and the mainland), ice-cliffs, 150 feet high, were again skirted, being evidently the seaward face of the great glacier subsequently explored by Lieut. Armitage. During the voyage eastward along the face of the Great Barrier, soundings for some time showed depths of more than 300 fathoms, the barrier edge being very irregular, and varying from 30 to 215 feet in height. In the neighbourhood of the eastern land discovered by the expedition (King Edward VII. Land) the soundings suddenly became less, varying from 70 to 100 fathoms. The bare patches seen among the snow slopes of the new land, which are evidently the sharp spurs of snow-capped hills, stand at a height of 2000 to 3000 feet. The balloon ascent and sledge expedition made in long. 196° 15′, showed that the surface of the barrier[1] undulated in long waves running W.S.W. and E.N.E. It was noticed that here the ship neither rose nor fell in relation to the ice, thus apparently indicating that the latter is floating.

The winter quarters were established in February, and the magnetic observatory was in readiness for the term-day observations of March 1, all the subsequent term days being kept by Mr. Bernacchi without a break. On May 3 a strong southerly gale brought the first heavy snowfall, also blowing the strait clear of ice to within 200 yards of the ship. Mr. Hodgson was constantly engaged on his biological work, keeping holes open for his nets and fish-traps, and all the officers assisted Lieut. Royds in the night meteorological observations. Auroral displays were infrequent and feeble, but were carefully observed. The winter sledge reconnaissances revealed much of the topography of the neighbourhood, both on the south side of Erebus and Terror Island, and between it and the mainland, where there are three smaller islands, named White,

[1] The whole southern ice-sheet is spoken of throughout as the "barrier," though this term would more naturally apply to its northern face only.

Black, and Brown, from their characteristic aspects; the first being snow-covered, while the two others displayed the bare basaltic rocks of which they are composed. In September and October minimum temperatures of −51° and −57° F. were experienced during two of the journeys.

During a visit to Mount Terror, the eastern slopes of which are terribly wind-swept and bare to the summit, Mr. Skelton made a perilous descent to the sea-ice, and was so fortunate as to discover a breeding-place of the Emperor penguin, obtaining several specimens of the young in down, besides photographs and notes. The attacks of scurvy which occurred about this time, brought about by severe work and exposure, were in reality very slight, and their importance has been much exaggerated, all symptoms quickly disappearing when the diet was restricted to seal-meat. Skua gulls, which were also obtained, were found to be excellent eating.

The southern sledge expedition undertaken by the Commander, with Lieut. Shackleton and Dr. Wilson, was carried out entirely on the surface of the great ice-sheet, it being found impossible to reach the land, though it was sufficiently near to allow of observations as regards the bearing and altitude of the different land-masses, as well as sketches and photographs. A remarkable feature seems to be the fiord-like openings by which it is penetrated at various points, though the intervening volcanic masses rise into magnificent ranges of mountains. These openings had the appearance of straits, nothing being seen behind, though the state of the ice-sheet opposite them showed that ice must be pressing out through them. On approaching the land at the furthest south, the ice-sheet was found to be separated from it by an immense chasm, the ice-foot resembling that seen elsewhere at the sea-margin of the lands, and forming a complete bar to further progress. The return journey was rendered difficult by the nature of the surface and the prevalent mist.

The further details supplied of Lieut. Armitage's western expedition show that, after proceeding up one large glacier, lying between precipitous granite mountains, a ridge was crossed by a pass 4000 feet above the sea to a second glacier, which had a general trend from south-west to north-east. Its right-hand branch was ascended to a range of remarkably bare granite mountains, the ice surface being much crevassed. A line of sticks set up during the ascent showed a maximum motion of 3 feet 8 inches in twenty-three days. On gaining a height of 9000 feet a smooth, open snow-covered plain stretched to the westward, its surface being soft, with successive crusts nine inches or a foot apart. There were no *sastrugi*. The whole horizon to the west was clear and unbroken, and the plain appeared to have a slight fall in this direction. Running streams, 7 feet wide, with occasional pools sometimes a mile in diameter, were seen on the return journey, and *Bergschrunds* 150 feet deep were found at the base of the mountains. Among the other journeys described, those of Dr. Koettlitz for the investigation of the ice and esker-like lines of débris in the neighbourhood of the Black and Brown Islands are of most interest.

An interesting complement to the narrative of the British expedition has been supplied by the report of Dr. von Drygalski, leader of the German expedition in the *Gauss*, which was published as a supplement to the official *Reichsanzeiger* on July 10. It describes the voyage from Kerguelen *viâ* Heard Island to the supposed position of the non-existent Termination Land, the southward advance to a previously unknown land, in the vicinity of which winter quarters were established, the scientific work done at the winter station, and the sledge journeys undertaken during the stay. The *Gauss* was frozen fast in the ice to the north of this land, the pack there remaining stationary owing to the shallowness of the sea over the "Continental Shelf." Only a few miles to the north it appears to be kept constantly in motion by the heavy swell caused by the westerly storms, which would have seriously impeded the scientific work, besides endangering the ship. From the land rose a bare volcanic peak 1200 feet high, which was named the Gaussberg. The *Gauss* was set free on February 8 by a strong easterly wind, but was caught again temporarily in a somewhat lower latitude, the final start northward being made on April 8, when the lengthening nights were already making navigation difficult.

THE STRUCTURE OF SPECTRA.[1]

THIS paper gives a very lucid account of the structure of various types of spectra, special attention being directed to the work on "series" which has been performed during recent years.

After referring to the splendid work performed by Ångström and Rowland in establishing trustworthy tables of standard wave-lengths, the author passes on to the evolution of the definite laws which have been found to govern the distribution of lines in the spectra of many elements, comparing the occurrence of similar definite groupings of lines in the spectrum of a substance to the "harmonics" obtained in acoustics.

In 1863 Mascart found that certain groups of lines of characteristic aspect were reproduced in different parts of the spectrum of the same metal, *e.g.* he found that similar triplets to the "b" group of magnesium were reproduced in the ultra-violet region of the spectrum of that metal. To-day it is known that altogether there are fourteen such groups in the magnesium spectrum, one in the infra-red, the "b" group and twelve in the ultra-violet.

Similarly in the spectrum of sodium there are twelve such "doublets" as that commonly known as D_1 and D_2 in the solar spectrum. If these "triplets" and "doublets" are represented on a scale of wave-lengths, they contract as they approach the ultra-violet, but if they are represented on a scale of frequencies, the groups of the same metal become identical, and are absolutely superimposable. Similar groups have been found for a large number of metals by Kayser and Runge.

The alkaline metals, like sodium, give a series of "doublets," as also do copper and silver, whilst the divalent metals (Mg, Ca, Sr: Zn, Cd, Hg) give triplets, although some of them, *e.g.* Hg, are so mixed up with other groups that at first this arrangement is difficult to recognise. Here then we have a simple law, which should be credited to Rydberg, viz. "In the spectra of a large number of elements there exist groups which are reproduced several times, the interval which separates the individual lines of each group (when represented on a scale of 'frequencies') being exactly the same for all the groups."

For the alkaline metals the length of the interval which separates the doublets varies as the square of the atomic weights, as is shown in the following table:—

Metal	Atomic weights (P)	Length of interval (ν)	$\nu/P^2 \times 10^4$
[2] Li	7	—	—
Na	23	0·17	3·25
K	39	0·57	3·81
Rb	85	2·34	3·22
Cs	133	5·45	3·09

It was then found that these groups arrange themselves in regular series capable of mathematical expression, and in 1885 Balmer found that on plotting the thirteen lines of hydrogen on a curve which had "m" (the number of the line counting in order from "3" in the red to "15" in the ultra-violet) for its abscissa and N (the frequency) for its ordinate, he obtained a perfectly regular curve which could be exactly expressed by the formula

$$N = B/4 - B/m^2,$$

where B was a constant. Later, Messrs. Hales and Deslandres discovered sixteen other hydrogen lines in the spectra of prominences and various stars, and it was found that these also might be represented by the above formula.

The spectra of metals also arrange themselves in similar series, although the relations are not so easily seen at first, because of the overlapping of the other lines. However, the spectrum of potassium may be taken as an example, and we find that on plotting the lines in a similar manner we obtain three such series, known respectively as "the principal," "the first subordinate," and the "second subordinate" series. In each of these series the brightness of the lines decreases as they approach the more

[1] "La Structure des Spectres," by Prof. Ch. Fabry, Marseilles, in the *Revue Générale des Sciences*, No. 5, March 15.

[2] The "doublets" for lithium have not been observed, but if the law is applicable in this case the interval would only be 0·016, which is too small to be observed.

refrangible end of the spectrum, acting in this respect in a manner analogous to the hydrogen lines. It is found that the potassium curve is exactly similar to the hydrogen, having a horizontal asymptote which corresponds to the limit of the series. Not only is it similar to the hydrogen curve, but by making two displacements parallel to the coordinates it is found to be superimposable, and both curves may be represented by a generalisation of Balmer's formula, due to Rydberg, as follows:—

$$N = A - B/(m+\mu)^2,$$

where A, B and μ are constants, B having sensibly the same value as in Balmer's formula.

It is interesting to compare the curves for the various members of the alkaline metals among themselves, when it is seen that both for the "principal" and the "subordinate" series the limits approach the red end of the spectrum in the order of the atomic weights of the metals, as if the greater masses of the atoms caused the frequencies of the vibrations to become less; this same fact becomes obvious when we consider, similarly, the spectra of the other metals classified into their natural groups.

Prof. Fabry next describes the "satellites" which accompany most lines in the several spectra. For an example he takes the spectrum of mercury, which is composed of triplets forming two series, one the "diffuse" and the other the "sharp" ("first subordinate" and "second subordinate" respectively) series of Rydberg. In the "diffuse" series the first element of each group is composed of four lines, the second of three and the third of two, but in the "sharp" series the elements are apparently single lines; this is probably due, however, to the very close proximity of the satellites in the latter series, and in several cases MM. Fabry and Perot have shown that, with special apparatus having great resolving power, these lines are of a compound nature, and have come to the conclusion, which at least is probably the correct one, that *all* the elements of the secondary series are accompanied by satellites. All these satellites appear to share the common property of varying greatly under different conditions of emission (*e.g.* as temperature, pressure and nature of the electric discharge), and these two observers have shown that, whereas the silver line at λ 547·2, which is a satellite of the line at λ 546·6, appears in the spark spectrum in air, it completely disappears when the spark takes place *in vacuo*. Many metals (*e.g.* Fe, Ni, Mn) produce spectra so complex that, as yet, it has not been possible to classify them, but this may be done when a means of distinguishing analogous rays is discovered and brought into use.

This latter means may be found when the phenomena first observed by Zeeman, and known as the "Zeeman effect," have received a more complete study. This observer found that if the emission took place in a strong magnetic field, each line was split up into a series of lines symmetrically placed as regards the original line, but differently polarised. Taking the spectrum of mercury as an example, we see that the second subordinate series is made up of triplets, or, as shown above, three separate parallel series of lines, which one may call, in this explanation, "a," "b" and "c" respectively. In the magnetic field the members of the "a" series split up into nine separate lines, *four* on each side of the original line, some of which are polarised in the plane of the lines of force, the others in the perpendicular plane, but the corresponding line on each side is similarly polarised. In the "b" series we get lines which are similarly placed as regards the original line, and similarly polarised, but there are only *three* on each side, the second member on each side in the "a" group having disappeared. Similarly in the "c" series only two extraordinary lines are seen, *one* on each side of the original, corresponding to the extreme lines in the "a" series.

To the first workers in this field these lines appeared greatly entangled, but, thanks to the labours of Cornu, Michelson, Preston, and more especially Runge and Paschen, order has been evolved from the chaos, and the study of the "Zeeman effect" will, in the future, form a ready means of recognising and determining series, for it has already been proved that "the various lines which go to make up similar series behave in an identical manner when the emission takes place in a magnetic field, and if one represents each line by its 'frequency,' the various members, in the same magnetic field, resolve themselves into groups which are strictly superimposable." It is also to be hoped, and even expected, that when the work of Humphreys and Mohler, and others, on the displacement of spectral lines under various conditions of pressure, comes to be further developed, similar laws as to the analogous behaviour of lines in their corresponding series will be evolved.

Prof. Fabry concludes his article with a discussion of the relations which exist between the absorption and emission of the same radiations, taking the example of the telluric absorption assigned to atmospheric oxygen in the solar spectrum as an example for discussion. He doubts the coincidence of these absorption bands with emission lines in the spectrum of the gas, although, as he points out, experimental means of proving their non-coincidence have yet to be devised.

CONGRESS OF THE SANITARY INSTITUTE.

THE annual congress of the Sanitary Institute was held at Bradford on July 7–11, under the presidency of the Earl of Stamford.

In his inaugural address Lord Stamford dealt with the history of hygiene, showing how closely the subject was allied to political, social and economic history. In describing broadly the various sanitary questions as they affected the home, factory, and the municipality, the president dealt with the important subject of school hygiene, and pointed out how essential it was that the training schools for teachers should form part of the coordinated system of national education. It should be one of the first requirements in the preparation of the teacher, and also of the inspectors who are appointed to visit the schools, that they should practically understand something of the nature of the child material upon which they are to work, the conditions under which the child can best develop by the teacher's guidance, and the proper use of the appliances provided in modern school buildings.

The sections and conferences to which the papers and discussions of the congress were allotted were presided over by well-known representatives of different sciences connected with hygiene. Prof. Clifford Allbutt, in his address on sanitary science and preventive medicine, brought forward for consideration the question if, within limits, the birth of fewer children under improved conditions may be better in the end than a more voluminous birth-rate of children of which some may be of lower vital capacity, and many less watchfully reared.

Mr. Fitzmaurice, of the London County Council, presided over the section of engineering and architecture, and in connection with some of the large engineering works in which he had been engaged he directed attention to the duty of providing for the medical and sanitary requirements of the large bodies of men temporarily collected for the purpose of carrying out the works, and showed that attention to these requirements was an economic advantage. In works like the Forth Bridge or others in the neighbourhood of large towns the difficulty could be overcome, but in works abroad, such as the Nile reservoir, the problem was a more difficult one, especially as smallpox and typhoid are endemic in the Nile valley, and a large outbreak of either in a camp where 15,000 persons were at times employed would have been disastrous; but by making careful provisions, health conditions were so well maintained that, during the five years the works were going on, there were only four deaths from smallpox and one from typhoid fever. He also dealt with the health aspects of cheap locomotion to the suburbs, and motor traffic.

Prof. Hunter Stewart, in addressing the section of chemistry, physics, and biology, discussed the spread of and immunity from Asiatic cholera, and referred to Great Britain as the most striking instance of acquired immunity. With a sea traffic from India greater than that of any other European Power, and in constant communication with the Mediterranean ports, with no quarantine and cordon regulations such as prevailed on the continent of Europe, this country has, since 1866, known cholera only in the sporadic

form, even though it was raging as an epidemic in France and Spain in 1884–1885. This immunity may be attributed to the great measures for sewage and refuse removal carried out in Britain, which had slowly resulted in such a purification of the soil as to make it unsuitable for conferring virulence on the micro-organism of cholera.

Among the subjects discussed in the sections were the notification of consumption, the several aspects of sewage disposal, construction of hospitals and public baths, and disinfection.

In addition to the sections, eight technical conferences were held dealing with the aspects of hygiene, particularly in reference to the different professions and various classes of the community.

In connection with the congress an exhibition of sanitary apparatus and appliances was arranged, containing exhibits brought by manufacturers from all parts of the country. The visits made to the various municipal undertakings and sanitary works in the neighbourhood served as a valuable object-lesson, illustrating many of the matters discussed in the meetings of the congress.

Among the exhibits at the exhibition, which were carefully examined by a board of expert judges, a special Rogers Field medal was awarded by the institute to the Northern Vacuum Cleaning Company for their apparatus for cleaning carpets, furniture, and house decorations without removing them from the house. The attendance of members and delegates numbered 1550.

E. WHITE WALLIS.

THE MUSEUMS ASSOCIATION.

THE fourteenth annual congress of the Museums Association was held in Aberdeen on July 13–16, and although the place of meeting was so far north, the attendance was exceptionally good, while the programme of business was one of the most varied and useful that has ever been brought before the Association. The president for this year is Dr. F. A. Bather, assistant keeper of geology, British Museum (Natural History), whose presidential address dealt chiefly with art museums. After defining generally the purport and breadth of museums, which he classified into three divisions, (*a*) investigation for the benefit of specialists; (*b*) instruction for the benefit of students; and (*c*) inspiration for the guidance of the general visitor, he entered into a critical survey of the Museum of Fine Art, specially condemning the present system of arranging pictures, and the lack of harmony between the architecture, decoration, and contents of an art gallery.

Mr. James Murray followed with a paper on the Aberdeen Art Gallery, which is about to be greatly extended; then came a paper by Mr. Alex. M. Rodger, "Method of Mounting Fish with Natural Surroundings," which can be commended to all curators who wish to make their museums attractive. Mr. W. P. Pycraft was rather severe on some of the methods of representing birds in a museum, and Mr. E. M. Holmes briefly described a method of preserving the natural colours of dried leaves and flowers for museum specimens, which had stood the test of many years' exposure, while a paper by Mr. H. Bolton treated of the "Re-shelving of Museum Cases." "On Good Form in Natural History Museums" was the title of a paper by Mr. F. Jeffrey Bell; another paper of the same character being "Neglect of Opportunities," by Mr. S. S. Buckman.

In addition to representatives from the leading museums of Britain, there were some foreign representatives who read papers. Dr. Jens Thiis, director of the Nordenfjeldske Kunstindustri-museum, Trondhjem, explained the practical work connected with that museum; Dr. G. Johanson Karlin, of the Kulturhistoriske Museum, Lund, gave some good advice in his paper on the museum system; while Dr. O. Lehmann, of the Altona Museum, advocated the cultivation of the habit of drawing in natural history museums.

Other papers were contributed by Prof. T. D. A. Cockerell, of the New Mexico Normal University; Dr. Anton Fritsch, of the Bohemian Museum, Prag; Mr. B. H. Woodward, of the Perth Museum, Western Australia; and Prof. Wm. M. Ramsay, of Aberdeen, who treated of the archaic art of the north-east of Scotland, and the urgent necessity for the preservation of existing examples of it, while Prof. J. Arthur Thomson, in a convincing paper, showed the need for a faunistic museum for the north of Scotland. All these papers, together with the discussions which they aroused, will be published in due course in the *Museums Journal*. The invitation of the City of Norwich to hold the conference in 1904 in that city was accepted, and Dr. S. F. Harmer, superintendent of the Museum of Zoology, Cambridge, was elected president, Mr. E. Howarth, of the Museum and Art Gallery, Sheffield, being re-elected secretary and editor.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE third reading of the London Education Bill was carried in the House of Commons on July 22, and the second reading passed the House of Lords on July 28. The measure will, therefore, doubtless soon be placed upon the Statute-book.

THE following awards have been made under the research scheme of the Carnegie Trust for the universities of Scotland, in addition to those announced last week:—*Research Scholarships.*—Pathological: Mr. C. T. Andrew, Mr. A. Matheson, Mr. M. Logan Taylor, Mr. S. A. K. Wilson. Economical: Mr. John Young.

MR. PHILIP J. HARTOG has been appointed academic registrar of the University of London in succession to Dr. H. Frank Heath, and Dr. E. R. Edwards secretary to the registrar of the board to promote the extension of university teaching, in succession to Mr. J. Travis Mills. The Drapers' Company has presented to the university the sum of 1000*l.* to be devoted to the assistance of Prof. Karl Pearson in his statistical researches at University College and in the higher work of his department.

THE Technical Instruction Committee of Leeds has decided to give support to the application of the Yorkshire College for the establishment of a university in Leeds, to be entitled Victoria University of Yorkshire, and, in the event of a Charter being granted, to give 4000*l.* per annum towards the university funds, in addition to the 1550*l.* granted from the "whisky" money. The finance committee also approved of the resolution. The *Gazette* of Friday last announces that a petition has been presented to the King in Council praying that a Charter be granted constituting an independent university in Sheffield.

AMONG many questions of educational interest considered in the report for 1902 of the council of the City and Guilds of London Institute is that of the relation between the amount of State aid for university and higher technical education and that of private munificence for the same purpose. The report states, "that State or public aid does not necessarily take the place of private and voluntary effort is shown by the experience of the United States of America. Notwithstanding the increasing revenue available there from the State land grants permanently assigned to education, the activity and munificence of private effort increases rather than diminishes, as shown by the large contributions which are continually being made to the principal universities and higher colleges. In the three months September to November of last year gifts to higher education, amounting in all to nearly five million dollars, equal to about one million sterling, have been publicly recorded." The report also shows that the executive committee of the institute has had under consideration the question of the length of the sessions of work of colleges providing systematic courses of higher instruction. It has been found that the number of weeks in the session at eight of the principal technical colleges in England varies from thirty-one to thirty-three, leaving between four and five months' vacation during the year. Vacations do not necessarily mean holidays, and in most colleges the work of advanced students continues into the vacations; nevertheless, the committee suggests that the length of the formal session might with advantage be increased.

TWENTY-EIGHT senior county scholarships and exhibitions have just been awarded by the London County Council Technical Education Board. The awards are made on the work and promise of the candidates, and most of the scholars will pursue their studies at universities or advanced

technical colleges. Among the awards we notice the following:—Mabel Gardner, who has gained the first science scholarship at Girton College, senior county scholarship of 90*l*. a year for three years. H. H. Mittell, a full senior county scholarship of 90*l*. a year for three years to enable him to proceed to Magdalene College, Cambridge, where he has gained an open scholarship, and to take the mathematical tripos. C. H. Pitt, a senior county scholarship of 90*l*. a year to enable him to proceed to Corpus Christi College, Cambridge, where he has won an open science scholarship. A. E. Baker, an exhibition of 75*l*. a year for two years in the first instance, in order to enable him to proceed to Trinity College, Cambridge, where he has obtained an exhibition and subsizarship, and to take the natural sciences tripos. W. H. Norris, an exhibition of 70*l*. a year for three years to enable him to proceed to Corpus Christi College, where he has gained an open science scholarship. J. W. Kuhrt, a free place at the London School of Economics and Political Science, together with an exhibition of 50*l*. a year for two years, in order to enable him to take the B.Sc. examination of the London University in economics. B. P. Williams, an exhibition of 50*l*. a year for two years, together with a free place at the college to enable him to take the B.Sc. degree in engineering. P. A. Houseman, an exhibition of 40*l*. a year for three years to assist him to proceed to Würzburg University for the study of chemistry. H. H. Hodge, an exhibition of 30*l*. for one year in order to enable him to travel on the Continent and study the French language and the French system of education.

THE Board of Education has recently published two sets of regulations, for the session 1903–4, for schools of various grades. One volume deals with secondary day schools, and does not appear to differ in any important respect from that of last year. The other contains regulations for all schools and classes in connection with the Board of Education which have not received attention in previous regulations already published for next year's work, such as evening schools, technical institutions, and schools of art and art classes. A circular letter respecting the latter volume has been issued by the Board, and describes for the benefit of managers of schools the important respects in which the regulations for next session differ from those of previous years. The volume may be said to concern all those institutions in which instruction of a specialised or technical character is given, whether in the day-time or in the evening, as well as evening schools and classes the scope of which may vary almost indefinitely with the attainments and aim of the students. The rule under which the rate of grant payable for science instruction given in the day-time was half the rate payable for such instruction if given in the evening is abolished, and grants for advanced instruction given during the day in technical institutions will now be assessed in accordance with regulations appropriate to the special circumstances of such instruction. The letter also urges the desirability of fixed salaries for teachers of classes of all kinds, and rightly insists that the amount of stipend should be in relation to the qualifications and experience of the teacher and the time given by him to the work of the class, and that cognisance should be taken of the time absorbed in preparing experimental lectures, in travelling, and in the correction of home-work. It is very satisfactory, too, to find that the new regulations definitely require a sufficient preliminary training for students in classes in scientific and technical subjects, and that every encouragement is given to managers to inaugurate a system of "courses of study" rather than one of isolated subjects in no way correlated.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 18.—"On the Synthesis or Fats Accompanying Absorption from the Intestine." By Benjamin **Moore**, M.A., D.Sc., Johnston Professor of Biochemistry at University College, Liverpool. Communicated by Prof. C. S. Sherrington, F.R.S.

The fats of the food are changed in the intestine into fatty acids and glycerine, and the fatty acids are then in part combined with alkali to form soaps.

Both soaps and free fatty acids have a very small solubility in water, and it is by the agency of the bile, in which both are much more soluble, that these constituents of the digested fats are made capable of being taken up in soluble form by the absorbing cells of the intestine.

The absorbed fatty constituents are not taken up by the blood stream, but pass by a separate system, namely, the absorbent lacteals of the intestinal area, to be finally carried to the circulating blood by the main lymphatic vessel, the thoracic duct.

Now, somewhere along the path of absorption, the absorbed soaps and fatty acids are recombined with glycerine to form fats, for in the thoracic duct after a meal containing fat only fats are found.

The seat of this transformation has not hitherto been known with accuracy, but in this paper experiments are quoted to show that the change occurs in the intestinal cells which first take up the consituents of the digested fat in soluble form, and not in the cells of the lymphatic glands of the intestine through which the absorbed fatty matter subsequently passes on its way to the thoracic duct.

This is shown by analyses of the fatty matter in the small lymphatic vessels leading from the intestine, which show that, even here before the absorbed fatty matter has reached the abdominal lymphatic glands, it has all been changed back into fat. A change in the same direction is shown by analyses for fatty constituents of the intestinal cells, but here the process is found in progress, and not yet complete.

It is further shown that the cell must be *in situ* and supplied with nutrient matter in order that this change can be brought about, for no synthesis of fat occurs when the isolated intestinal cell or extracts of it are allowed to act upon the fatty constituents *in vitro*. The only change then occurring is the formation from soap of free fatty acid, which is probably the initial stage in the change occurring in the living intact cell, and is further a protective action, which would prevent the entrance of the poisonous soaps into the circulation.

This demonstrates that the living cell supplied with energy by the nutrient matter which bathes it is capable of acting as an energy transformer for chemical energy, and of carrying out syntheses impossible for enzymes which cannot add energy to the ingredients upon which they act, and hence cannot carry out complex syntheses requiring the addition of chemical energy to those ingredients, as can the living cell.

"The Theory of Symmetrical Optical Objectives." By S. D. **Chalmers**, B.A. (Cantab.), M.A. (Sydney), St. John's College, Cambridge. Communicated by Prof. Larmor, Sec. R.S.

This paper deals with the relations between the aberrations of a lens system, used with a front stop, and those of the compound system formed by two such systems disposed symmetrically with respect to the stop. The results justify the practice of correcting a single component —the back one—for astigmatism and spherical aberration, *provided* due attention is paid to the securing of the condition for no distortion.

PARIS.

Academy of Sciences, July 20.—M. Albert Gaudry in the chair.—The manner of flow of a spreading sheet of water on a plane surface, applied to the case where the surface is curved, by M. J. **Boussinesq**.—On a new method for the detection and estimation of small traces of arsenic, by M. Armand **Gautier**. It is based on the principle that ferric oxide precipitated in the presence of arsenic carries down with it the whole of the latter, even in the presence of chlorides and other salts. The arsenic in the precipitate can then be directly estimated in a Marsh apparatus. In this way the thousand millionth of its weight of arsenic can be detected in a substance, and its presence was shown in the purest distilled water and many common reagents.—On the torsion movements of the eye when looking in certain directions, the socket remaining in the primary position, by M. Yves **Delage**.—On a new action produced by the rays *n*, and on several facts with regard to these radiations, by M. R. **Blondlot**. The rays *n* falling on platinum foil heated to dull redness cause it to glow more brightly. This effect is not due to increase of temperature. The increased brilliancy is observed on both sides of the

foil owing to the fact that cold platinum, which is opaque to these rays, becomes transparent on heating.—Study of the molecular deformations of a steel bar submitted to thrust, by M. L. **Fraichet.**—Photographs of the Borelly comet (1903 *c*), by M. **Quénisset.** These photographs were taken at the author's observatory at Nanterre, and in pairs, so as to give a stereoscopic representation.—On the theory of the acoustic field, by M. **Charbonnier.** The theory serves to explain certain photographs of projectiles obtained by Dr. Mach, of Vienna, and is the basis of Gossot's method of measuring the velocity of projectiles.—Contribution to the study of superheating, by M. A. **Petot.**—Sublimation curves, by M. A. **Bouzat.** A comparison of the sublimation curves of carbon dioxide, ammonium sulphide, and ammonium carbonate with the dissociation curve of the compound of silver chloride and ammonia.—On the law of recombination of ions, by M. P. **Langevin.** An expression is developed which gives the ratio of recombinations to the number of collisions between two ions of opposite sign, and is verified by comparison with the experimental values for air and carbon dioxide.—On commutation in continuous current dynamos, by M. **Iliovici.**—The influence of temperature on the dichroism of mixed liquids, and a proof of the law of indices, by M. Georges **Meslin.** Substances are chosen for which the value of the index of the liquid but very slightly exceeds the mean value for the solid. The change in sign of the dichroism with rise of temperature was experimentally verified in a number of cases.—On photographic spectrophotometry, by M. C. **Camichel.** Various catalytic reactions brought about by metals and the accelerating and retarding influences, by M. A. **Trillat.** Reactions between copper or platinum and the vapour of alcohols of oxidising, reducing, condensing, or saponifying effects. The reactions are considerably affected by traces of impurities, and the copper must first be tarnished by heating in air.—On ferrisulphuric acid and ethyl ferrisulphate, by M. A. **Recoura.** The ethyl ester is obtained by boiling the acid with alcohol as a yellow solid. On heating the acid, it loses simultaneously one molecule of sulphuric acid and two of water, leading the author to assign to it the formula $Fe_2O_3.3SO_3.H_2SO_4.2H_2O+6H_2O$.—Prussian and Turnbull's blues. A new class of complex cyanides, by M. P. **Chrétien.** A soluble acid blue or hydrodiferrocyanic acid, $Fe_2Cy_6H_13H_2O$, is obtained by the spontaneous decomposition of hydroferrocyanic acid at about 20°. It reacts with alkalis as follows:—$Fe_2Cy_6H + 4KOH = FeCy_6K_4 + Fe(OH)_3 + H_2O$. This and other reactions are studied thermochemically.—On spartein. General characteristics; action of some reducing agents, by MM. Ch. **Moureu** and A. **Valeur.** This communication contains a repetition of previous work on spartein, and an account of unsuccessful attempts to obtain reduction products.—On the isonitrosomalonic ethers and their conversion into mesoxalic ethers, by MM. L. **Bouveault** and A. **Wahl.** The methyl and ethyl ethers were obtained pure, and converted into the corresponding mesoxalic ether by means of nitrogen peroxide.—Action of ammonia on the compound of oxide of ethylene and *β*-*o*-cyclohexanediol, by M. Léon **Brunel.** With an excess of ammonia *o*-aminocyclohexanol is obtained; with less ammonia, more complicated substances.—Researches on the nutrition of etiolated plants, by M. G. **André.**—On the phospho-organic reserve material of plants, by M. S. **Posternak.** The method is given for the separation of this substance as the salt of an acid, CH_5PO_5, from seeds and other parts of plants. In this way 70 per cent. to 90 per cent. of the phosphorus in the seeds can be accounted for, lecithine representing only 1 per cent. to 7 per cent. of the phosphorus.—On roots trained by experiment to grow upwards, by M. H. **Ricome.** The plants (beans) were attached to the end of a long thread kept oscillating. The development of the root and longitudinal growth were perfectly normal.—A resinous Granadilla, by M. Henri **Jumelle.** The exudation from the base of the stem of this plant, the *Ophiocaulon Firingalavense*, is a resin rather than a wax, and contains 83 per cent. of true resin, which is deposited as an amorphous mass from solvents.—Contribution to the study of the Aepyornis of Madagascar, by M. Guillaume **Grandidier.** Particulars of the lower portions of a skeleton of the *Aepyornis ingens*.—On basic inclusions from the volcanoes of Martinique and St. Vincent, by M. A. **Lacroix.**—Contribution to the study of congenital changes in the nervous system, by MM. Claude **Vurpas** and André **Léri.**—On the organic respiratory gases in diabetes, by M. J. **Le Goff.** These gases contain acetone, which was separated as iodoform and estimated. In one case it amounted to nearly 3 grammes in twenty-four hours.—On the retention of irritability of certain organs separated from the body and immersed in an artificial nutritive medium, by MM. E. **Hédon** and C. **Fleig.**—The formation of callus, by MM. V. **Cornil** and P. **Coudray.**—Observations on the sea-level since historic and prehistoric times, by M. Ph. **Négris.** From the fact that two ancient piers at the south entrance of the Straits of Leucade are now nearly three metres under water, and from the encroachments of the sea in various parts of the Mediterranean during the last 2500 years, conclusions are drawn as to the change of level of the latter during a long period.—On the use of fluorescein in subterranean hydrology, by M. E. A. **Martel.**

THE MINERAL WEALTH OF AFRICA.

Les Richesses Minérales de l'Afrique. By L. de Launay. Pp. 395; with 71 figures and maps. (Paris: Ch. Béranger, 1903.) Price 20 francs.

PROF. DE LAUNAY gives a further proof of his indefatigable industry in this new volume from his pen. It is a formidable task to deal even briefly with the mineral wealth of a huge continent, which has been only imperfectly explored; but fortunately the author is eminently qualified for the task. He is no novice in writing upon mineral deposits, and he has visited many mines in North Africa, besides the most important districts in the south. The book is arranged so as to suit two classes of readers, those who wish to learn all they can about the occurrence of some given mineral, such as gold, copper ore, phosphate of lime, &c., and those whose interest relates only to some particular country or region. This arrangement involves a certain amount of duplication, but it is certainly a convenience. Thanks are likewise due to the author for his little sketch maps. Who has not experienced the want of such maps? For when seated in an easy chair the reader is apt to be too lazy to get up and fetch his atlas, and he consequently often fails to derive full benefit from the work he is perusing.

What is the mineral wealth of South Africa? Of the future mineral resources of the Dark Continent we are ignorant; further explorations may reveal new treasures; but if by "mineral wealth" is understood the value of the present output, the question is answered by the following tables, which have been compiled from the Blue-books published annually by the Home Office. Though the information is necessarily incomplete, it will suffice for the purposes of the present article.

In a normal year, such as 1898, gold is seen to be far ahead of any other mineral as regards value; and when we consider that before the war with the Boers Africa was furnishing more than one quarter of the world's supply of the precious metal, it is evident that Prof. de Launay is fully justified in devoting his first chapter to a description of the auriferous deposits of the continent. The gold mines of the Witwatersrand naturally claim a full share of attention. Excellent figures, with full descriptions, explain the nature of the "banket" or gold-bearing conglomerate, and the question of the origin of the gold is discussed at some length. The three usual hypotheses are brought forward; they may be spoken of briefly as "previous origin," "contemporaneous origin," and "subsequent origin." In other words, it is supposed by some geologists that the gold is a detrital product, like the pebbles of quartz; others suggest that it was deposited from solutions while the pebbles were finding a resting place; whilst most mining engineers favour the idea that solutions brought it into the conglomerates long after their consolidation. The pros and cons are given in each case; however, there are difficulties in accepting any one of the three theories advanced, and Prof. de Launay honestly confesses that he is puzzled, and that he cannot make up his mind on the matter.

He is careful to point out that the Rand must be regarded as an exceptional case, and that it by no means follows from the discovery of "banket" in West Africa that the "Jungle" gold mines, as they are known on the Stock Exchange, will necessarily prove to be rich and valuable properties.

The pages relating to the occurrence of gold in Egypt contain matter of much antiquarian interest; the public are only now beginning to learn that Egypt was the California of the Old World, and that gold was being extracted from quartz veins between the Nile and the Red Sea at least 2500 years B.C. But the author makes a mistake in saying that the gold occurs under conditions similar to those under which it is found in *Cornwall*. In that county we have no auriferous deposits, for the small grains of the precious metal occasionally found in working stream tin in olden days were, practically speaking, mineralogical curiosities.

Next in importance come diamonds; for though the emeralds of Gebel Sabara and the turquoises of Sinai were known and worked by the ancients, the only gem-mining which need be taken into consideration at the present time is that of South Africa. It is a curious fact, on a continent in which both gold and gems were obtained in considerable quantities even in very remote ages, that the deposits which are now yielding so lavishly should have remained undiscovered until the latter part of the last century. The mode of occurrence of diamonds in South Africa is thoroughly well known to geologists; but the precise manner in which they were originally formed still affords room for speculation. Prof. de Launay repeats the hypothesis, already suggested in his previous work, "Les Diamants du Cap," that a bath of supercarburetted molten iron and magnesium existed beneath the granite, and that the diamonds were formed on a large scale after the fashion of the minute ones obtained artificially by Moissan.

The discovery of workable deposits of phosphate of lime is one of recent date; it now appears that they extend more or less continuously from Morocco to Egypt. Algeria already produces more than 300,000 tons a year, and Tunisia more than 200,000 tons from strata of Eocene age. The Egyptian deposits, which occur in Upper Cretaceous rocks, are extensive but poor.

There are reasons for believing that the dry Sahara and Algeria may contain deposits of nitrate of potash and nitrate of soda similar to the "caliche" of Chili; the matter is now being investigated officially.

Practically speaking, all the copper of Africa comes from Namaqualand; the advent of better means of transport may render this statement incorrect in the course of a few years, for ores of the metal are known to exist in many parts of the continent.

Coal of Permo-triassic age is worked in the Transvaal, Natal, and Cape Colony, and Rhodesia will soon become a producer.

The total value of all the minerals produced in

[2] Output for the last four months of the year only. [3] Output for the last six months of the year only.
[4] No work was done at the Jagersfontein Mine during the financial year ended March 31, 1902. The output for the financial year ended March 31, 1901, was 18,002 carats, valued at 37,079*l*.

Africa in 1898 was about 23 millions sterling. This amount seems small for the huge continent, when we reflect that in 1901 the coal output of Wales alone was worth 19½ millions, and that of Northumberland and Durham about the same amount. But after reading Prof. de Launay's book, it needs no prophet to predict that Africa's mineral deposits will soon be more largely utilised.

ROWLAND'S WORK.

The Physical Papers of Henry Augustus Rowland. Collected for publication by a Committee of the University. Pp. xi + 704. (Baltimore: Johns Hopkins University Press; London: Wesley and Son, 1902.) Price 30s. 6*d.* net.

PROF. ROWLAND'S friends have been well-advised in issuing as a memorial to their late colleague this volume of his collected papers. It enables us to realise more fully all we owe to him and to grasp the value and importance of his work.

Commencing with an early note sent to the *Scientific American* when the author was seventeen, the list of scientific papers concludes with an article on diffraction gratings, published in the new edition of the "Encyclopædia Britannica" after Rowland's death. Then there follow some six addresses on scientific subjects, a bibliography, and an account of the dividing engines he designed.

Dr. Mendenhall's commemorative address, delivered shortly after Rowland's death, fitly forms an introduction to the whole, and gives us a glimpse of his life and methods of work.

Rowland's fame came to him early, though not without some severe struggles and disappointments on his part, and it is a satisfaction to us Englishmen to know that it was Maxwell who first recognised his genius. Prof. Mendenhall tells again the story of his first serious paper, "On Magnetic Permeability and the Maximum of Magnetism of Iron, Steel, and Nickel," *Phil. Mag.*, 1873. The paper was more than once rejected in America because it was not understood, and finally it was sent to Maxwell, who wrote immediately that since the temporary suspension of their meetings made it impossible to communicate the paper to the Royal Society, he would send it to the *Philosophical Magazine*, where it appeared in August, 1873, Maxwell having himself, to save time, corrected the proofs. In this paper Rowland introduced the idea of the magnetic circuit as the analogue of Ohm's law, and developed the now well-known ring method of measuring permeability. In 1875, on his appointment as first professor of physics at the Johns Hopkins University, he came to Europe and worked for a time in Helmholtz's laboratory at Berlin, and by his researches answered Tait's question, put to Maxwell in these words—

Will mounted ebonite disc
  On smooth unyielding bearing,
When turned about with motion brisk
  Nor excitation sparing,
Affect the primitive repose
  Of + and − in a wire?

To which Maxwell replies—

The mounted disc of ebonite
  Has whirled before nor whirled in vain,
Rowland of Troy that doughty knight
  Convection currents did obtain
In such a disc of power to wheedle
  From its loved North the subtle needle.

And Maxwell goes on to explain that such convection currents will not produce electromotive force in a neighbouring wire unless the speed of the disc were variable.

The paper on the "Magnetic Effect of Electric Convection," No. 12, in the volume before us, was presented in the *American Journal of Science* for 1878; von Helmholtz had already announced the result to the Berlin Academy in 1876. Rowland returned to the problem with the same result in 1889, in a paper presented in the *Philosophical Magazine*, No. 43 of his collected works. As is well known, the results were challenged by Crémieu shortly before Rowland's death. Many readers of NATURE will remember the interesting occasion in Section A of the British Association at Glasgow, when Crémieu described how he had failed to obtain the effect. Those present felt that in view of the confirmation of Rowland's results obtained at Baltimore by Pender, Crémieu must have been misled, but no one could put his fingers definitely on the error. It is satisfactory to know, from the recently published joint work of Crémieu and Pender, that Rowland was right, and that a convection current of electricity does produce a magnetic field.

The research into the value of the British Association unit of resistance, No. 15, and a determination of the value of "*v*," No. 44, complete the series of fundamental electrical researches, though his collected papers contain many other memoirs of real importance.

In his experiments on the absolute unit of resistance, Rowland shows his usual acumen as a critic and skill as a mechanic and observer. Various lines of argument had shown that the B.A. unit, supposed to represent 10^9 C.G.S. units of resistance, was in error. Rowland sums up effectively his criticisms on the method of the B.A. committee and points out the sources of error in Weber's method by damping adopted by Kohlrausch. He then describes his own method, a modification of that originally proposed by Kirchhoff, and, after a careful account of his apparatus and measurements, arrives at the result 1 B.A. unit$=0.9911\times10^9$ C.G.S. units. A repetition of his experiments in 1884 gave 0.98627, while about the same time his pupil, Kimball, using Lorenz's method, arrived at the result 0.9864. The value obtained at the Cavendish Laboratory was 0.9867.

Part iii. of the collected papers deals with the work on Heat, and foremost among these is the great memoir on the "Mechanical Equivalent of Heat," a work which, if it stood alone, would have made Rowland's name as the foremost physicist of his nation.

The refinements of modern thermometry have enabled us to introduce some small corrections into certain of the results, but the work remains unrivalled.

Rowland was an engineer, and this stood him in good stead in all his researches, and nowhere more so than in the paper under consideration.

In arranging his laboratory, Prof. Mendenhall tells us, many of his friends thought he was giving undue prominence to the workshop, its machinery and tools, and to the men to be employed in it, but he planned wisely, for in original work "a well-manned and equipped workshop is worth more than a storehouse of apparatus already designed and used by others."

So, too, it was in the optical work described in part iv.; the concave grating is the child of the perfect screw, and he who would make a perfect screw must follow Rowland as he described his method in the article, "Screw," "Encyclopædia Britannica," ninth edition, No. 33 of the Collected Papers.

The secret is to correct the screw by grinding it in a long adjustable nut longer than the screw itself; thus, if the finished screw is to be 9 inches long, the nut should be 11 inches; as the grinding progresses the nut is closed in, and the grinding continues for two weeks, the nut being turned end for end every ten minutes and the screw kept in water constant in temperature to within 1° C. all the time.

It is not strange that machines which can rule gratings are rare.

The original paper on "Concave Gratings," No. 29, is a short one, but valuable details are given in No. 49, "Gratings in Theory and Practice," and in the "Encyclopædia" article already referred to.

The addresses which fill the last hundred pages of the book are full of interest. To many who have followed the accounts recently given in the pages of NATURE of the wealth and endowments of American universities, "A Plea for Pure Science" will appeal forcibly. Rowland was not satisfied that even America was doing all that was needed.

"The whole universe is before us to study. The greatest labour of the greatest minds has only given us a few pearls, and yet the limitless ocean, with its hidden depths filled with diamonds and precious stones, is before us. The problem of the universe is yet unsolved, and the mystery involved in one single atom yet eludes us. The field of research only opens wider and wider as we advance, and our minds are lost in wonder and astonishment at the grandeur and beauty unfolded before us. Shall we help in this grand work or shall we not? Shall our country do its share or shall it still live in the almshouse of the world?"

Or, again, in his last address, "On the Highest Aim of the Physicist," note his words, after speaking of the work of the Physician:—

"The aims of the physicist, however, are in part purely intellectual; he strives to understand the universe on account of the intellectual pleasure derived from the pursuit, but he is upheld in it by the knowledge that the study of nature's secrets is the ordained method by which the greatest good and happiness shall finally come to the human race."

Rowland unlocked some of the hidden chambers himself; he did more than this, he put into our hands the machine by which we may hope to forge the key which will open the door leading to some of the innermost recesses.

R. T. G.

A VINE DISEASE.

Annales de l'Institut Central Ampélologique Royal Hongrois. Tome ii. Pp. vii+288+plates. (Budapest: Société d'Imprimerie et d'Editions Pallas, 1902.)

THIS admirably printed volume is devoted entirely to an exhaustive study of the *Rot livide* of the vine, a destructive disease due to the ravages of a minute fungus known to botanists as *Coniothyrium Diplodiella*. The memoir reflects credit on the author, Dr. Istvánffi, not only on account of the thoroughness and clearness of the 288 pp. of text, but also from the beauty and completeness of the numerous (215) excellent figures set forth on the 24 plates.

Of the fifteen chapters into which the work is divided, the first deals with the somewhat extensive history of this now almost ubiquitous malady, the place of origin of which is not known with certainty, but which appears to have been more probably south-eastern Europe than the America to which we owe so many pests.

Chapters ii.–iv. are concerned with the description of the rot as manifested on the shoots and leaves of both native and American vines grown in Europe, and the pathological alterations induced in the tissues by the parasite.

The principal signs when the disease is advanced are brown spots and patches on the leaves, in the dead tissues of which the minute black pycnidia appear; the cortex shrivels, turns brown, and peels in fibrous masses as it dries. The dead twigs also show that the pith is destroyed, and similar pycnidia—frequently accompanied by other fungi such as Botrytis, Pestalozzia, Colletotrichum, &c.—appear on the surface. The dead twigs easily disarticulate at the nodes, and the leaves above, even if not directly attacked, shrivel and die because the diseased internodes cannot supply them with water. A characteristic chambering of the dying pith often precedes its total destruction, and may remain visible at the nodes long after the pith of the internodes has dried up.

Microscopic examination shows that the hyphæ of the fungus causing these destructive effects permeate all the softer tissues, and rapidly destroy the cortical parenchyma with the formation of large gaps filled with mycelium, and an interesting struggle for the mastery between fungus and host is evinced as the medullary rays, parenchyma and cambium attempt to heal up the wounds already made; in vain, however, and the hyphæ pass from cortex to pith *viâ* these medullary rays.

It is, of course, impossible to enter here into the numerous microscopic details, which, as might be expected from so able a histologist as Dr. Istvánffi, are very thoroughly done, and embrace many discoveries of interest, such as the sugar sphærocrystals in certain cells of the diseased cortex, the curious, cambium-like callogene layer, &c. Every botanist will find the careful microchemical reactions valuable, and the coloured diagrams of the behaviour of the diseased tissues are particularly instructive.

But it is not only the stems and leaves that are invaded by this fungus; it also attacks the grapes

themselves, either *viâ* the pedicels or from outside, and the author gives an instructive set of figures illustrating the development of the flower and young fruit in connection with chapter v.

Chapter vi. is concerned with the development of the fungus in the different organs of the vine, and with descriptions and figures of its numerous reproductive phases, comprising two forms of conidia, two forms of pycnidia, the perithecia, and certain sclerotium-like stages.

In chapter vii. the results of pure cultures are described, and the conclusion established that the spores may germinate in rain-water, and the young mycelium suffer desiccation, and again revive if wetted; further, that spores germinating on the surface of the plant may remain alive and active for as much as six days in damp weather, awaiting a moment favourable for infection, as it were. Dry spores may be kept twenty-three months, and still germinate on placing in water. The numerous morphological details must be passed over here.

In chapter viii. the various modes of infection are dealt with, and the results are that the fungus may enter by the pedicel, by the peduncle or one of its branches, or at the articulation of the fruit to its stalk, or it may enter the fruit directly. A valuable series of coloured figures shows the various tints assumed by the diseased grapes, and we are reminded of one form of the disease termed "shanking" in this country.

Chapter ix. is devoted to the experimental infections. Many points of interest are given here, *e.g.*, the tips of the germ-tubes directly dissolve the cuticle; a cellulose dissolving enzyme also occurs; liquefied walls resist attack, &c.

Chapters x. to xii. deal very thoroughly with treatment, and the numerous experiments show that calcium bisulphite and free sulphurous acid are practically the only efficacious remedies, Bordeaux mixture and other copper compounds, or mixtures, as well as several other media being found useless.

In chapter xiii. an account is given of the various other fungi which may accompany the Coniothyrium.

Chapter xiv. is devoted to a discussion of the systematic position of the fungus, while chapter xv., and last, again returns to the question of treatment, this time dealing with it in the form of advice as to methods, quantities, periods, &c.

There can be no question that Istvánffi's memoir has a three-fold importance, (1) to the vegetable pathologist, owing to the clear and exhaustive account of the parasite and its relations to the host; (2) to the histologist and morphologist, because it contains so many interesting anatomical details concerning the host and its parasite, and (3) to the practical vine-grower, who will get from it one of the best accounts of symptoms and treatment we have ever met with.

The scientific value of Istvánffi's book is undoubtedly dependent on his clear recognition of the fact that, to deal properly with any parasitic disease, it is essential to take into account not only the peculiarities of the fungus, but also the reactions of the host-plant.

The one great fault we have to find with it is the want of summaries to the several chapters and to the whole work.

OUR BOOK SHELF.

Kinematics of Machines. By R. J. Durley, B.Sc., Ma.E. Pp. viii + 379. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 17s. net.

THIS is a carefully written elementary text-book dealing with the subject from the Reuleaux standpoint. In the first chapter the author introduces the notions of kinematic links and chains and the pairing of elements, and gives some fundamental propositions relating to degrees of freedom and constraint, and to instantaneous centres and centrodes in plane motion.

The next chapter treats pretty fully of motion in a straight line and about a fixed axis. Position, velocity and acceleration, linear and angular, in regard to both time and displacement, are exhibited by means of rectangular and polar diagrams, and problems are worked by graphical processes, the scales for measuring the results being always most carefully determined. The alternative, and often more desirable method of tabulation and the numerical calculation of differences seems to have been overlooked; it might well have been introduced and illustrated in an example like that of the electric car found on p. 47. Several problems on simple harmonic motion are given; but the author is scarcely alive to the great and growing importance of this branch of the subject. The fruitful idea of a rotating vector is not fully taken advantage of. A few additional pages are all that would be required in order to show how, in many cases of periodic motion, being given or having plotted a number of suitable positions in the cycle, the motion could be quite easily analysed and expressed approximately in the first three or four terms of the Fourier series, and thus readily comprehended and dealt with.

In the next two chapters the various mechanisms contained in the quadric and slider crank chains are well described and excellently illustrated. In all the more important cases the relations between the linear and angular velocities and accelerators are obtained both graphically and analytically, the principles established in the first two chapters being now applied.

Chapter v. is interesting, being an investigation of the motion in plane mechanisms in general. The author establishes and uses the velocity and acceleration images of Prof. R. H. Smith. As an example it is shown how to find the velocity of any point in a Stephenson link. The direct and powerful method of working from point paths is also illustrated, but is deprecated on account of its supposed inaccuracy. We, however, have found that, by the use of suitable appliances, large scale plotting can be carried out expeditiously, and with a degree of precision which render it possible to obtain not only velocities, but accelerations (or second differences), with quite surprising accuracy, and sufficient for most purposes.

Subsequent chapters relate to mechanisms containing higher pairing and non-rigid links, illustrated by spur gearing, cams, ratchets, escapements, belt and chain gearing, springs, chamber trains, &c. And there are chapters on screw and spheric motions, the latter containing an instructive investigation of the rolling and spinning velocities in various types of ball-bearings. The book concludes with a short historical account of the attempts which have been made to classify mechanisms.

The rigid exclusion of kinetics and of all dynamical considerations from a book like the present seems artificial, and to restrict its value; but those who do not take this view, and who follow Reuleaux, will welcome the volume. The descriptions are clear, the illustrations well selected, and the diagrams beautifully executed. Graphical and analytical calculations are judiciously mixed without an undue use of either.

Determination of Radicles in Carbon Compounds. By Dr. H. Meyer. Translated by J. Bishop Tingle, Ph.D. Pp. xii + 162. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 4*s.* 6*d.* net.

DR. MEYER has brought out a book of considerable value to chemists engaged in research work; it is hardly a book for students, unless working along research lines. Such a work as this is very difficult to criticise, because it is really a small dictionary of methods; such dictionaries are naturally very useful, provided they are carefully drawn up, which we consider to be the case in the book before us. Take, for example, the first chapter, which consists of 37 pp., and includes practically all the methods which may be used for determining the hydroxy-groups. One might be inclined to think this rather an unnecessary amount of space to devote to such an apparently simple matter as the determination of the $-OH$ radicle, but as there is very little padding, it really points out that in organic chemistry conditions govern everything; that a method which, under certain conditions, may be applied with success is quite useless when these conditions are altered or modified.

In the next chapter we have the determination of the methoxy- and ethoxy-groups by means of Zeisel's method. Three diagrams of complicated pieces of apparatus are given for the carrying out of this important determination. It is a pity, considering both the author and translator have evidently taken considerable trouble to bring the book up to date, and the importance of the method, that they missed Hewitt's simple modification described in the *Journal* of the Chemical Society for 1902; this is probably an oversight, because at another place they give a reference from the same journal.

Under the determination of the carboxyl groups, the method by means of the electrolytic conductivity of the sodium salts is described. It is doubtful, however, whether the description will be of much value to anyone who has not previously carried out such a determination. Not that this matters very much, because in a foot-note a reference to Ostwald's work is given, where a description of the parts of the apparatus may be found.

Dr. Meyer has evidently taken great pains in preparing this book, and has considerably added to its value by the copious references to original literature which he has added. For the rest the translator and publisher have carried out their part of the work with discretion and care. F. M. P.

A Laboratory Guide for Beginners in Zoology. By Clarence Moores Weed, D.Sc., and Ralph Wallace Crossman, B.A., M.Sc. Pp. xxiv + 105. (London: D. C. Heath and Co., 1903.) Price 2*s.* 6*d.*

THIS handy and very moderately priced laboratory guide will be useful in those courses of elementary instruction in zoology which aim at a fairly wide survey of the types of animal life without going into great detail in regard to any. Thus there are instructions in regard to six Protozoa, two sponges, three Hydrozoa, a rotifer, three Echinoderms, the earthworm and Nereis, Cyclops, the wood-louse, the lobster, the crab, the centipede, three insects and a spider, three molluscs and three vertebrates, altogether thirty-two types. The directions for study are for the most part really directions, and not little paragraphs of condensed information; many of them take the form of questions. The student is not supplied with ready-made diagrams; he is asked precisely to draw certain things. There is a directness and business-like clearness about the whole book that we like, and its partiality is frankly admitted, supplementary text-books being indicated. It would have been well if the authors had always stated what particular species they had in view, *e.g.* what Tubularian and Campanularian hydroid or hydroids. In some cases the headings do not read very happily, if the book is to be used in Britain, *e.g.* "The simple Marine Sponge (Grantia sp.). This sponge is a marine animal, found commonly along the Atlantic coast of the United States." But we can recommend the little book as a terse, unpretentious, and clear guide to introductory studies of the structure of animals.

A Manual of Drawing. By C. E. Coolidge. Pp. iv + 200 (alternate pages blank). (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1902.) Price 1 dollar.

THE drawings and designs made by the professional draughtsman in a good manufacturing workshop are characterised by a style and completeness which easily distinguishes them from the amateur productions commonly met with in the technical school and college. The object of the author in this book is to give to students precise and minute instructions relating to the numerous small details of manipulation and drafting that must be followed if drawings are to be such as would command respect in a commercial establishment.

Thus we find information about drawing and tracing papers, black and coloured inks, printing processes, drawing boards and squares, compasses, scales and protractors, indiarubber, drawing pens and pencils, and, in fact, about drawing tools and implements in general. Instruction is given as to the proper way of arranging the several views in a drawing, of inserting the dimensions, printing the titles, &c. Various types of drawing are described, including detail sheets fully dimensioned, with the machining and materials specified; general views, with only leading features exhibited; patent office drawings made in conformity with the United States' regulations, and suitable for photographic reproduction, &c.

The student is assumed to have obtained elsewhere a practical knowledge of workshop processes, of machine construction, and of the forms and proportions of machine parts. The author gives that kind of information which would be gradually acquired, almost unconsciously, by any one working alongside an expert in a commercial drawing office. The book contains a useful index and a number of plates in illustration of the text. Alternate pages are left blank in order to induce and enable the student to collect and record additional notes and observations of his own, or which his instructor may impart.

Zoologische Wandtafeln. Gezeichnet und herausgegeben von Prof. Dr. Paul Pfurtscheller, Wien. (Wien und Leipzig: A. Pichler's Witwe und Sohn.)

THIS is a new series of large wall diagrams for lecture-rooms, similar to those which we owe to Leuckart and Nitsche. The two samples we have seen—of the sea-urchin and the snail—command our admiration, especially the former. They are boldly and clearly drawn, with more shading than colour, and they stand out admirably from a distance. Two of those on the sea-urchin sheet are even beautiful. Our only criticism is that it seems a mistake to mix up *mere* diagrams, *e.g.* two simple figures on the snail sheet, with the chief picture, which shows things more or less as they are. The mere diagram can be drawn on the blackboard in a minute, and should not be put on the same plane as the elaborate drawing of the half-opened sea-urchin, which the teacher requires as a permanent part of his illustration equipment.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Radium and Cancer.

IT has occurred to me that perhaps you would care to publish the enclosed letters, and thus start some one experimenting with the radium rays in the manner suggested.

Dr. Sowers is a distinguished physician of Washington, D.C., now spending a portion of his summer vacation in Baddeck, Nova Scotia.

ALEXANDER GRAHAM BELL.

Baddeck, N.S., July 21.

Dr. Z. T. Sowers,
1707 Massachusetts Avenue,
Washington, D.C.

Dear Dr. Sowers,

I understand from you that the Röntgen X-rays, and the rays emitted by radium, have been found to have a marked curative effect upon external cancers, but that the effects upon deep seated cancers have not thus far proved satisfactory.

It has occurred to me that one reason for the unsatisfactory nature of these latter experiments arises from the fact that the rays have been applied externally, thus having to pass through healthy tissues of various depths in order to reach the cancerous matter.

The Crookes's tube from which the Röntgen rays are emitted is, of course, too bulky to be admitted into the middle of a mass of cancer, but there is no reason why a tiny fragment of radium sealed up in a fine glass tube should not be inserted into the very heart of the cancer, thus acting directly upon the diseased material. Would it not be worth while making experiments along this line?

Yours sincerely,
(Signed) ALEXANDER GRAHAM BELL.

Baddeck, N.S., July 21.

Dr. A. Graham Bell,
Baddeck, N.S,

Dear Dr. Bell,

The suggestion which you make in regard to the application of the radium rays to the substance of deep seated cancer I regard as very valuable. If such experiments should be made, I have no doubt they would prove successful in many cases where we now have failures.

Yours sincerely,
(Signed) Z. T. SOWERS, M.D.

Baddeck, N.S., July 21.

The American Tariff and the St. Louis Exhibition.

As a member of the Royal Commission appointed to make a success of the British Section of the St. Louis Exhibition, I have, in common with some of my colleagues, been met by the difficulty, which for a time seemed an insuperable one, that our manufacturers could not be prevailed upon to send their goods to this exhibition, even though they would be admitted duty free, because the tariff had practically killed their trade with the country.

Even in the subject in which I am interested, instruments of precision, I have been met with this answer to such an extent that for a time I feared that the formation of a representative collective exhibit would be impossible.

I wish, if you will afford me the space, to point out to our manufacturers that in our class the incidence of the duty need not be so disastrous to trade as it must be in many others. Not only will instruments and other goods sold from the exhibition to public institutions in the United States be allowed to be sold free of duty, but instruments and other goods sold to public institutions in the United States from this country are also admitted free of duty. (See extract from Tariff Law below.)

As in the case of instruments of the highest class the requirements of public institutions are necessarily large in comparison with the demands of the public, more especially, I believe, in a country like the United States, where institutions of this kind are so liberally supported, and as this disparity is probably greater in the case of goods in this class than in any other, I hope you will enable me through your columns to urge our makers to reconsider any refusal to assist the Royal Commission in the formation of an adequate collective exhibit that may have been made on these grounds, and to avail themselves of such advantages as we are able to offer.

Section 638 of the Tariff Law of 1897 provides as follows:—

"638. Philosophical and scientific apparatus, utensils, instruments and preparations, including bottles and boxes containing the same, specially imported in good faith for the use and by order of any society or institution incorporated or established, solely for religious, philosophical, educational, scientific or literary purposes, or for the encouragement of the fine arts, or for the use or by order of any college, academy, school, or seminary of learning in the United States, or any State or public library, and not for sale, subject to such regulations as the Secretary of the Treasury shall prescribe."

It should be noted, however, that surgical instruments are not classified as philosophical or scientific.

C. V. BOYS.

The Eucalypts.

YOUR reviewer of two recent works on Eucalypts (April 2, p. 524) seems to require correction on certain points. *Eucalyptus globulus* cannot be considered as the first in economic importance amongst the Eucalypts. In almost every shade of extra-tropical climate there is to be found a Eucalypt which will grow as well, or better, than *E. globulus*, and yield a far superior timber. It is generally held now that Eucalypt planting has suffered by the indiscriminate praise showered on *E. globulus* by the early Eucalypt enthusiasts.

Your reviewer says, further, that Eucalypt plantations now exist in Italy, France, Algeria, California, and other countries. He does not appear to be aware that there is probably more Eucalypt plantation in South Africa than in any other country, and that at the present rate of progress there will, in a few years, be more Eucalypt plantations in South Africa than in all the other countries combined. There is no group of trees in the warm temperate regions of the world that can produce hardwoods of good quality so rapidly and so cheaply as Eucalypts, and their cultivation bids fair to become the central factor in the forestry of these regions. At this moment train-loads of Eucalypt timber are pouring into South Africa, Eucalypt sleepers displacing metal and creosoted-pine sleepers. South Africa will soon be paying out something like a *quarter of a million pounds yearly* for Eucalypt timber imported for railway sleepers and mining timber (little or none of this, by the way, *E. globulus*), so that any delay in the prosecution of Eucalypt planting in South Africa would be a most expensive proceeding. It is noteworthy that, so long as the Eucalypt is properly fitted to its climate, it seems to grow better in South Africa than in Australia, the explanation being probably that all the Eucalypts in South Africa have been raised from seed, and are thus growing in South Africa free from their Australian pests, both fungoid and insect. With the view of preserving this happy immunity from disease, the importation of Eucalypt plants into Cape Colony is placed under stringent restrictions.

The meritorious work of Messrs. R. T. Baker and H. G. Smith, if carried to a conclusion, should be the classic for many years on Eucalyptus oil. Your reviewer is mistaken in saying that practically all the Eucalypt species indigenous to Australia are included in their work. Practically, all the Eucalypts are indigenous to Australia, but they are not included in Messrs. Baker and Smith's work, which em-

braces 111 out of 120 described species of New South Wales and a few others from the neighbouring colonies of East Australia, but none of the well-known timber Eucalypts of Western Australia, Jarrah, Kari, Touart, red gum, York gum, &c.

It is a little disappointing that the authors were unable to obtain leaves of such a prominent Eucalypt as *Eucalyptus regnans*, the tree which shares with *E. diversicolor* the honour of being the tallest tree in the world. It is common enough in the Government plantations near Cape Town, as is also *E. alpina*, which figures also in the list of unprocurables. It is particularly unfortunate that they have not tested *Eucalyptus calophylla*, the type of the parallel veined Eucalypts. This is a West Australian species.

Messrs. Baker and Smith state that forty tons of Eucalypt leaves were used and 500 distillations made. Their work is a model of painstaking investigation, and to the chemist and those interested in the oil industry will no doubt prove extremely useful.

But the authors have not confined themselves to the chemistry of Eucalyptus oil. They propose a number of new Eucalypt species and a new classification of Eucalypts. How far the numerous new species will stand the test of critical investigation in the field remains to be seen. Many of their new species have already been contested.

Messrs. Baker and Smith have discovered that there is a relation between the venation of Eucalypt leaves and the chemical constitution of the oils of those leaves. Parallel veins and pinene go together. Many of the parallel veined leaves smell of turpentine like a pine leaf. Then come the peppermint Eucalypts, containing piperitone, with a more complex venation; and then a still more complex venation yielding oils rich in eucalyptol or cineol, which is the valuable constituent in the best Eucalypt oils. This is a very interesting and important correlation, especially if further investigation shows that it holds good through the whole Eucalypt genus. As chemists, one can pardon the authors their enthusiasm over it. But whether it is sufficient to found a new classification of Eucalypts on may be doubted. We have numerous Eucalypt classifications in the field. There is that which is generally accepted in default of a better, the anthereal system of Bentham, somewhat modified and simplified, but not improved in Mueller's subsequent works. There is a (perhaps more practical) bark system, and there are various obsolete systems founded on the shape of the cones and the flower buds. As Messrs. Baker and Smith most justly remark, a natural classification founded on a combination of all these, including the quality and structure of the timber, has yet to be made. It is not likely that their oil-and-vein classification will be sufficient in itself. It seems unlikely that anyone, except a scientifically trained forester, who has spent a large portion of his life among the Eucalypts in their natural forests, will be able to construct a sound natural grouping of the species of this difficult genus. The work will require a Mathieu, a Brandis, or a Gamble, that is to say, a practical forester with special scientific qualifications. It is not to be done with botanical specimens as Bentham and Mueller attempted it, nor with practical knowledge alone as Wools attempted it, nor in a chemical laboratory where Messrs. Baker and Smith have done most of their work! It is true that Mr. Maiden is now bringing out a "Critical Revision of the Genus Eucalyptus," and from this, with his great reputation as a practical botanist, much is expected. The first number, on that very important species *Eucalyptus pilularis* and its allies, has already appeared, also part ii. on *E. obliqua* and the gum-top stringy barks.

In view of the differences in the quality of the oil yielded by various Eucalypts, the authors advocate plantations in certain circumstances of good oil-yielding species. The lopping they suggest a forester would replace by coppicing. It is believed that all Eucalypts coppice well. Most of them will stand a considerable amount of lopping, but it eventually kills them. It is only in a few instances that species of Eucalyptus are found predominating over an area of country to any great extent, so that a particular species being worked for its oil may soon be cut out in close proximity to a permanent plant. But some Eucalypts are very tenacious of life, and "suckers" soon spring from the stumps of the trees cut down; it is thus only a matter of a few years when fresh material is again obtainable. This may be seen from the photograph of *E. Smithii*, where most of the dense growth is from "suckers" of this nature. We have been able to show, in several instances, that the oil obtainable from this young growth is of the same character as that obtained from the mature leaves, so that no great differences in the quality of the oil need be expected. But we think it to be a pity that the trees should, in many instances, be felled for their leaves alone. By judicious lopping a fresh supply of leaves could more quickly be obtained, so that a permanent supply might be assured. There are a few species of Eucalyptus, however, which form the prevailing vegetation in certain localities, and are found growing gregariously in their native habitat; this is particularly the case with some of the "Mallees." In New South Wales there are several species of this nature, as, for instance, the "Blue Mallee," *E. polybractea*; the "Red" or "Water Mallee," *E. oleosa*; the "Grey Mallee," *E. Morrisii*; and the "Argyle apple," *E. cinerea*; all these species give good eucalyptol oils, and all are more or less gregarious in their habits, so that natural plantations of these species are practically ready to hand; but besides these naturally covered areas the question of the cultivation of certain Eucalyptus species is of importance in this connection.

It may possibly be accepted as conclusive that some Eucalyptus species are not inexhaustible under certain conditions, and it is worthy of consideration whether plantations of young trees of *Eucalyptus Macarthuri*, for instance, might not be profitably cultivated for the preparation of its valuable geranyl-acetate oil. So with the eucalyptol oils, it is probable that the cultivation of some species, *E. Smithii*, for instance, could be profitably undertaken, and from which young growth an oil could be distilled that would compete satisfactorily, both in price and eucalyptol content, with any European oil of this class.

A minor fault running all through their book is their use of the word "sucker." By "sucker" is properly understood shoots from the roots, such as one sees in poplars, elms and willows. Eucalypts do not sucker (except rarely and accidentally), and the authors use the word in the sense of "coppice-shoot." No doubt "sucker" is an Australian colloquialism, but naturally the use of slang expressions is to be avoided in a scientific work. To be accurate the authors should use the term early or first foliage, or its equivalent, since this important diagnostic feature is seen in the first foliage of Eucalypt seedlings equally with coppice-shoots.

As yet no one of the Australian colonies has taken the first step in scientific forestry. Though Mr. Maiden in his various writings has let in a flood of light on the subject, and the student of Eucalypts stands deeply in his debt, there is not a line by a scientifically trained forester descriptive of the forests of Australia. There is no want of liberality on the part of Australia in endowing the researches of scientific men living in cities, but there is a woeful neglect of forestry in the field. Scientific forestry as understood on the Continent of Europe is unknown in Australia, and unless the Commonwealth can bring its attention to bear on the terrible waste of its natural forest resources now going forward, its future history will be a black one, comparable only in modern times to that of the Spaniards in Mexico.

In the older settlements of East Australia the forests, pillaged of their best species, or burnt and ruined, have greatly declined in value. Gone are the valuable reserves of iron-bark, tallow-wood, and forest mahogany among the Eucalypts, and the splendid cedars (*Cedrela toona*) which should have been the country's pride. South Africa is getting most of its timber from the comparatively newly settled West Australia. The Australian has yet to learn to take the honey without destroying the bees!

When your reviewer takes us to America, we get amongst a people awakening to the fact that there is such a thing as scientific forestry. As he remarks, the American volume on Eucalypts is excellently got up. It is a pleasure to turn over the pages with their life-like pictures of Eucalypts. It is not likely, however, that there will ever be any great production of Eucalypt timber in North America. It is only South California that quite repeats any Australian climate, namely, South-West Australia. It is doubtful if Eucalypts will ever do much in the eastern States. The Gulf States, which are alone suited to Eucalypts, have their cold snaps and freezes, together with an all-the-year-round rainfall which we do not find in Australia, while there is

an abundance of good hardwood already in the country, and the four pitch-pines, rivalling hardwoods in strength and durability. Eucalypt culture in America is still in its infancy; they have not yet discriminated the valuable from the many worthless species, nor fitted, as far as may be, the species to its climate.

D. E. HUTCHINS.
E. HUTCHINS.

Cape Town, June 23.

A Simple Form of Tide Predictor.

FOR the past four years a very simple form of tide-predicting machine, the invention of Captain A. Inglis, the harbour-master, has been in use at Port Adelaide for the construction of the yearly published tide tables. The tides at Port Adelaide are rather peculiar in their behaviour, this being due principally to the fact that the solar and lunar semi-diurnal components are almost exactly equal. At and near the neaps these neutralise one another, and the diurnal components, which are relatively large, are then the main sources of the tidal movement. Before these tides were harmonically analysed, their prediction by ordinary methods was quite impossible, except near the springs. By means of this machine, however, they are now predicted yearly with considerable accuracy. The essential principles of the machine are as follows:—A number of thin wooden templets are cut, each in the form of a sine curve, representing the various tidal components (Fig. 1). These waves are of different lengths, the length of each component wave bearing

FIG 1.

the same ratio to the solar semi-diurnal as its angular speed does to 15°. The templets are all fixed side by side, with their planes vertical and parallel, being supported on a carrier, which can be moved forward in the direction of the waves by means of a rack and pinion underneath. A number of vertical plungers rest in a transverse line with their lower ends resting on the tops of these templets, and are moved up and down as the curves progress forward. The motions of the plungers are then compounded by means of a fine wire passing over pulleys at the top of each one, and under fixed pulleys between adjacent ones. This wire is connected to an indicator, which moves up and down alongside a vertical scale, thus marking the height of the compound wave at any instant.

The wire passing over the plungers is an endless wire, going round a pulley on the indicator and round a larger pulley at the other end of the line of plungers. This larger pulley is attached to a plate which is movable backwards and forwards by means of a fine screw. This gives a means of adjusting the height of the indicator, and also of allowing for the effect of the annual and semi-annual tides. The rise or fall due to these long period tides is treated as constant for fourteen days, and the screw adjusted so as to alter the height of the indicator by the proper amount at the end of each such interval. In front of the frame of the machine, between it and the indicator, is a vertical slide, which is moved forward at the same rate as the carrier, and carries a sheet of paper on which the tidal curve may be traced if required (Fig. 2).

Each templet is fixed in the carrier in proper relative position according to its phase at the start, as determined by previous harmonic analysis. When the handle of the machine is turned, the carrier, vertical slide and clock are set in motion, and the indicator shows the height of the

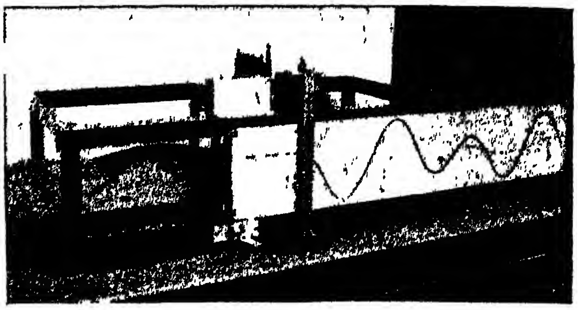

FIG. 2

tide at the time shown by the clock, and the curve may at the same time be traced on the vertical slide.

There are three carriers and three or four templets to each component. When one of the carriers has been worked forward far enough, it can be disconnected from the others and connected up again at the other end. The curves are again placed in their respective grooves, and, by means of a suitable attachment, butted close up to the preceding ones. In this way the process is made continuous.

The setting of the curves can easily be checked at every month, to see that there has been no slipping.

The machine involves no expensive construction, and enables a year's tides to be predicted expeditiously, and, as experience has proved, with quite sufficient accuracy.

The University, Adelaide. R. W. CHAPMAN.

[In a subsequent letter, Mr. Chapman informs us that he made the following errors in the list of values of the tidal components at Port Darwin, printed in last week's NATURE (p. 295). "The amplitude of N should be 1·04, of ν 0·48, and of T 1·53. The phase of ν should be 141°, and that of T 70°."—ED. NATURE.]

Sympathetic Song in Birds.

IN your issue of April 30 (vol. lxvii. p. 609) Mr. George Henschel describes an interesting vocal duet between a bullfinch and a canary, and invites contributions to the subject.

In 1893 I obtained a nestling Australian magpie (*Gymnorhina tibicen*, Latham), and taught it on the flute to pipe the following:—

Some years later I acquired another bird of the same species; this learned the tune from the original magpie. I do not know how the birds agreed upon the duet (or fugue) rendering, but it was performed in the following way:—When the first bird commenced its song, the second one immediately came to attention, and with half-open beak awaited the point marked *, whence it finished the strain alone. The birds were kept in a large outdoor aviary in company with many others, and no matter where or how engaged, the second bird would, on hearing its mate, assume an attentive attitude, and await the conclusion of the first portion of the theme.

The second bird died, and the original one, which I still have, now pipes the whole strain alone, as was its original custom.

I may also mention that this bird has the faculty of absolute pitch, and pipes the theme in F as originally taught.

EDGAR R. WAITE.

Australian Museum, Sydney, June 18.

THIRTY YEARS OF UNIVERSITY EDUCATION IN FRANCE.

THE modern conception of a University in France dates from the Revolution. In place of the old Sorbonne, veritable Bastille of scholasticism, the new University was conceived as a kind of laboratory and clearing-house in which every form of knowledge was to be pursued or dispensed. Yet in spite of the multiplicity of the subjects, unity was to be secured by the natural connection between the different branches and the common aims and ideals of the teachers themselves. Unfortunately the Revolution failed to realise the grandiose ideas of Talleyrand and Condorcet. With the exception of the Institute, the only establishments it created were the so-called "special schools" limited to the study of a single science or group of subjects, such as, for instance, the school of mathematics, the school of medicine, the school of Oriental languages, &c. To these the Consulate added the schools of law and altered the title of many of these schools into that of "faculties." It further increased the number of faculties by adding those of letters and of science. The research side of university work was ignored, the faculties were mere examination machines for turning out professional men. The only university was the University of France, which, though made a corporate body by Napoleon, was above all things an institution for the propagation of an official education most favourable to Imperialism. To this university all the different faculties in the different towns were subordinated. But here all connection ended. Although often existing three and four together in the same town, they were completely strangers to one another, having no unity or even relationship with one another, almost entirely devoid of the necessary resources, not merely for original investigation, but also for their ordinary work.

The evils arising from such an excessive centralisation combined with the practical isolation of the local faculties were certain to make themselves felt in the long run. "Paris," wrote Guizot in his "Memoires," "morally attracts and absorbs France." For this, in his eyes, the only remedy was the creation of a few large provincial universities. Recognising the impossibility of creating seventeen complete and fully equipped universities, he proposed to limit their number to four. Unhappily he was in advance of his time. The second Republic reduced the status of the university itself from that of a corporation to a mere branch of the central Government. The most enlightened Education Minister of the Empire, Victor Duruy, seeing the impossibility of reforming the faculties, determined to establish alongside of them a scientific institution called the École des hautes Études, which reminds one, though its scope was wider, of the Royal College of Science, inasmuch as the savants who formed the "personnel" were chosen on their merits alone, and no question was made as to whether they were members or not of the university. The school had no fixed quarters, but any professor of ability in the Sorbonne, the Collège de France, the Museum of Natural History, or in any laboratory, was pressed into the service of this new corps of learned and scientific teachers. The effect of the opening of this "opposition shop" was most beneficial on higher education throughout the whole of the country.

Nevertheless the general condition of higher education was, in the words of M. Liard, "very lamentable, and what was most lamentable of all was not the insufficiency of the buildings, the poverty-stricken state of the laboratories, collections and libraries, or the dearth of resources, but the almost absolute misconception of their real functions by the professors of those faculties which ought to have been above all the instruments of scientific progress and of the propagation of scientific methods. With a few exceptions, in the faculty of letters the teaching was above all rhetorical and fashionable, in that of science it was nearly everywhere limited to the mere popularisation of discoveries. The highest work of university education, the training and formation of the man of science, was almost unknown. The admirable savants of the time were self-taught persons without a university degree."

Such was the state of things when the disaster of 1870 occurred. With the conclusion of peace, savants and patriots joined forces in favour of a radical reform of the university system. It was felt that inefficiency in higher education had been one of the causes of national defeat.

The most competent judges were agreed that the essential defect in university education was the multiplicity and isolation of the faculties. The remedy in their eyes was the concentration of the faculties of the different orders into a limited number of "powerful centres of study, science and intellectual progress." Jules Simon affirmed the necessity of "having a certain number of intellectual capitals in which are to be found united all the necessary resources for the complete development of the young." Again, according to M. Laboulaye, universities were the one thing needful. "Let them cease to scatter over the surface of France faculties the isolation of which condemned them to sterility."

Some of the strongest arguments in favour of reform came from the men of science of the day. It was pointed out that the duty of the Universities was not merely to distribute the existing stores of knowledge, but also to lead in the van of discovery. "Close the laboratories and libraries," said Bertholet, "stop original investigation and we shall return to scholasticism." Insistence was also laid on the extreme value of scientific discovery as a factor in the industrial struggle between the different nations, while at the same time the importance of introducing the scientific spirit into the mental life of a people only too often swayed by sudden emotions was strongly emphasised.

But the advocates of university reform had a very serious difficulty to encounter at the outset. Alongside of the faculties there already existed the big scientific establishments like the Collège de France, the Museum of Natural History, and the professional schools, such as the École Polytechnique and the École Normale, in which the flower of military engineers and university professors were being trained. All these bodies were bitterly hostile to incorporation. Fortunately they were all situated in Paris, where in reality there was room both for themselves and the University. The main problem after all was the creation of provincial universities.

Here the difficulties were far more real and pressing. To begin with, many of the existing professors in the faculties were by no means in sympathy with the reformers. For them the function of the faculties was to turn out lawyers, magistrates, doctors, pharmaceutical chemists (the calling of chemist in France ranks as a liberal profession); not to conduct original research. Did not the Collège de France and the Museum of Natural History exist specially for these purposes? The answer was one which has since been given in higher technical education in England and elsewhere, that science should be the centre of professional training. Practice without science was pure empiricism, and empiricism was out of date. Claude Bernard had already converted medicine into an experimental science, and the historical method had wrought a similar transformation in the study of law. Whether the faculties remained isolated or not, they would henceforth have to

adopt scientific methods. Naturally every student could not be turned into a man of science, but every one had a right to know the scientific truths on which his professional education was based, while the small élite of really talented students should have the opportunity of engaging in scientific investigation. In the case of these exceptional students the method of working in common with their masters had hitherto been largely neglected. Yet its importance in working out a discovery to its fullest extent is not only beneficial to all parties, but often of the highest importance to the country at large. Another objection urged by the opponents of reform was that a university by definition implies the concentration of subjects, whereas modern science on the contrary is fissiparous by nature, ever splitting up into new branches and specialities. To this it was easily answered that one of the chief dangers of the day was excessive specialisation, and that the university is therefore the best antidote, as its chief function is to coordinate knowledge and make it a general object of culture. Warned by the excessive specialism that is rampant in German universities, the French have taken for their motto, "Specialisation subordinated to a general culture."

In 1883 Jules Ferry brought the question within the sphere of practical politics by a circular addressed to the faculties; after speaking of the efforts he had made to develop in higher education the sentiment of responsibility and the habit of self-government, he went on to say:—

"We shall have obtained a great result if we are able to constitute one day universities uniting within themselves the most varied kinds of teaching, in order mutually to assist one another, managing their own affairs, convinced of their duties and of their merits, inspiring themselves with ideas suitable to each part of France with such variety as the unity of the country allows, rivals of adjoining universities, associating in these rivalries the interest of their own prosperity with the desire of the big towns to excel their neighbours and to acquire particular merit and distinction."

In conclusion he invited the faculties to give their opinions on his suggestion. These were, in the main, favourable. It was left, however, to his successor, M. René Goblet, to take the first official steps. It was evident to all that the new universities could not be constituted after some ideal plan, but would naturally have to be built up out of the existing faculties. To group the latter in collective wholes, effacing all distinction between them, would have proved too drastic a measure. The best way of building up a university was to begin by strengthening and not by weakening the faculties. This was done by restoring to them the "personalité civile" which had lapsed, and recognising their capability to receive and hold property. At the same time another decree, without giving them the absolute right to frame a budget, allowed them the right to expend all subventions, to which no conditions had been attached by the parties making them, whether departments, communes, or private individuals, on the creation of new courses of instruction, on laboratories and libraries, and on scholarships. To regulate this expenditure a council was created called the "Conseil général des Facultés." This council, established for purely financial reasons, was destined to become the real nucleus in the development of the universities. As M. Liard has well said, "the decree of 28th December, 1885, was truly the provisional charter of the universities before the universities." Linking together the faculties of a single town, the Council not only dealt with the functions for which it was first created; it was soon allowed, under certain conditions, to draw up the programmes of courses and lectures, to exercise certain disciplinary powers, to make financial proposals to the Minister, and to engage in a multiplicity of tasks which fall to the lot of an ordinary university to perform. In 1889 the separate faculties received the right to frame budgets of their own. At the same time those grants were directly paid to them which the Ministry previously had itself expended on buildings and equipment. So far the Government had only proceeded by way of decrees, a method which is not unknown in England, and corresponds roughly to an order in council, but in 1890 the moment seemed to have come for legal enactment, and M. Léon Bourgeois, the then Minister of Public Instruction, brought forward a Bill to settle the whole subject once for all.

Nothing gives a better idea of the enormous sacrifices made by the Republic for the sake of higher education than the preamble of the Bill, which ran as follows:—

"The Republic has understood that university education is in the highest degree necessary; that if primary education is, according to the phrase of one of our predecessors, the canalisation by which knowledge is distributed to the very lowest strata of democracy, university education is the source where it collects and whence it flows. It has understood that a particular dignity and utility are attached to this grade of education, that in it especially are formed and trained the men who are capable of conceiving general ideas, by the power and novelty of which the real influence of nations is measured to-day. Therefore it has liberally given to it the necessary millions which had been persistently refused by former administrations.

"In the last 15 years it has renewed the buildings of the faculties.

"It has supplied almost entirely their equipment, their laboratories, their libraries.

"It has enlarged and increased the scope and range of their teaching.

"It has more than doubled their budget.

"It has improved the position of the 'personnel' and endowed their teaching with the requisite resources.

"It has created two categories of student, formerly unknown in France, students in science and in letters.

"It has introduced more science into those courses in which the preoccupations of professional studies predominated, and it has imposed a professional task on those orders of faculties which were without it.

"It has restored to the faculties the 'personalité civile,' a right which a suspicious *régime* had denied they possessed.

"It has rendered relationship possible between them by giving them a common function to fulfil.

"It has given full liberty to science and theory.

"It has favoured the coming together of students as well as that of teachers.

"In conclusion it has seen the number of its students rise from 9000 to more than 16,000, foreigners returning to its schools, and frequenting them in greater numbers than in any other country in Europe."

The Bill itself proposed to create universities in the fullest sense of the word out of the existing groups of faculties in the seven largest towns. Unfortunately local influences proved too strong; the other ten towns possessing two or more faculties demanded equality of treatment. The former adversaries of the project joined forces with them; and in the end the Government was obliged to withdraw the Bill.

Beaten on the question of establishing local universities of the fully equipped type, the reformers took once more the line of least resistance, and in 1893 an Act was passed investing with the "personalité civile" the groups of faculties formed by the union of several faculties, and represented by the Conseil Général. This was followed in 1896 by an Act introduced by M. Poincaré, which converted these groups of faculties into

universities. The idea of full and complete universities, which had been the underlying conception of the Bill of 1890, was abandoned, and wherever an academy existed, even if it had but two faculties, its place was taken by a university. As M. Liard well says, "it was a choice between having too many universities or of having none." To provide funds, the tuition fees, which had hitherto gone to the Treasury, were handed over to the new bodies. The examination fees, however, were still retained by the Treasury. The law contained but four clauses. The first decided that the groups of faculties should take the name of universities. The second decided that the Conseil Général should receive the title of university council. The third enlarged the disciplinary powers of the new council. The fourth dealt with the financial arrangement mentioned above, the new funds provided being "earmarked" for certain definite purposes, such as expenditure on laboratories, &c. Certain other financial rearrangements were made, with the result that the extra cost to the State came to about 15,000*l.* a year. The existing "personnel" was paid, as before, by the State, and the regular grant, variable year by year, for buildings and equipment was likewise continued. By the law of 1899 the universities were allowed to establish "degrees of a purely scientific kind." This was largely done to encourage the attendance of foreigners, while the proviso that they conferred no rights or privileges safeguarded the State from incurring any responsibilities *vis à vis* their recipients.

The preamble of the Bill of 1890, quoted above, gives an adequate summary of the progress made from 1870 up to the university year 1888-1889. More detailed information of the progress since that date is to be found in the "Statistique de l'Enseignement Supérieur," which brings up the record to the university year 1897-98 (the last year available). The following are some of the principal items of interest. Though the French universities have not, with very rare exceptions, found any benefactors on the scale of the Rockefellers and Carnegies, the list of benefactions published in full shows that the power of the new universities revived in 1875 to receive donations and legacies has not remained unappreciated. The University of Paris has received such lump sums as 210,000*l.*, Montpellier such as 60,000*l.*, while several have received donations of 4,000*l.* or less. In 1889 the annual grant from the State amounted to about 456,284*l.* In 1898 it was more than 523,640*l.*, showing an increase of 67,000*l.* odd over the grant of ten years before, which itself was more than double the grant under the Empire. Though the universities received the above sums in hard cash, the actual cost to the State was less, as one must deduct from it the fees for degrees, which, as has been already stated, go into the coffers of the State. These amounted to 5,135,162 francs in 1898, or, roughly, 205,406*l.* The net expenditure, therefore, of the State was about 318,000*l.*

The departments and municipalities make contributions to nearly all the universities, their contributions being "earmarked," as a rule, for specific purposes. They practically support all the medical schools, whether situate at the seat of the university itself or within its area of control, the only exceptions being Paris and Bordeaux, which also receive a State subvention. The contributions of the departments and municipalities to the budgets of the university and faculties amount to about 68,000 francs and 132,000 francs respectively; their contributions to the medical schools unsupported by the Government, and to the so-called preparatory classes in letters and science amount to about 135,500 francs and 882,000 francs respectively. The total income of the universities, including these medical schools, but excluding the Collège de France, the Museum, and the various special schools, amounts to about 14,142,000 francs for the universities, and 1,582,858 for the medical and preparatory schools, in all a grand total of about 15,725,000 francs. Towards this total the State contributes 13,096,664 francs, the departments about 203,000 francs, and the municipalities about 1,014,000 francs; the rest is made up of students' fees, legacies, and contributions by societies and private persons. As, however, the towns receive from university sources the sum of 421,837 francs, their net contribution is only about 593,000 francs, or roughly about 23,720*l.*

Since 1888-89 the number of students has risen in a remarkable fashion, though no doubt this increase is due in part to the law which grants two years' exemption from military service to those who have passed certain examinations. In 1888-89, the number of students was about 16,000, in 1898 the total had risen to 28,782, of whom 871 were women, and no less than 1784 of foreign nationality. All the faculties show an increase in the number of students during the same period, but those in science (a school which did not exist before the Republic) show the greatest increase. Their numbers have risen in the last ten years from 1187 to 3424.

The Baccalauréat shows the same remarkable increase. Certain changes in the examination do not permit of a comparison being drawn with any year earlier than 1892–93. In that year there were 25,612 candidates for the different sections of the examination, of whom 11,518 passed. In 1897-98 there were 36,922 candidates, of whom 16,688 passed. The other establishments of university rank, the Collège de France, the Museum of Natural History, the École Normale Supérieure, the École pratique des hautes Études, &c., all received an increased grant in 1898 in comparison with the last decennial account. The Collège de France, which is entirely devoted to research work, contains no less than forty-two chairs, and receives from the State nearly 21,000*l.* a year. The Museum of Natural History, equally devoted to research, has a budget of more than 38,000*l.* The school of Oriental languages, which has no counterpart in England, though we have a far greater need of one, receives more than 6000*l.* a year. The École des Chartes receives more than 3000*l.* The École pratique des hautes Études receives more than 12,500*l.*, as well as more than 1500*l.* a year from the City of Paris. The majority of these institutions have enormously developed, if they have not been actually created, under the Republican *régime*.

One word must be said in conclusion for the free universities founded in 1875, when the university monopoly in higher education was abolished. At first permitted to grant degrees similar in name to those of the official world, they have since lost the right. In spite of this they have none the less continued to increase. In 1888-89 their students numbered 726, in 1897-8 they had increased to 1407. It is difficult to say what will be their fate under the present campaign to re-establish the monopoly of the State in education. The higher schools of art and technology being under more or less separate authorities do not figure here in the list of higher education.[1] The present *régime* has been equally liberal and equally successful in dealing with these important branches of national education. Whatever may be the final verdict of history on the Republic, its bitterest critics will never be able to contest the fact that only Prussia after Jena can compare in any way

[1] The schools of art are under a separate department in the Ministry of Public Instruction and Art. The higher schools of commerce and technology are under the Ministry of Commerce.

with the thoroughness and success with which it has reformed and revivified every branch of higher education.

THE RESUSCITATION OF THE APPARENTLY DROWNED.

IN 1862 a committee, which included several eminent medical men and physiologists—amongst the latter Dr., now Sir, John Burdon Sanderson—was appointed by the Royal Medical and Chirurgical Society to investigate the phenomena attendant upon drowning, and the methods which had been recommended for the recovery of apparently drowned persons. That committee made a number of experiments in man upon the dead subject, and upon animals during life, and the results they obtained were duly published in the *Transactions* of the society. But it appeared important to renew the inquiry with modern methods, and a second committee for the investigation of this important subject was accordingly appointed a few years ago, with Prof. Schäfer as chairman. This second committee attempted, in the first instance, to pursue the inquiry as to the best means of carrying on artificial respiration, in the same manner as the 1862 committee, *i.e.* upon the cadaver, but met with grave difficulties from the outset in the enormous resistance which the condition of *rigor mortis* sets up to effecting changes of volume of the chest, a difficulty which had been also met by the earlier committee, and very imperfectly surmounted. The new committee accordingly decided to discard the cadaver, and to endeavour to determine in the living human subject how great an amount of air could be moved into and out of the lungs by movements imparted to the thorax by the agency of external force. This force was applied either by intermittent traction upon the arms, or by intermittent pressure upon the thorax, the subject being either in the supine or prone position, and remaining perfectly passive during the short period of the experiment. The amount of air taken in and given out was measured in a graduated vessel, or by means of an ordinary gasometer.

The results showed that by all methods which have been suggested for the performance of artificial respiration, viz. the Silvester traction method, the Marshall Hall rolling method *plus* compression of thorax, the Howard method of compression of thorax in the supine position, and also a similar method of pressure upon the thorax with the subject in the prone or semi-prone position, an amount of air can be drawn into and driven out of the thorax which is at least as great as the amount of air exchanged in the ordinary tidal respirations of the individual. This being so, it is evident that, in selecting a method of artficial respiration for restoring the drowned, one should be guided less by the actual amount of air which any given method is capable of exchanging than by other considerations, such as the facility offered for the escape of water and mucus from the air passages, and the preventing of the tongue from falling back and blocking the fauces, both of which objects are better attained by the lateral and prone than by the supine position. It was further clear that it is more easy to effect artificial respiration by exerting intermittent pressure upon the thorax than by arm traction, and although the committee do not give instructions for the restoration of the apparently drowned in their report, it is obvious that their conclusions point to the adoption of the prone or semi-prone position of the subject, and to rhythmically intermitted pressure upon the thorax, as the methods which are likely, in the circumstances of drowning, to yield the best results.

The experiments upon animals (which were performed almost entirely upon anæsthetised dogs) are, it is believed, the first in which all the phenomena connected with the circulation and respiration have been graphically recorded during the process of drowning and subsequent resuscitation by artificial respiration. The chief points which they illustrate are the very large amount of water which can be taken into the lungs and become entirely absorbed into the system within a few minutes, without producing any but quite temporary symptoms, the great amount of vagal stimulation which is produced during drowning, and which is, in some instances, sufficient to arrest the heart's action almost entirely, and the extreme variability in the power of resistance to drowning in different individuals of the same species, so that, while a submersion of two minutes is fatal to some individuals, one of seven or eight minutes, or even more, can be borne by others with a fair chance of recovery as the result of the application of artificial respiration. The experiments all point to the supreme importance of commencing artificial respiration at the earliest possible moment, and are, therefore, condemnatory of all instructions for the recovery of the apparently drowned which direct that, before proceeding to apply artificial respiration, the patient should be divested of clothing, hartshorn should be applied to the nostrils, and various other remedies attempted—all of which merely serve to waste time, every second of which is invaluable for combatting the actual condition which is threatening life, viz. the lack of oxygenation of the blood. Incidentally it was found in the course of these experiments that, without sufficient aëration of the blood, even the most powerful cardiac and vascular stimulant—such, for example, as the extract of suprarenal capsule—is entirely unable to assist recovery.

The experiments upon the cadaver were chiefly performed by Mr. Pickering Pick, Mr. Henry Power, and Dr. J. S. Bolton, in London; those upon the living subject by Prof. Schäfer and Dr. P. T. Herring in the physiological laboratory of the University of Edinburgh. The report of the committee was read by Prof. Schäfer at a largely attended meeting, held on May 26 last, at the rooms of the society in Hanover Square.

NOTES.

WE regret to learn that on Saturday, July 25, M. Prosper Henry, of the Paris Observatory, was found lying dead in the La Valoise Valley near Pomogen at an altitude of 1600 metres, in the French Alps. His death appears to have been due to congestion caused by extreme cold. M. Henry was buried at Nancy, his birthplace, on August 1. A number of astronomers was present at the sad ceremony, among them being M. Callandreau, of the Paris Academy of Sciences; MM. Borchart and Fraissinet, of the Paris Observatory; and M. Trépied, director of the Algiers Observatory. M. Prosper Henry and his brother, M. Paul Henry, were attached to the Paris Observatory in 1865, and their work is well known in the astronomical world. Between 1872 and 1882 they discovered fourteen asteroids,

and in the latter year took up the work in celestial photography which has rendered their name famous. It is not too much to say that in many ways they have been the real founders of La Carte du Ciel.

AN International Conference on Wireless Telegraphy was opened at Berlin on Tuesday. We learn from the *Times* that Great Britain is represented by Mr. J. C. Lamb, Mr. J. Gavey, and Mr. R. J. Mackay, of the General Post Office, Captain H. L. Heath, R.N., Lieut. C. R. Payne, R.N., and Colonel R. L. Hippisley. Herr Kraetke, the Imperial Secretary of State for the Post Office, who opened the conference, said that it was intended "to make a clear road for the further extension of wireless telegraphy in order that, all special interests being set aside, the new means of communication might gradually develop to the common benefit of all seafaring peoples. This could only be brought about by the harmonious cooperation of the States interested in the shipping trade." The business of the conference is, however, only preliminary, the main object being to fix upon matter for discussion at a subsequent international conference. This later conference will probably be largely occupied in considering the possibility of standardisation with a view to intercommunication between different systems. We have often pointed out in these columns the extreme desirability of such intercommunication from the point of view of public safety and convenience. When the problem of syntonisation is solved, it will no doubt be possible for one system to work entirely independently of all others, but until that time it is practically necessary that some working arrangement should be made between the different systems which will allow the public to derive from wireless telegraphy the full advantage that it can, as yet, bestow.

MR. R. LYDEKKER, F.R.S., has been elected a foreign member of the R. Accademia dei Lincei, Rome.

MR. W. R. OGILVIE-GRANT, of the Natural History Museum, has returned from his trip to the Azores with a large collection of birds, insects, and land molluscs, the latter including some forms of special interest.

WE learn from the *Times* that Dr. Ludwig Mond, F.R.S., whose death was incorrectly announced by some papers last Saturday, is approaching complete recovery from a nervous breakdown on the shores of Lake Leman.

THE Civil Service Supplementary Estimates include the sum of 45,000*l.* to pay the expenses of the two relief ships *Morning* and *Terra Nova,* which are being sent out by the Admiralty to the relief of the *Discovery*. The estimate includes provision for the purchase of the *Terra Nova* and for the wages of the crews of both vessels; also for stores, coals, provisions, &c.

SEVERE earthquake shocks were experienced in several parts of Italy and Spain last week. Reuter's correspondent at Rome states that several houses and churches at Filattiera and Mulazzo were destroyed by an earthquake on July 31, and a message from Madrid states that at Albuñon, in the province of Granada, severe earthquake shocks, followed by loud and prolonged subterranean rumblings, were felt on July 26, 27 and 28.

THE council of the Institution of Electrical Engineers has now, with the approval of the Physical Society, undertaken the publication of *Science Abstracts* as an Institution publication. In connection with this work, Mr. Louis H. Walter has been appointed editorial assistant to the secretary, and will take up his duties in the autumn.

THE death is announced of Prof. Edmond Nocard in his fifty-fourth year. Prof. Nocard, who was principal of the Veterinary School at Alfort, near Paris, had a world-wide reputation as a veterinary pathologist, and was the author of several important works, of which his "Maladies microbiennes des Animaux" (written in collaboration with Prof. Leclainche) has just reached a third edition. He was also one of the co-editors of the Pasteur's *Annals*. He attended the Tuberculosis Congress in London in 1901, and was a strenuous opponent of Koch's view of the non-transmissibility of bovine tuberculosis to man.

A MEETING of the general committee of the Cancer Research Fund was held on Friday last, July 30, Mr. Balfour, one of the vice-presidents, occupying the chair in the absence of the president, the Prince of Wales. The first annual report, which was submitted, showed that a large amount of preliminary work had already been accomplished during the few months the Cancer Research Fund has been in existence. It was deemed premature to make any detailed statement of the experimental work in progress, but an indication was given that considerable importance is attached to the study of cancer as it occurs spontaneously in the lower animals. For the purposes of this branch of the inquiry, it is sought to secure adequate farm accommodation. Certain statistical data are also in progress of compilation with regard to the proportion of cases in which the clinical diagnosis is verified by the pathological findings, in order that the value of the data upon which existing statistical conclusions are based may be determined and sources of fallacy obviated in future. Sir William Broadbent, in moving a vote of thanks to Mr. Balfour, stated that he thought that in the course of the work now being inaugurated, the nature, cause, and cure of cancer would be arrived at. Whatever method of cure might be proposed, it would receive careful investigation. Mr. Balfour, in his reply, alluding to the interest which everyone must take in the cancer problem, said he was surprised that only 213 persons had contributed to the fund. One anonymous donor had promised 5000*l.* if thirteen other individuals, or groups of persons, would each contribute a like amount, but up to the present this appeal had not been successful. Considering the progress that had been made in all departments of medical science during the last century, he believed that there was every reason to hope that the investigations of the committee would ultimately prove successful. The Cancer Research Fund now amounts to about 52,000*l.*, but in order to pay the expenses of the work out of the income of the fund, the amount originally estimated, viz. 100,000*l.*, will be necessary.

A CORRESPONDENT of the *Times* states that Lieut. Kolchak has started from the Arctic coast for the New Siberian Islands in search of Baron Toll, the head of the Russian Polar expedition which left St. Petersburg three years ago in the yacht *Zaria*. If Baron Toll be not found on the New Siberian Islands, then Lieut. Kolchak will endeavour to reach Bennett Island, about eighty miles further north-west. A year ago last May Baron Toll, with the astronomer Seeberg and two native Yakuts, left the *Zaria* off Kotlin Island with a view of reaching Bennett Island over the ice. In case the *Zaria* should not be able to follow them, which eventually turned out to be the case, the party hoped to be able to return independently to the New Siberian Islands; but it is supposed that Baron Toll had not dogs enough with him for this purpose, and was therefore obliged to winter on Bennett Island. In regard to food, all the members of his party are excellent hunters, and in case

the baron should have succeeded in making his way back to the New Siberian Islands in the spring, he and his companions will have an ample supply of provisions in the stores which he himself left there for Nansen in 1893. According to notes left by Seeberg on New Siberia, which is the last news received of the expedition, Baron Toll's party must have left there about the beginning of July of last year to explore Bennett Island.

IT is announced that a wireless telegraphy station is to be erected at Port Arthur at a place known as Golden Mountain. The object is to establish regular communication with Russian warships in the Gulf of Pechili. The system to be used is not stated.

THE Cable Makers' Association, which represents the chief makers of insulated wire in this country, has decided to put on the market a special quality of flexible cord which shall be quite safe and trustworthy under all conditions of ordinary use. The importance of installing good quality flexible cord cannot be overestimated, as the loose wire is subjected often to rough treatment, and is very liable to be in the neighbourhood of inflammatory material. The cord which the Association proposes to make is to be insulated with pure and vulcanised indiarubber, and will have a minimum insulation resistance of 600 megohms per mile after twenty-four hours' immersion in water; the insulation will also be tested with 1000 volts alternating current for fifteen minutes. The cord will bear a special label and trade mark for the purpose of distinguishing it.

THE twenty-fifth annual report of the Deutsche Seewarte for 1902 will be noteworthy in the history of that useful institution by the retirement of Dr. von Neumayer, who had been director since January, 1876, and of Captain Dinklage, marine superintendent, after twenty-two years of very active work. The long list of meteorological logs received from the navy and mercantile marine shows that this branch of the service has been carried on with great activity; 556 steamships and 198 sailing vessels contributed observations during the year. The results appear in various useful publications, including daily synoptic charts and monthly pilot charts of the North Atlantic Ocean. The department of storm warnings and weather telegraphy has also been conducted with unabated vigour, to the success of which the recent establishment of a telegraphic service at 7h. a.m. has greatly contributed. The daily weather report issued by this department is one of the most valuable publications of the Seewarte, and includes observations from all parts of Europe.

WE have received the report of the Government astronomer of Western Australia, containing meteorological observations made at the Perth Observatory and other places in the colony during the year 1901. Very complete observations are published for the observatory, including temperature of the soil and evaporation, together with monthly means from the year 1876. General summaries are also given for more than forty climatological stations and rainfall statistics for a large number of places. Morning and evening weather forecasts form part of the routine work, and the results show that they have been remarkably successful; the general forecasts issued at noon, for the whole State, attained a complete success of 93 per cent. During the latter portion of the year astronomy also formed a prominent feature of the work of the observatory.

IN the *Zoologist* for July Mr. T. E. Lones discusses the identification of some of the birds mentioned by Aristotle, and shows that certain of the names have a generic rather than a specific sense. It appears that the name *boscas*, now used for the mallard, really indicates the widgeon, while *netta*, now employed as the generic title of the red-headed pochard, properly denotes the first-named bird. In a second article Mr. R. C. J. Swinhoe publishes a fuller account of the *gisement* of the now celebrated chipped flints from Yenangyoung, Burma, and concludes that, in place of Pliocene or Miocene, they are really of late Neolithic, if not of the Iron, age. Mr. Lydekker has a note on the gaur of Burma, which is regarded as subspecifically distinct from the wild ox of India, and named *Bos gaurus readei*.

A COLLECTION of molluscs from the Vicksburg marls has enabled Mr. T. L. Casey to describe a considerable number of new species and genera in a recent issue of the *Proceedings* of the Philadelphia Academy. In the same journal Mr. A. E. Brown attempts to bring into something like order the various forms of garter-snakes (Eutænia) from the Pacific Coast of North America which have received distinct specific and subspecific names. Much interest attaches to a note by Miss S. P. Monks in the serial under consideration in regard to regeneration in starfishes. It has been stated that a fragment of a ray, without any portion of the central disc, cannot give rise to a new animal. This is disproved by the new experiments, in which the amputated free rays developed new bodies, while the mutilated starfishes produced new rays.

FROM among a series of papers published in the *Proceedings* of the U.S. Nat. Museum, special mention may be made of the following. In No. 1345 Mr. B. A. Bean records from Barbados an example of the small eel, *Ahlia egmontis*, hitherto known only by the type specimen from Florida. Reference is also made to a third example of the species from Florida. In No. 1341 the Rev. T. R. R. Stebbing describes two new species of amphipod crustaceans from Costa Rica. The walking-stick insects (Phasmidæ) of the United States form the subject of a paper (No. 1335) by Mr. A. N. Caudell, while Mr. W. H. Dall (No. 1342) contributes a synopsis of the bivalves of the family Astartidæ, with special reference to the American species. Finally, Mr. S. F. Clarke (No. 1343) shows that the Alaskan hydroid polyp, described by himself as the representative of a new family and genus (Rhizonema), belongs to one or other of the well-known genera Corymorpha and Lampra, the imperfect condition of the Alaskan specimens preventing closer identification.

IN *Animal World Illustrated* (the official organ for the R.S.P.C.A.) for July, Mr. E. V. Windsor, in an article entitled "Reflections by a Lover of Nature," passes an unqualified condemnation on insect collecting, as practised by the school-boy and the amateur entomologist. Stuffed birds as objects of decoration are likewise condemned, and we presume, although this is not stated in so many words, that collections of birds' skins, except in museums, would likewise come under the writer's ban. While we have much sympathy with Mr. Windsor's views, more especially as regards the stuffed birds, we believe that he carries these views somewhat too far. For instance, when he says that "there is little or nothing to be learnt from a creature when dead," we beg to join issue with him. Again, we have the following passage:—"In every branch of natural history this wanton slaughtering is, I fear, practised. In branches other than those I have just referred to it is practised almost exclusively by men who have a real claim to the title of naturalist, because these branches of natural science not being so popular, there are fewer amateurs." If by this the author means to condemn museum collecting, he cannot have our sympathy. As regards the contention

that nobody should collect without fully studying the habits of the species collected, we are in full accord with Mr. Windsor; but this by no means implies that collecting, under proper restrictions, should be abolished *in toto*. Were this to be done, it is probable that young collectors would confine their attentions to stamps and such like, whereby many a promising recruit would undoubtedly be lost to science.

THE *Agricultural Journal of the Cape of Good Hope*, the official publication of the Cape Department of Agriculture, is meant to circulate among the farmers of the Colony, and contains popularly written accounts of investigations conducted by the experts attached to the Department, articles on general farming, reports on farmers' congresses, legislative enactments, and other matters of agricultural interest. The current number (vol. xxii. No. 6, June) contains plenty of evidence of the difficulties which beset the South African farmer—infectious and parasitic diseases of all kinds among his stock, insect and fungoid pests among his crops. The two most active branches of the department are evidently those dealing with veterinary medicine and insect entomology; investigations of soil and manure problems are hardly of much consequence to the Cape farmer as yet. While the greater part of this number deals with veterinary matters, we get incidental allusion to one of the questions upon which the future of South African agriculture must depend, the successful introduction of suitable forage crops to carry stock through the winter; such plants as lucerne (alfalfa) or turnips are not in the regular routine of farming, and through the winter, when there is no grass on the veldt, the animals practically starve. We learn, too, that wheat-growing, as in some of the Australian colonies, must depend upon the introduction of rust-resisting varieties; in the absence of sorts remaining rust-proof there is at present little prospect of South Africa contributing to the "Granary of the Empire."

THE geology of the Cheadle Coal-field is described by Mr. George Barrow in a handy pamphlet of sixty-two pages, with a small colour-printed map attached to it, issued by the Geological Survey. The price is 2*s*. The area is an outlying portion of the North Staffordshire Coal-field, and Mr. Barrow gives full particulars of the seams of coal, with records of borings, and remarks on the probable extent of the workable measures. The underlying Millstone Grit and overlying Bunter and Keuper formations are likewise described, and special reference is made to the water-bearing strata. Attention is also directed to the Glacial drift, to the great amount of rain-wash, and to the recent river deposits.

THE fourth part of the memoir on the geology of the South Wales Coal-field, being an account of the country around Pontypridd and Maes-têg, has been written for the Geological Survey by Messrs. A. Strahan, R. H. Tiddeman, and W. Gibson. It is issued at 1*s*. 6*d*., with a separate colour-printed map (without Glacial drifts) also priced at 1*s*. 6*d*. The map, which is very clearly printed, embraces a tract almost wholly of Coal-measures, including much of the Pennant Grit, which forms the bold moorland features of the Coal-field. Millstone Grit, and small areas of Carboniferous Limestone, as well as Lias, Rhætic Beds, Keuper Marl, and Dolomitic Conglomerate are shown on the south. Tracts of river gravel, peat, alluvium, and blown sand are also depicted. The Glacial drifts are represented on another edition of the map, which is at present hand-coloured. The memoir deals chiefly with the details of the Coal-measures, and more especially with the lower measures of the south crop, comparative sections of which are given. The upper or Llantwit measures occur only in two small outliers. The structural geology is fully described, the Pontypridd anticline and other faults and disturbances being dealt with. A study of the Glacial deposits indicates that the main ice-flow had its source in Brecknock. It followed and filled the chief valleys, but failed to surmount the Pennant Grit scarp of Carn Mosyn. Subordinate ice-flows were, however, generated on these higher regions. Economic deposits are briefly described in a separate chapter. The Pennant Grit and the Llynfi rock in the lower measures supply materials for building, paving, and road-mending. The water-supply is obtained chiefly from springs and reservoirs, seldom from wells.

A SOCIETY for spreading information about St. Michael's in the Azores has published an illustrated booklet setting forth the charms of St. Michael's as a health resort and as a station for tourists. The brochure certainly contains much interesting information about this Atlantic island.

A NEW edition, making the twenty-sixth thousand, of Miss Agnes Giberne's "Sun, Moon, and Stars" has been published by Messrs. Seeley and Co., Ltd. A new chapter, part iv. of the volume, has been added, and deals briefly with celestial photography, the planets Mars and Eros, comets and new stars, as well as other topics. With the exception of these additions, the present edition is the same as the last.

A SIXPENNY booklet describing the legends and the story of the building of Stonehenge has been received from Messrs. James Henderson and Sons. In an appendix to the pamphlet a short account is given of recent attempts to ascertain the age of Stonehenge, and a reference is made to the wire fence with which Sir Edmund Antrobus has had the ruin enclosed. This action of Sir Edmund Antrobus is characterised as wise and public-spirited, since it will help in the preservation of this valuable monument of antiquity.

WE have received a copy of the meteorological observations for the year 1902 made at the Rousdon Observatory in Devonshire, which is continued under the superintendence of Lady Peek. The publication was prepared under the supervision of Mr. W. Marriott, of the Royal Meteorological Society, and contains remarks on the weather experienced during each of the months of 1902, and a useful collection of nine tables dealing with such subjects as the pressure, temperature, and hygrometric state of the air, temperature of the soil, wind direction, rainfall, amount of sunshine, &c The concluding table affords a useful summary of the annual results for the years 1884–1902.

Two more numbers of the "Rural Handbooks" published by Messrs. Dawbarn and Ward, Ltd., have been received; one is by Mr. C. F. Townsend, and is entitled "Heating and Ventilation of Houses," the other is on "Utility Fowl Feeding and Management," and is by Mr. H. Francklin. These little books are simply written, and will serve to supply the principles upon which success in many pursuits depends. The book on ventilation is well illustrated, and contains practical information of a kind to enable any intelligent householder to secure good ventilation. The amateur poultry farmer will find numerous helpful hints in the second handbook as to how to make his hobby a profitable one.

THE current number of the *Quarterly Review* contains two exhaustive articles on subjects of scientific technology. The first is by Mr. J. Nesbit on the improvement of British forestry, and begins with a historical retrospect of the attempts made by legislation and otherwise to encourage

tree-planting and to preserve the forests. This is followed by an account of present practice and ideals. The work of the departmental committee appointed by the late Mr. Hanbury is dealt with very fully. The second article is on submarine vessels, and is unsigned. It is accompanied by four plates, and gives a full description of the attempts made to perfect this form of boat, and of the best models now in existence.

In reviewing Prof. G. P. Merrill's "Stones for Building and Decoration," when the book was first published in 1891, we cited it as affording an admirable example of the value of exact scientific knowledge when applied to the treatment of economic questions. The fact that since the date mentioned, as Prof. Merrill points out in the preface to the third edition which has now been issued, there has been a very notable increase in the output of building stone from American quarries, serves to emphasise the real connection between the scientific treatment of an industry and its success. The present edition differs from the previous ones in containing a revised chapter on methods of testing, a new chapter on the use of drift boulders for building purposes, and five maps showing the geographic distribution of the more important building stones. The new edition is published in this country by Messrs. Chapman and Hall, Ltd., and its price is 21*s*. net.

The additions to the Zoological Society's Gardens during the past week include a Chimpanzee (*Anthropopithecus troglodytes*) from West Africa, presented by Mr. H. Freeland; a Chacma Baboon (*Papio cynocephalus*) from South Africa, presented by General Sir Henry de Bathe; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. H. Baker; a Levaillant's Cynictis (*Cynictis penicillata*) from South Africa, presented by Mr. C. Marsh; an Egyptian Ichneumon (*Herpestes ichneumon*) from North Africa, presented by Dixon Bey; a Nagor Antelope (*Cervicapra redunca*), a Crowned Duiker (*Cephalophus coronatus*), a Serval (*Felis serval*), an African Civet Cat (*Viverra civetta*) from West Africa, presented by Sir G. E. Denton, K.C.M.G.; a Cuckoo (*Cuculus canorus*), British, presented by Mr. J. O. Pickington; a Back-marked Snake (*Coluber scalaris*), South European, presented by Mr. W. H. St. Quintin; a Common Toad (*Bufo vulgaris*), European, presented by Mr. H. Verrall; a Common Mynah (*Acridotheres tristis*) from India, a Chameleon Lizard (*Chamaeleolis chamaeleontides*), two Large Cuban Anolis (*Anolis equestris*) from Cuba, deposited; three Peacock Pheasants (*Polyplectron chinquis*) from British Burmah, purchased.

OUR ASTRONOMICAL COLUMN.

The Spectrum of *o* Ceti.—No. 41 of the Lick Observatory *Bulletin* is devoted to a discussion of the spectrum of *o* Ceti by Mr. Joel Stebbins.

Using the Mills spectrograph modified to a one-prism instrument, he obtained a series of twenty-five good spectra during the period June, 1902, to January, 1903, in which period the star decreased in magnitude from 3·8 to 9·0. The spectrograms were obtained on Cramer's "Crown" or "Isochromatic" plates, are 28mm. in length, and extend from λ 3700 to λ 5600.

Mr. Stebbins finds that the absorption spectrum of Mira is very different from that of the sun; the calcium lines *g*, H and K are all present, but *g* is much stronger than in the solar spectrum. From measurements of six suitable lines he found that the velocity in the line of sight is constant, with a value of +66km. A summary of the dark lines discovered indicates the undoubted presence of Fe, Va, Cr and Ca, and the Al and Sr lines are prominent, whilst the presence of Mn and Ti is as yet considered doubtful.

The general conclusion arrived at is that many of the lines become broader as the star's magnitude declines, and this is undoubtedly true of the *g* calcium line at λ 4227·84. In the later photographs some new lines, not definitely coincident with solar lines, were observed, the chief of these being λ 3990·64, λ 4045·16, λ 4093·55, and λ 4097·08.

As regards the continuous spectrum, the photographs show that as the star declines in magnitude the continuous spectrum between λ 4300 and λ 5000 decreases in intensity as compared with that between λ 4000 and λ 4300.

Amongst the bright lines the hydrogen series is undoubtedly present, although previous observers have doubted the presence of $H\alpha$, $H\beta$ and $H\epsilon$; the two latter seem to have become stronger, compared with the other hydrogen lines and the continuous spectrum, as the star became fainter. The presence of bright metallic lines is as yet open to question. In 1898 Campbell observed $H\gamma$ as a triple line, and it was intended in this research to make polariscopic tests for the Zeeman effect, but, as the line was found to be single on the first spectrograms obtained, no such tests were made.

Mr. Stebbins discusses the principal theories concerning the remarkable variation in the magnitude of Mira, and is led to the conclusion that it is due to internal forces. Numerous tables and diagrams, and several reproductions of the spectrograms of Mira, accompany the dissertation.

Photographic Efficiency of a Short Focus Reflector.—In an abstract from No. 539 of the *Astronomical Journal* Prof. Schaeberle discusses the photographic efficiency of short focus reflectors, and describes some remarkable photographs obtained by himself with a 13-inch parabolic reflector of 20 inches focus. This reflector is mounted alongside a similar one, which is used as a finder and has an aperture of 12 inches, a focal length of 46 inches, and an eye-piece magnifying 360 diameters, on an ordinary English equatorial mounting, the photographic plate ($1\frac{1}{4}'' \times \frac{3}{4}''$) being placed at the focus of the mirror.

The results obtained showed that with less than five minutes' exposure the 13-inch revealed stars which are apparently beyond the reach of the 36-inch Lick telescope, and also revealed all the stars obtained by the 3-feet Crossley reflector with two hours' exposure.

The Ring nebula just shows on plates having had four seconds' exposure, and the central star and Lassell's No. 1 star (mag. 13) plainly show on an eight seconds' exposure. These photographs disclosed the true form of the Ring nebula, showing that it is a two-branched spiral which commences at the central star, and in a clockwise direction emerges on opposite sides near the minor axis. A reproduction of a photograph, which has been enlarged 150 times, accompanies the article, and shows the details of the nebula very clearly; this photograph was obtained on October 30, 1902, with an exposure of 128 seconds.

It has been shown by the photographs obtained that, under favourable conditions and using fast plates ("Seed" No. 27), this instrument can photograph stars fainter than the seventeenth visual magnitude in less than five minutes.

The Godlee Observatory.—In a brochure issued from the printing department of the Manchester Municipal School of Technology, the principal gives a detailed description of the Grubb telescope presented to the observatory connected with the school by Mr. Francis Godlee, of Manchester.

The mounting is of the twin equatorial type, and carries an 8-inch refractor and a 12-inch Newtonian reflector, besides a 6-inch achromatic doublet intended for astrographic work.

The refractor is provided with a filar micrometer, a finely divided position circle, and the usual accessories necessary for delicate visual observations. The polar axis is fitted with two R.A. circles, one of which may be set to sidereal time and rotates with the axis, so that the R.A. may be obtained by finding the difference between the readings of the two circles. The driving of the telescopes is performed by the usual clockwork arrangements, and is electrically regulated by a pendulum having a perfectly *free* movement; the mounting is so designed as to permit the instrument to make the whole circumpolar revolution without interruption.

THE MARINE BIOLOGICAL ASSOCIATION.

THE council of the Marine Biological Association, in the report for 1902–1903, presented to the annual general meeting of the association on June 24, state that the work of the association has been considerably augmented in consequence of the fact that a commission has been accepted from H.M. Government to carry out in the southern British area the programme of scientific fishery investigation adopted by the International Conference, which met at Christiania in 1901. The work in connection with these investigations is being carried out in the southern part of the North Sea and in the English Channel. In connection with the North Sea work, a laboratory has been fitted out at Lowestoft, and the steam trawler *Huxley* has been hired. Some difficulty was experienced in obtaining a vessel suitable for the work with the funds provided by Government, but the council were fortunate in securing the assistance of one of their members, Mr. G. P. Bidder, who himself purchased the *Huxley* from her former owners and let her upon favourable terms to the association. Accommodation for the naturalists has been fitted up in the old fish-hold of the trawler, and a small laboratory has been built on deck.

The investigations in the North Sea include a scientific survey, by means of the s.s. *Huxley*, of the trawling grounds between the east coast of England and about 3° 30′ E. longitude, in connection with which observations are made on the nature of the bottom, the nature and abundance of animal life living on the bottom and serving as food for fish or otherwise, the size and weight of the fishes caught, the food of the more important fishes, the condition of the fishes as regards sex, maturity, or spawning, and the temperature of the sea at surface and bottom. A simultaneous survey is being carried out of the regular fisheries on the trawling grounds, with the assistance of reliable masters of commercial fishing vessels. Experiments are also being made on the migrations of fishes, by marking and liberating fishes in large numbers over wide areas. These experiments are designed to throw light on the extent and direction of the seasonal and other migrations of food-fishes at different stages of their growth, particular attention being paid to the migrations of undersized flat-fish, and also to give an indication of the percentage of fish on the trawling grounds actually caught by the trawling fleets from one year to another. In addition to the above lines of research, special investigations are to be made on the rate of growth, age, fecundity and racial varieties of fishes, on the abundance of floating fish-eggs, and on the variations in the size and weight of fish landed at the various fishing ports throughout the year.

Up to the middle of June the *Huxley* completed twelve scientific trawling voyages in the North Sea. More than 34,000 fishes have been measured, the animal life of the bottom has been systematically studied from the point of view of distribution, and the food-contents of about 3000 fishes have been examined and determined. Plaice have been marked and liberated in different parts of the North Sea. In November and December a number of small flat-fish were marked on the grounds west of the Borkum Reef, and the results obtained are already of great interest and importance. They indicate that during December and January there was a marked migration southwards and westwards of the small plaice previously congregated on the inshore grounds of the northern and western coasts of Holland, the distances travelled being in many cases quite unprecedented, viz. from one hundred to one hundred and sixty miles in six weeks or two months. More than 10 per cent. of the fish liberated have already been recovered.

The English portion of the international scheme of hydrographic and plankton observations, the execution of which has been assigned to the Marine Biological Association, is to be carried out in the western half of the English Channel. These investigations have for their object the study of the seasonal changes which take place in the physical and biological conditions prevailing over the entire region covered by the international programme, though more particularly directed to a study of the waters entering the North Sea from different directions. They are designed to determine (1) the origin, history, and physical and biological characters of the water found in each locality at different seasons of the year and at corresponding seasons in different years, changes in which must necessarily have a profound influence upon the distribution and abundance of the fish-life in the sea; and (2) the variations which take place in the floating and swimming organisms (plankton) which constitute the fundamental food-supply of the sea.

The investigation is being carried out (1) by means of a series of quarterly cruises made simultaneously over the whole area by the vessels of the participating countries, as a result of which a thorough knowledge, based upon the most accurate available methods, is obtained of the conditions prevailing at all depths at certain fixed stations, together with a less detailed knowledge at intermediate points; and (2) by observations, more especially of the surface conditions, at as many points as possible during the time intervening between the seasonal cruises.

Complete series of observations at twenty stations in the English Channel were obtained during the first fortnights of February and May.

The ordinary work of the association has been carried on at the Plymouth Laboratory during the year. Work on the detailed record of the Plymouth fauna has been continued, the trawling experiments in the bays on the south coast of Devon have been completed, and a considerable number of naturalists have made use of the laboratory for their special researches. The statement of receipts and expenditure for the year shows a deficit of 117*l.* 1*s.*

THE PARSONS STEAM TURBINE.

THE recent launching of the cross-channel turbine steamer, the *Queen*, to which reference was made in our issue of July 2 (p. 209), has directed attention to the efficiency of turbine engines for many purposes. An ideal engine is one which has only one rotating part, and in which the direction of movement is not varied. Engineers have for many years recognised this fact, and much time and money have been expended in their endeavour to perfect a rotary engine. No practical success was, however, attained until 1884, when the Hon. C. A. Parsons, F.R.S., placed on the market his first compound steam turbine applied to driving a dynamo. Since then Mr. Parsons has effected many and various improvements, until, at the present time, the Parsons steam turbine is recognised by engineers to be a thoroughly efficient and practical engine, which, in the larger sizes, has attained an unprecedented degree of economy in steam. In the latter few years, the Parsons steam turbine has been applied to the propulsion of ships with very satisfactory results, and bids fair, in the near future, to supersede the reciprocating engine for certain classes of vessels.

A description of the Parsons turbine was given in NATURE several years ago (vol. lxi. p. 424), with illustrations of its parts. The turbine consists of a cylindrical case with numerous rings of inwardly projecting blades. Within this cylinder, which is of variable internal diameter, is a shaft or spindle, and on this spindle are mounted blades, projecting outwardly, by means of which the shaft is rotated. The former are called fixed or guide blades, and the latter revolving or moving blades. The diameter of the spindle is less than the internal diameter of the cylinder, and thus an annular space is left between the two. This space is occupied by the blades, and it is through these the steam flows.

In the arrangement of turbine machinery as adopted in the turbine Channel steamer the *Queen*, there are three turbines, viz. one high pressure in the centre of the ship and two low pressure, one on each side of the ship. Each turbine drives a separate shaft, with one propeller on each shaft, three in all. Inside the exhaust casing of each of the low pressure cylinders a reversing turbine is fitted. In ordinary going ahead, the steam from the boilers is admitted through a suitable regulating valve to the high pressure turbine, and after expanding about 5-fold, it then passes to each of the low pressure turbines in parallel, and is again expanded in them about 25-fold, and then passes to the condensers, the total expansion ratio being 125-fold.

The *Queen* is the third passenger vessel built by Messrs. Denny and Brothers fitted with the turbine system of propulsion supplied by the Parsons Marine Steam Turbine Co.,

Ltd. The *King Edward* was the first, and at her trial in June, 1901, this vessel obtained a mean speed of 20·48 knots. The *Queen Alexandra* was the second vessel; she was built in the following year, and obtained a mean speed of 21·63 knots. Both these vessels are now running on the Clyde.

A very important feature of these turbine vessels is the economy of coal consumption. In support of this it is of interest to mention that, at the launch of the *Queen Alexandra*, Mr. James Denny stated that if the *King Edward* had been fitted with balanced twin screw triple expansion engines of the most improved type, and of such size as would consume all the steam the existing boiler could make, the best speed that they possibly could expect would be 19·7 knots, as against the 20½ knots actually attained by the *King Edward*. The difference between 19·7 knots and 20½ knots corresponds to a gain in indicated horse-power in favour of the turbine vessel of 20 per cent.

Mr. Parsons, in a paper before the Institution of Naval Architects in Dublin recently stated that "the engining of larger vessels and liners is not a very long step beyond what has already been proved to be successful. The experience with the marine turbine up to 10,000 horse-power in ships of fast as well as of moderate speed, has tended to justify the anticipation, guided by theory, that the larger the engines the more favourable will be results as compared with reciprocating engines. The saving of weight, cost, space, attendance, and upkeep will become still more marked with turbine engines of above 10,000 and up to 60,000 horse-power, for which designs have been prepared."

It may be added that the results of moderately large turbines have shown an increased economy in steam consumption of 10 per cent. to 15 per cent., as compared with the best triple expansion engine.

Among the principal advantages of the steam turbine compared with ordinary engines are the following:—complete absence of vibration from main engines; increased economy in steam and coal consumption; increased accommodation and stability of vessel owing to low position of machinery; increased safety to engine room staff, owing to absence of reciprocating parts; reduced weight of machinery; reduced cost of attendance on machinery; and reduced consumption of oil and stores.

ANTHROPOLOGICAL NOTES.

TRUSTWORTHY studies on Australian languages are still greatly needed; it is therefore with pleasure that we welcome the elementary grammar, by the Rev. N. Hey, of the language of the Nggerikudi, a tribe of some 400 natives of North Queensland in the neighbourhood of Batavia River. Although Mr. Hey has been connected with the Presbyterian Mission to these people for ten years, he does not yet quite understand all the intricacies of the language. He notes that the aboriginals are fast disappearing. The vocabularies will be of some use to ethnologists who cannot profess to grasp the structure of the language. This study forms the sixth *Bulletin* of North Queensland ethnography that the Department of Public Lands, Brisbane, is bringing out under the editorship of Dr. Walter E. Roth.

The last issue of the *Reliquary and Illustrated Archaeologist* maintains the interest of former numbers. Messrs. Miller, Christy, and W. W. Porteous deal with a selection of Essex brasses that range from the reign of Edward IV. to nearly the end of that of Charles I., that is, almost to the time when the custom of wearing armour and the practice of laying down monumental brasses were both discontinued; the illustrations show clearly the various styles of armour worn during this period, as well as the modifications in the costume of the ladies. Papers of this kind are calculated to form a valuable adjunct to the teaching of history. Mr. J. Romilly Allen describes some late survivals of primitive ornament on wooden spoons, stay-busks, and knitting-sticks which were made for the special purpose of being given away as presents from young men to their sweethearts. Mr. Arthur Watson traces the tumbler's art during the last few hundred years; it was an accessory to the banquet in the middle ages; in the sixteenth century it had risen to a position of greater importance and independence; later it entered a new phase as an accompaniment to the drama; in modern times our streets yet retain traces of the ambulatory troups of performers, and acrobatic performances are still in vogue in the circus and music-hall.

The annual report for 1901–1902 of the Field Columbian Museum, Chicago, is a record of considerable progress, even for this enterprising museum. The cost of new installation for that year was about 10,000*l*., more than half of which amount was spent on new cases. Attention is directed in the report to the unsatisfactory condition of the fabric of the museum, which, it will be remembered, was one of the admittedly temporary buildings of the World's Fair. Judging from a paragraph in *Science* for July 10, this will soon be remedied, as the park commissioners of Chicago have approved the transfer of the museum from Jackson Park to Grant Park, which is on the lake front in the centre of the city. It is understood that Mr. Marshall Field has agreed to give 1,000,000*l*. for the construction and endowment of the museum. In the department of anthropology all the collections, with the exception of two important purchases, have been derived from field expeditions, consequently they are of unusual interest and of great

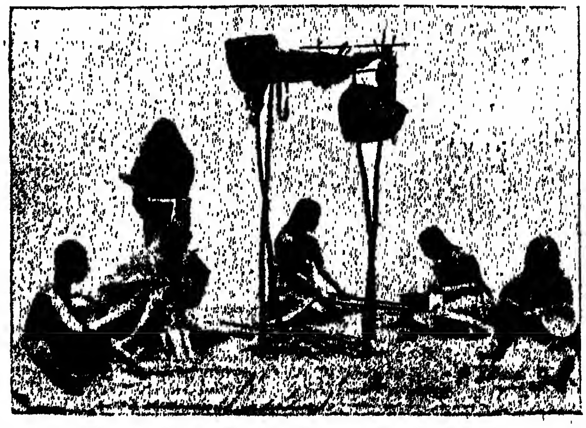

FIG. 1.—Salish House Group, Puget Sound, Washington Field Columbian Museum.

scientific importance; this is undoubtedly the most satisfactory manner of stocking a museum. The zoological collections were also augmented in a similar manner. The report is illustrated with excellent plates, which show that this museum is determined to keep the lead in the naturalistic and artistic excellence of its large animal groups. The Salish house group shown in the accompanying figure is an instructive addition to the many ethnological groups in the museum. Specifications are given of the new geological cases, and the botanist describes the reasons why he has adopted dead black labels printed with aluminium ink. Other educational aspects of the museum are its library, numerous popular lectures, and various publications. There is a very large attendance of school children accompanied by their teachers, and there can be no doubt that the schools and colleges are availing themselves more and more of the facilities of the museum as teaching adjuncts to books.

A BURIED TRIASSIC LANDSCAPE.

OUR older rocks have naturally diversified the scenery during many a past period. Bent and hardened by various processes, and ridged up into hilly ground, some of them have so long withstood the assaults of eroding agents as to have fairly earned the title of "everlasting."

This may truly be said of the buried mountains of Charnwood Forest. Visitors to that picturesoue and elevated district will have been struck with the curious rocky eminences that protrude here and there from what otherwise is a somewhat rounded, pastoral region. These isolated

barren stony tracts, with highly inclined slabs of rock and a fringe of fallen blocks, call to mind descriptions of kopjes.

Prof. Watts, in an interesting essay (*Geographical Journal*, June), shows clearly that here we have the "veritable peaks and arêtes" of a mountain system, formed of slates, hornstones, and agglomerates, with intruded syenites and granites, which jut out from a thick covering of Triassic marls, with basement breccias and sandstones.

Pre-Cambrian in age, these rocks have been subjected to various earth-movements, producing cleavage and jointing, and such intense induration that they appear to be equally strong, and the structures probably were impressed upon them in Cambrian times. Be this as it may, Prof. Watts concludes that they must have formed a mountainous tract in Old Red Sandstone times, and that then the mass was cut up by rapid streams into fiord-like valleys with ever-sharpening ridges. Some features are indicative of marine action, and it is probable that these were formed when the area was submerged in Lower Carboniferous times, and the ridges appeared as islands. After re-elevation in Permian times, subaërial waste contributed the materials of the breccias, and the conditions led on to those of the Trias, when salt-lake and desert, akin to the features of the Great Salt Lake and of Baluchistan, characterised the scene. The landscape which had been blocked out in Old Red Sandstone times, and modified in the Carboniferous period, was now subjected to much weathering, and ultimately the thick deposits of Keuper Marl buried up many, if not all, of the summits, to be partially revealed again by later denudation. Not until the Glacial period is there any positive evidence of the subsequent exposure of the ancient rocks, but blocks from the higher summits do appear in the Boulder-clay of the neighbourhood.

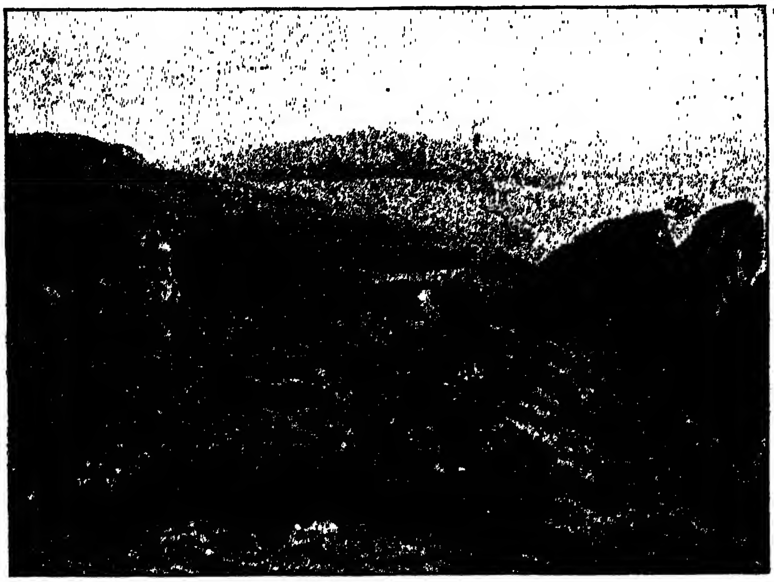

FIG. 1.—Bradgate Park, Charnwood Forest. Crags of Charnian Rock rising from Triassic ground. (From the *Geographical Journal*.)

Of the development of the present features Prof. Watts gives an interesting sketch. The Trias appears to have filled fiords which have been revealed by the present streams, and although they have deepened and altered the character of the older rocks when they excavated to them, the main outlines of the old scenery, uncovered by the denudation of the Keuper Marls, belong to the original Triassic landscape. As he points out, the granite of Mount Sorrel, when unbared for quarrying, shows often a smoothed and terraced surface, which was at first attributed to glaciation. More recently these surfaces have been found to extend beneath coverings of Keuper Marl, and the evidence is conclusive that the rounding and terracing must have been due to wind-erosion in the Triassic deserts before the peaks were buried under the Keuper Marl. H. B. W.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Howard Marsh, surgeon to St. Bartholomew's Hospital, London, and formerly professor of pathology and surgery at the Royal College of Surgeons of England, has been elected to the professorship of surgery, which has been vacant since the death of Sir G. M. Humphry, F.R.S.

Prof. Ewing, F.R.S., has sent in his resignation of the chair of mechanism and applied mechanics, to take effect on September 30.

Mr. C. E. Inglis, King's, and Mr. A. H. Peake, St. John's, have been appointed demonstrators in the engineering department.

Mr. W. E. Hartley, Trinity, has been appointed assistant observer at the observatory, *vice* Mr. A. Graham, retired.

THE eleventh summer meeting of university extension students was opened last Saturday at Oxford, when the United States Ambassador, Mr. Choate, delivered the inaugural address, taking for his subject American university education. After describing how Harvard was founded in 1636, and referring to the rise of the other older universities in the United States, such as Yale and Columbia, Mr. Choate explained that it was found at the beginning of last century that, if American universities were to hold their own, they must greatly increase their numbers, change their methods, and assume new and closer relations with the people. At that time there were only twenty-six colleges and universities in the whole territory of the United States, and many of these were in an undeveloped state. They are now numbered by hundreds, many of them richly endowed, and most of them furnishing an adequate training, adapted to qualify youths for business and for any duty to which they may be called. These new colleges are not all on the same model, but afford a wide choice of courses of study to suit the varied necessities of a diversified community. With the exception of a few of the older States which are already well provided with them by private means, each State in the Union has, by the use of public funds and lands, created a State university; and it has been the ambition of several of their multi-millionaires to create universities by the generous application of portions of their fortunes. By this means powerful institutions of learning have been created in a few years. The University of Chicago, founded in 1892, and endowed chiefly by the generosity of one man, now numbers more than 3000 students. By far the most signal advance in university extension yet made in America is the latest in date—the creation of the Carnegie Institute at Washington—with an endowment of ten million dollars to be devoted absolutely to original research. Another reason for the success of the efforts to improve university education in the United States was brought out by Mr. Choate, who made it clear that the work of the universities, colleges, and technical schools rests on the broad and firm foundation of the common schools, which from the beginning have been the peculiar care of the people, and that educational authorities in America adhere rigidly to the theory that special study for professional or business life should be postponed until a broad and general education has developed the faculties and character. Referring to the Rhodes scholarship scheme, Mr. Choate remarked that it provides that henceforth there shall at all times be at Oxford 100 American youths selected from all the States, there to receive the best fruits of her nurture and instruction. "And now would not some rich American respond to Mr. Rhodes's challenge, and forthwith in his lifetime make a similar and equal provision for 100

young Britons—English, Scotch, and Irish—to be maintained at universities in the United States?"

THE Lord Mayor of Liverpool, Mr. W. Watson Rutherford, has received in his capacity of chairman of the university committee the charter of the new University of Liverpool. Since the publication of the first draft of the charter, a clause has been added specifying that degrees representing proficiency in subjects of technology shall not be conferred without proper security for testing the scientific and literary knowledge underlying technical considerations. Mr. Rutherford has addressed a letter to the Liverpool City Council suggesting that the new university "be directly allied with the city, and should be free," and the letter is to be considered by the council as we go to press. In his letter Mr. Rutherford says:—"Let the matriculation examination be as severe as any in the country, and let every degree remain as high a standard of knowledge as that of any university in the world; but let there be no fees, no financial barrier whatever to the poorest citizens of Liverpool obtaining all the advantages of the Liverpool University," and he goes on to point out that a maximum rate of one penny in the pound would cover the students' fees and leave a considerable margin. The letter maintains that another benefit would be a sense of proprietary interest in the university on the part of the citizens of all classes in Liverpool, who would thereby at this juncture have not only elementary, secondary, and technical instruction, but the highest regions of advanced education, placed at their free disposal, and would, therefore, be far more likely to take a keener interest in the Liverpool University. The objections that what is not paid for is not valued, and that the course proposed would discourage private munificence, are regarded by Mr. Rutherford as ill-founded. The experiment of conducting a free university in this country has not yet been tried, and should the proposal be put into practice, the results will be awaited with keen interest by all who desire the spread of higher education. At the first meeting of the council of the university held on Tuesday, Lord Derby, the Chancellor, pledged himself to the utmost of his power to help to lay the foundations of a university in which studies of the arts, science, and other subjects should receive all possible expansion. Mr. E. K. Muspratt was appointed president, and Mr. J. W. Alsop vice-president, of the university council.

THE Board of Education has published "Syllabuses and Lists of Apparatus Applicable to Schools and Classes other than Elementary" for next session, that of 1903–4. The divisions in science and art subjects other than mathematics, formerly described as Elementary Stage and Advanced Stage, are now described as Stage 1 and Stage 2, and the divisions in science subjects, formerly known as Honours Part i. and Honours Part ii., are now described as Stage 3 and Honours. We notice that the examination tables supplied to mathematical candidates have been revised, and that notice is given that the alternative Stage 1 of theoretical inorganic chemistry will probably be discontinued after next session's work. Section i. of the first stage of the hygiene syllabus has been transferred to the subjects in which the Board of Education does not hold examinations. The second part of the volume is wholly devoted to two sets of syllabuses, styled concise and detailed respectively, in a great variety of subjects suitable for evening continuation schools, but in which the Board does not hold examinations.

NEW buildings, for which the sum of 80,000*l.* is required, will shortly be erected for University College, Reading. Of this amount, 30,000*l.* has already been contributed by five donors, including 10,000*l.* given by Mr. G. W. Palmer, M.P., and 10,000*l.* by Lady Wantage. The late Lord Wantage was president of the college from 1896 to 1901.

THE "Year-book" of the Armour Institute of Technology at Chicago for the session 1903–1904 contains not only full particulars of the courses in mechanical, electrical, civil, and chemical engineering, as well as in architecture, at the College of Engineering, but also of the preliminary studies which have been arranged at the Armour Scientific Academy, where students are prepared for the more advanced work of the college. Taking into their own hands in this way the early training of their engineering students, the authorities of the Armour Institute are able to provide the professors with students possessing a sufficiently good education to benefit by the lectures.

THE issue of *Science* for June 19 reprints Prof. R. H. Thurston's address at the dedication of Engineering Hall, Iowa State College. The subject chosen is the functions of technical science in education for business and the professions, and in the course of the address Prof. Thurston pleads powerfully for the full recognition of the importance of scientific knowledge to men whose business is in any way connected with technical matters. Perhaps the part of the address which will most interest the English reader is that which deals with the employment of American students after they have left the universities or colleges. The demand for college-trained men seems to be much greater in America than it is here, the "captains of industry" in that country having apparently realised the value of sound theoretical training in those whom they put in charge of their technical manufactures. "I have a deep file of letters calling for such men," says Prof. Thurston. "There is practically none unemployed unless on the sick list. All the professional engineering schools are thus situated. Turning out a thousand or more annually, the whole output is absorbed by the great industries, and immediately upon leaving the doors of the college." Can English professors say the same?

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 28.—"On a Remarkable Effect produced by the Momentary Relief of Great Pressure." By J. Y. **Buchanan**, F.R.S.

The experiment was made first during the cruise of the *Challenger* on March 27, 1873, in lat. 21° 26′ N., long. 65° 16′ W., where the depth of the sea was 2800 fathoms, and it was repeated on board the yacht *Princesse Alice* (H.S.H. the Prince of Monaco) on March 11, 1902, in lat. 43° 8′ N., long. 19° 48′ W., where the depth of the sea was 3000 fathoms.

FIG. 1.

Fig. 1 shows the effect produced on a stout brass tube 13 inches long and 1⅝ inches in diameter, which was perfectly cylindrical before it was exposed to the momentary relief of high pressure which has produced so deep a corrugation. In Fig. 2 the corresponding effect on a copper sphere of 5 inches diameter is shown; it takes the form of a multitude of small creases in place of the single deep corrugation produced on the tube. The experiments were made on the sounding cord on board the yacht *Princesse Alice* on September 10 and 11, 1902. The brass tube contained an ordinary 50 c.c. pipette sealed up at both ends, and empty except for the air which it contained. It occupied the part of the tube which has been so disfigured, and was kept in its place by a loose packing of cotton waste. Water had free access both at top and bottom.

The copper sphere contained a small spherical glass flask of 1 to 1½ inches in diameter, and it was kept more or less in the centre of the sphere by loose cotton packing; small holes at each pole of the sphere admitted the outer water. The brass tube was attached to the sounding cord and sent

to a depth of 3000 metres. The copper sphere was sent first to 3000 metres, but with no effect, and then to about 6000 metres, when the effect shown in Fig. 2 was produced. The *rationale* of the proceeding is:—at some depth less than 3000 metres in the case of the brass tube, and less than 6000 metres in the case of the copper sphere, the glass tube in the former and the glass sphere in the latter case collapsed suddenly. Considering, for brevity's sake, only the brass tube; immediately before the collapse the pressure inside and outside the brass tube was equal and uniform. The collapse of the glass tube produced a sudden and very considerable relief of pressure inside the brass tube. In ordinary circumstances the void so produced would have been filled by water from the outside entering through the perforated ends of the tube. But as the glass tube was subjected to a pressure of nearly 300 atmospheres before it collapsed, the difference of pressure produced in a moment of time was between 200 and 300 atmospheres. The deep corrugation shown in Fig. 1 proves that it was easier *in the time* for the pressure to pinch up the stout brass tube than to shove in the plugs of water at either end. The sudden action of the pressure is due, not to the settling of the column of 2000 to 3000 metres of water on the tube, but to the resilience of the enormous quantity of water of high tension produced by the pressure under which it finds itself.

FIG. 2

The effect produced on the copper sphere when the enclosed glass sphere collapsed is of exactly the same kind.

The experiment was originally made on board the *Challenger* on the day after she made her deepest sounding in the Atlantic in the neighbourhood of the West India Islands. On that occasion both the thermometers attached to the sounding line collapsed under the enormous pressure of 3875 fathoms, amounting to 700 atmospheres, and the experiment was made with tubes of three different widths in water of 2800 fathoms in order to obtain data for the construction of future thermometers. Two of the tubes collapsed, only the narrowest, having a diameter of 6 millimetres, withstood both the pressure assisted by the shock of the others collapsing near it. In all three cases the glass tubes were converted into a fine powder like snow.

The collapse of the brass tube, in the peculiar circumstances of the experiment, is the exact counterpart of the experiment which is frequently, but unintentionally, made by people out shooting, especially in winter. If, from inattention or other cause, the muzzle of the gun gets stopped with a plug of even the lightest snow, the gun, if fired with this plug in its muzzle, invariably bursts. Light as the plug of snow is, it requires a definite time for a finite pressure, however great, to get it under way. During this short time the tension of the powder gases becomes so great that the barrel of the ordinary fowling-piece is unable to withstand it and bursts.

June 18.—"New Investigations into the Reduction Phenomena of Animals and Plants." Preliminary Communication. By Prof. J. B. **Farmer**, F.R.S., and J. E. S. **Moore**.

In this communication the authors in the first place pointed out that the attention which investigators have recently paid to reduction phenomena occurring in animals

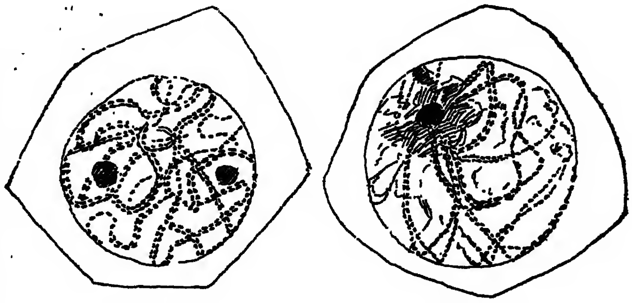

Fig. 1. Fig. 2.

and plants has resulted so far in an increasing divergence of opinion, both respecting the nature of this process and its significance. At the same time it was, however, apparent that there were several important points upon which all were now agreed; it had, for example, been clearly shown that, during this process, the number of the chromosomes occurring in the cells affected was reduced by one-half, and that this reduction was brought about during the rest preceding two cell divisions, which appeared to be invariably related to the process. Consequently it was rendered probable that the explanation of reduction was to be sought through a minute study of this, the synaptic rest phase, in a number of selected animals and plants. With this object, the authors had made a close examination of a large number of types, including mammals, elasmobranchs, amphibia and insects among animals, phanerogams, ferns and liverworts among plants, and the results of this investigation are at variance with the common existing conceptions of the process, while at the same time they seem to indicate a possible reconciliation between the different views which have been, and still are, held by other investigators. It will be remembered that there are two main theories of reduction. In the first we have the process regarded as a qualitative division of the chromatin by the separation into daughter nuclei of entire somatic chromosomes.

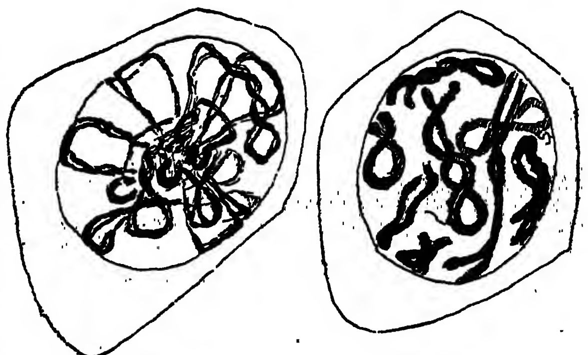

Fig. 3. Fig. 4.

In the second, the identity of the original somatic chromosomes becomes lost during the synaptic rest, and these are then replaced by half the number of new ones, which, during their formation, become longitudinally split twice in planes at right angles to each other. This double longitudinal division serves for two mitoses which take place almost simultaneously.

The authors find that at the end of the synaptic rest

the spirem thread certainly undergoes longitudinal fission. Connected with this there is a stage when the thread is arranged in loops, the split sides of which are approximated together in U-shaped figures. Although at their first formation the sides of these U-shaped loops are far apart, and still show the original longitudinal fission, they ultimately become approximated together, and at the same time the original fission, running throughout the length of the loops, disappears from general view. Through this process the approximated sides of the loops have hitherto been generally mistaken for the thickened halves of the originally split spirem thread, whereas in favourable cases it is seen that this fission can still be traced running along both sides of the loops.

The number of these loops arising during the synaptic rest corresponds to the reduced number of the chromosomes, and the further process in the formation of these chromosomes is simply a thickening and shortening of the loops already formed. When these become divided during the next mitosis they break transversely at a point corresponding to the original bends of the loops, and as the halves thus severed separate, the original longitudinal fission can be clearly traced running along their entire length. It is thus this original fission of the spirem thread, which serves to distribute the halves of the disunited somatic chromosomes during the following homotype division, and the hitherto enigmatical figures described by Flemming Meyès and others in the diaster of the heterotype find their natural explanation.

It would thus appear that the synapsis and the so-called heterotype mitosis constitute a phase which has been specially intercalated in the reproductive cycle. In it the reduction in the number of the chromosomes is produced by their adhesion in pairs, and the completion of the original longitudinal fission of the spirem thread is deferred until the following homotype mitosis.

The authors purposely refrain from discussing the general bearing of these observations, reserving this for a further and more detailed communication.

PARIS.

Academy of Sciences, July 27.—M. Mascart in the chair.—The preparation and properties of a silicide of ruthenium, by MM. Henri **Moissan** and Wilhem **Manchot.** At the melting point of ruthenium this metal combines with silicon with ease, giving a silicide of the formula RuSi, of density 5.40, perfectly crystalline, possessing great hardness, and very stable in the presence of most reagents.—Arsenic in sea-water, in rock-salt, kitchen salt, mineral waters, &c. Its determination in some common reagents, by M. Armand **Gautier.**—On dividing waves, by M. P. **Duhem.**—On cyclohexane and its chlorine derivatives, by MM. Paul **Sabatier** and Alph. **Mailhe.** The authors have shown that the aromatic nucleus really persists in the hydrocarbon; the vapour of cyclohexane directed alone on to recently reduced nickel maintained between 270° and 280° is regularly decomposed, [illegible] benzene and hydrogen, which at this temperature reacts on the benzene, transforming it into methane, $3C_6H_{12}=2C_6H_6+6CH_4$. The presence of the aromatic nucleus is also proved by the reactions of the chloroderivatives. One monochlorocyclohexane, two dichloro-, three trichloro-, and one tetrachloro-cyclohexane are described.—Photograph of Borrelly's comet, 1903 *c*, by M. **Quénisset.** The photograph was taken at the Nanterre Observatory on July 24–25, with an exposure of one hour. The photograph shows that the coma measures 16′ in diameter, that is, a little more than half the apparent diameter of the moon. Several tails can be distinguished, the most luminous and longest of which is at least 7° 50′ in length.—On the conditions of synchronisation, by M. **Andrade.**—On the measurement of the dichroism of crystals, by M. Georges **Meslin.**—On the electrical dichroism of liquids containing crystalline particles in suspension, by M. J. **Chaudier.** With the advice of M. Meslin, who has examined the modifications produced in ordinary light by its passage through a liquid containing crystalline particles and placed first in a magnetic field and secondly in an electric field, the author has continued the experiments with other mixtures in an electric field. A certain number of the mixtures presented a decided dichroism, which took a certain time to appear and disappear after the discontinuance of the field. The liquids which entered into the composition of the active mixtures usually contained no oxygen. No direct relation seems to exist between the chemical properties of the solid and the electrical dichroism it is able to cause when associated with a suitable liquid.—On the separation of gaseous mixtures by centrifugal force, by MM. G. **Claude** and E. **Demoussy.**—On the laws and the equations of chemical equilibrium, by M. **Aries.**—On a combination of two bodies which unite as a result of an elevation of temperature then separate below −79°, by M. D. **Gernez.**—Separation and simultaneous determination of baryta, strontia, and lime, by M. Lucien **Robin.**—On the condensation of ethers with alcohols, by M. Ch. **Moureu.**—On the composition of allyl cyanurate, by M. R. **Lespieau.**—Contribution to the study of the quinones-diketones, by M. **Œchsner de Coninck.**—Albuminoid substances in Indian corn, by MM. **Donard** and **Labbé.**—The use of a calorimetric bomb to demonstrate the presence of arsenic in the organism, by M. Gabriel **Bertrand.** With camphor or pure sugar no trace of arsenic was obtained, but a few grams of tortoise-shell, of sponge, of the white or yolk of an egg, gave clear indications of arsenic.—Influence of temperature on the production of sulphuretted hydrogen by albuminoid substances, extracts of animal organs and extracts of yeast, in the presence of sulphur, by MM. THURSDAY, AUGUST 13, 1903.

THE UNIVERSITY IN THE MODERN STATE.

V.

SINCE the earlier articles under the above heading appeared, the views we have attempted to express touching the importance of universities in the lives of States and even of Empires from a national or political, as well as from an academic point of view, have been strengthened in a remarkable manner by the inauguration of a new movement in relation to the universities of the British Empire.

The important departure to which we refer is due to the initiative of Sir Gilbert Parker, and was recently discussed at a conference in London, at which official representatives, specially approved by every one of the governing bodies of degree-conferring universities throughout the Empire, including Canada, Australia, New Zealand, and the Cape of Good Hope, as well as the home institutions, were present. By the kindness of one of the delegates we were enabled to give an account of what took place at the time. The publication of a full account of the proceedings, which has now appeared in the *Empire Review*, enables us to enter into some details.

One of the most important and interesting announcements made during the meeting, showing how much may spring from a closer union of university with other national aims, was made by Sir John Buchanan, the Vice-Chancellor and delegate of the Cape of Good Hope University, who reported that the first step to the union of the different States of South Africa had been accomplished by the Cape University, which this year, for the first time, had conducted its examinations in each of the five States of South Africa at the request of the Governments of the several States.

Now that this conference has taken place, we are in a position to gauge its importance. There is no question that a movement has been begun which is bound to go on from strength to strength; which, if the committee appointed does its work thoroughly, will bring all information bearing upon our university organisation together, and so enable a levelling up process to go on. Nothing is more distressful in English history than the way in which, since the introduction of scientific processes into modern civilisation, our schools and universities, for want of proper endowment for the new learning, have failed to provide the scientific spirit and the brain power which are now recognised as the most important weapons in a nation's armoury, and with which, to our detriment, the competing nations are now so fully equipped.

The Prime Minister in his admirable speech at the inevitable dinner left no doubt as to the origin of our present backwardness. While properly pointing out that the collective effect of our public and secondary schools upon British character cannot be overrated, he frankly acknowledged that the boys of seventeen or eighteen who have to be educated "do not care a farthing about the world they live in except in so far as it concerns the cricket-field or the football-field or the river." On this ground they are not to be taught science, and hence, when they proceed to the university, their curriculum is limited to subjects which were better taught before the modern world existed, or Galileo was born.

The first great result of the conference was the distinct recognition of the importance of arrangements for the mutual benefit of all the academic bodies in the Empire, and this complete agreement is all the more satisfactory at a time when the question of fiscal arrangements is dividing the country into two hostile camps. Again, the absence of such academic arrangements at present was shown to be detrimental. Unlike the fiscal problem, therefore, on the proper discussion of which much time may be spent, the university problem may be tackled at once, and we need not delay to profit by any benefits it may bring.

The resolutions passed at the conference were as follows:—(1) In the opinion of this conference it is desirable that such relations between the principal teaching universities of the Empire should be established as will secure that special or local advantages for study, and in particular for post-graduate study and research, should be made as accessible as possible to students from all parts of the Empire. (2) That a council consisting in part of representatives of British and colonial universities be appointed to promote the objects set out in the previous resolution, and that the following persons be appointed a committee to arrange for the constitution of the council:—Lord Kelvin, Lord Strathcona, Mr. Bryce, M.P., Mr. Haldane, M.P., Sir William Huggins, Sir Michael Foster, M.P., Sir Oliver Lodge, Sir A. Rücker, the Rev. Dr. Mahaffy, the president of Magdalen College, Oxford, the president of Queens' College, Cambridge, the Hon. W. P. Reeves, and Sir Gilbert Parker, M.P.

One of the most important matters raised in connection with the first resolution was the value of the education imparted in the British universities in relation to those of other countries. Sir John Buchanan told the conference that they were endeavouring at the Cape to send their best graduates abroad for further training, "and it was much to be regretted that at present those students could not always get what they sought for in the mother country."

In the United States, where the university system is more complete and far better endowed than with us, the students who wish to go afield for further study do not come to Britain, they go to Germany or France, and before we can expect colonial students to come to the mother country exclusively, our university system will require to be brought up to date, which can only happen when many millions are available for proper endowments, in other words, when the principle of State endowment already accepted has been effectively acted upon.

If one effect of the conference is to bring this home to the minds of those who have to deal with such matters, it will have already accomplished an important work when as great freedom and facility for study and research can be obtained within the King's dominions as are available elsewhere.

That the facilities referred to by the colonial university authorities included ample means for the prosecution of original research was made perfectly

clear, and to this part of the inquiry Prof. Ewing contributed a most important statement as to the educational value of research as demonstrated by his experience at Cambridge. We may hope that at least after thirty years' debate this matter can be considered settled. In the language of our correspondent, "Since Germany has given to our disadvantage a definite experimental proof of the success of research as an instrument of education, the delegates probably felt that the matter had gone beyond the range of academic discussion."

When once this idea of the proper function of universities is re-established and in full operation, not only at Oxford and Cambridge, but in many other British universities, it may happen that not everybody will agree with Mr. Balfour's comparisons between the old and the new seats of learning.

"I daresay that many of us have looked back with a certain regret, and a certain feeling of shame, to the medieval passion for learning without fee and without reward—with no desire to make the universities stepping-stones to good places or to successful mercantile or industrial undertakings—but with an ideal which made thousands of students from every country in Europe undergo hardships which would be regarded in these softer days as absolutely intolerable, for the sole purpose of seeking, and it might be finding, the great secret of knowledge. We despise, and we perhaps rightly despise, their methods. We know that they were not in touch with the actual realities of the world in which they lived. Yet, after all, we have something to learn from them; and if we in these days could imitate their disinterested passion for knowing and for extending the bounds of knowledge, surely we, with our better methods, and our clearer appreciation of what we can know and what we cannot know, might accomplish things as yet undreamed of. Now, what did they do? They moved from university to university, from Oxford to Paris, from Paris to Padua, from country to country, in order that they might sit at the feet of some great master of learning, some great teacher who might lead their thoughts into undreamed of paths. I hope that in the universities of the future every great teacher will attract to himself from other universities students who may catch his spirit—young men who may be guided by him in the paths of scientific fame; men who may come to him from north or from south."

We agree as to the facts as to the past, but it is not the carelessness and greed of the modern student that are in question, but rather the decadence of our universities, which are no longer seats of learning in the old sense, that is, they do not supply the knowledge most useful to those who attend them in relation to the needs of the time. They are chiefly conducted as playgrounds for the sons of the rich, learning is too little endowed, and great teachers are too little encouraged, especially in the matters in which the modern world is concerned.

If only students of science found at our universities of to-day what students of theology, law, medicine, and *les trois langues*, found in the old time at all universities, that is, perfect teaching, and the endowment of research at the university itself, things might be righted, and, as of old, many fitted for the battle of life would go out into the world to apply their knowledge as did their forerunners, and show neither more nor less "disinterested passion" than the well paid ecclesiastics, lawyers, and doctors of the past.

It is because the universities of Germany, France, and the United States, aided by wisdom and endowments, conform to the old ideal, while our ancient ones remain as *hauts lycées*, as Matthew Arnold called them, and our modern ones are crippled for want of funds, that the students of both Britain and Greater Britain find an advantage in going abroad to build up their brain power.

It is to be hoped that as a result of the conference the educational federation of the Empire will some day be brought about. It must not be forgotten that the first step in this direction was taken when the Royal Commissioners for the Exhibition of 1851 founded its research scholarships, in which every university in the Empire has a share—a share which it has fully used, and with the best effects. That other similar scholarships should be founded by the different Governments and private individuals may be one of the results of the conference.

Our plea for better brain power for the nation was not lost sight of in the deliberations, and we may fitly conclude by the following quotation from a speech by Mr. Haldane, which brought the discussion to a close.

"To-day we are a step further on towards doing that which, as a people, as the great English-speaking people, we need more than anything else. We have got the splendid energy of our race, we have got the power which is ours, in a unique degree, of adapting ourselves to new conditions, of overcoming difficulties which to others might even seem to be insurmountable, and yet we have been deficient in the capacity of organisation. What we have lacked in this country, somehow, has been the thinking faculty, and it is the work of education to develop the thinking faculty in a nation. And never before was the thinking faculty so much needed as to-day when the weapons which science places in the hands of those who engage in great rivalries of commerce leave those who are without them, however brave, as badly off as were the dervishes of Omdurman against the Maxims of Lord Kitchener."

THE SPECTROSCOPE IN ASTRONOMY.

Problems in Astrophysics. By Agnes M. Clerke Pp. xvi+567. (London: A. and C. Black, 1903.) Price 20s. net.

THE triple alliance of astronomy, physics and chemistry has extended the boundaries of each in unexpected directions. Astronomy is no longer a dependency of mathematics, but an independent power having a high place in the hierarchy of the physical sciences; instruments of research in physics have been turned from earth to sky, and chemistry now looks to the stars for evidence as to the distribution and ultimate structure of the elements.

The spectroscope is the chief means by which these new territories have been gained for science and explored, and the photographic plate has not only been its faithful scribe, but has also gained distinction as an astronomical artist. Individually and jointly, the prism and the camera have increased our knowledge of the nature and number of all classes of celestial

objects. The general study of the solar spectrum has given way to investigations of the sun in detail; and spectrum analysis now not only reveals the constitution of the stars, but measures their movements with an exactitude impossible by any other means. The light of nebulæ has been shown to be but the manifestation of molar activity having a vastly greater sphere of influence than that suggested by the visible limits; and nebulæ themselves, from being regarded as a peculiar class of celestial bodies, have been linked to stars and shown to be the amœbæ in a scheme of inorganic evolution.

The story of this development is related by Miss Clerke in the exuberant style with which all readers of astronomical literature are familiar. The first part of her book, occupying about one-third of the whole, is devoted to the sun, and the remainder to sidereal physics. Among the subjects of chapters in the former part are peculiarities of the solar spectrum, the reversing layer, the spectrum of sun-spots, the chromospheric spectrum, the sun's rotation, and the solar cycle. The forty-one chapters of the second part deal with many varieties and characteristics of stars and nebulæ, the subjects including helium stars, carbon stars, the spectra of double stars, rotation of the stars, spectroscopic binaries, dark stars, star clusters, nebulous stars, variable nebulæ, the nature of nebulæ, and the physics of the Milky Way.

For the collection and analysis of contributions to the study of these and other problems in astrophysics, Miss Clerke merits the thanks of astronomers. As is the case with every branch of science in its youth, questions arise much faster than they can be answered, and it requires a fine critical faculty to separate results of transient value from those of significance to scientific progress. The historian has to decide what things matter and what may be neglected when considered from the point of view of their influence upon development; and success is achieved when this power of discernment is combined with insight which enables the relationship to be seen between cause and consequence.

With the best desire in the world to give Miss Clerke credit for her work, we must confess to a feeling that it is not altogether satisfactory. In the first place, the net which she has used in her explorations of astronomical literature is of too fine a mesh, so that she has gathered in results and ideas which ought to have been discarded as being of little value, or immature. Next, as we shall show later, she has not understood the real nature of some of the material collected; and finally, she passes judgment and gives advice on matters which can only be rightly understood by investigators actively engaged in spectroscopic work.

A man who has had a scientific training can quickly grasp the essential points of progress in any branch of natural knowledge if they are brought before his notice, but he will rarely venture on criticism of results, or lay down the lines of further research unless he has a personal and practical acquaintance with the subject. Miss Clerke does not always exercise the same caution, with the result that she sometimes labours the obvious. Her function as an historian is to assimilate and describe, and when she is exercising her talents in this direction she is at her best. She surveys the work from the point of view of the spectator, and should describe fairly and clearly what she sees, without irritating the men who are doing the work by expressing her opinion upon it or suggesting what course they ought to take next. In other words, she should remember that "Passengers are respectfully requested not to speak to the man at the wheel."

In preparing a statement of the position of fact and theory in any branch of science, great care must be exercised, and not a single assertion should be made without substantial reason for it. A cynic has said that it is a characteristic of women to make rash assertions, and in the absence of contradiction to accept them as true. Miss Clerke is apparently not free from this weakness of her sex. Referring to the line 1474 K she says (p. 117):—"Eclipse-spectrographs do not include it, while they have afforded some other quite unexpected results." An examination of spectrum photographs of the eclipses of 1893, 1896, and 1898 would have shown Miss Clerke that 1474 K is included in all of them. There are other instances in which statements of an *ex cathedra* character are made without a full appreciation of the facts. Thus, the identification of a "dozen and upwards" chromospheric lines in the spectra of krypton and xenon (p. 120) is doubtful, to say the least; and the Stonyhurst origins referred to on p. 187 in connection with the spectrum of γ Cassiopeiæ are in the same case. Again, in the table of nebular lines on p. 477, the line at λ 4122 has a note of interrogation placed after the word helium indicating its origin, though there is practically no doubt that the line is helium λ 4121. Moreover, the line λ 4715, said to be of origin "unknown," is really the helium line λ 4713.3.

It is in such matters as these that Miss Clerke shows she is not a working spectroscopist possessing an intimate acquaintance with the subjects she describes. The result is that she is led to pass unsound judgments, and to be satisfied with an imperfect record of the facts available. Thus, on p. 48, in considering the relation of the chemistry of the chromosphere to the depth she quotes a paper by Mr. S. A. Mitchell, but makes no reference to the Royal Society report on the 1893 eclipse, where a full discussion of the conditions is given. Again, for evidence of the existence of more than one gas in the solar corona reference is made (p. 131) to a paper by Mr. S. J. Brown, but a note on the discussion of the photographs of the 1898 eclipse, presented to the Royal Society and published in the *Proceedings* (vol. lxvi. p. 189), is not mentioned, though it shows that three groups of lines, indicating three gases, are recognisable in the corona spectrum.

Miss Clerke demurs to the late Prof. Rowland's conclusion that there is no fundamental difference between solar and terrestrial chemistry. "*Quantitative*, if not *qualitative*, dissimilarity must," she believes, "be recognised"; and she instances titanium among other elements which are clearly represented in the solar spectrum, and yet are scarce here. Titanium is more widely distributed than Miss Clerke supposes, but, even if it were extremely rare, her

suggestion as to the relative amounts of this and other elements existing in the sun and earth is misleading. Remembering that nothing is known of the chemical constitution of the earth a few miles below the surface, it is possible that rare elements in the crust may be abundant nearer the centre. The differences between solar chemistry as manifested by the solar spectrum, and terrestrial chemistry as represented by mineralogical knowledge, are therefore only apparent, and Rowland was justified in his remark, "were the whole earth heated to the temperature of the sun, its spectrum would probably resemble that of the sun very closely."

The distinction between spark and arc spectra is not sufficiently recognised, with the result that unsound judgments are sometimes reached. A case of this kind occurs in connection with the discussion of the chromospheric spectrum. The green line of the chromosphere is coincident with one of the members —due to iron—of the triplet known as Kirchhoff 1474 in the Fraunhofer spectrum. Miss Clerke says:—

"Now the chromospheric ray agrees in position with the iron line, which is one of secondary importance; yet it cannot at present be asserted confidently that it really emanates from glowing iron vapour. If it did it should be ordinarily associated with other iron lines, and none have been ascertained to make part of the fundamental chromospheric spectrum."

If the spark spectrum of iron had been considered instead of the arc spectrum, these remarks would, we think, have been modified. The iron line at 1474 K is not of secondary importance in the spark spectrum; indeed, the fundamental chromospheric spectrum consists largely of iron lines—not the ordinary lines of the arc spectrum, but lines such as those at $\lambda\lambda$ 1474 K, 5018, 4924, 4584, and 4233, which are enhanced in relative importance in passing from the arc to the spark.

In connection with the subject of the temperature of the stars, the behaviour of lines of magnesium at different temperatures is referred to. Other conditions being the same, the magnesium line 4352 becomes finer with increase of temperature, while that at 4481 becomes thicker, and this opposite behaviour provides a test of increasing or decreasing temperature. But it is not pointed out that the test must be applied with caution; for the line 4352 in the spectra of hot stars is not due to magnesium, but is really an enhanced line of iron. If 4352 in the hot stars were a magnesium line, then other lines of the same series ought to be present, but they are not.

The chapter on new stars is characteristic of a large part of the book. Details are given of observations of new stars from Nova Aurigæ to Nova Persei, but the record can scarcely be described as complete, and the chief lesson taught by Novæ is overlooked. Many years ago, Sir Norman Lockyer expressed the view that "new stars, whether seen in connection with nebulæ or not, are produced by the clash of meteor swarms." When this conclusion was arrived at, few precise observations of the spectra of Novæ were available, but it is not too much to say that visual and photographic inquiries made since then into the phenomena of new stars have substantiated it in a very remarkable manner. By the meteoritic hypothesis, new stars approximate to nebulæ as they fade, until their light at the last stage is indistinguishable from that of a nebula. This association of new stars with nebulæ is now an accepted fact, but the consequences have not been so clearly acknowledged. As a new star reverts to the condition of a nebula when it cools, evidently nebulæ are not masses of gas at transcendental temperatures. Just as in biology, the course of evolution is traced in the development of the embryo, so we may consider that in its brief life a new star passes in some respects through the various stages which mark the growth and decay of worlds.

The spectroscopic history of Nova Aurigæ was a surprise to astronomers, who regarded the meteoritic interpretation of the phenomena of new stars as a hypothesis of doubtful validity. For, though there might be a difference of opinion as to the meaning of the displacement of the bright and dark lines in the spectrum, there could be none on the fundamental fact that the Nova became a planetary nebula, both visually and spectroscopically, as it sank into obscurity; and this course of events was precisely that previously found to have been exhibited by new stars which had been subjected to spectroscopic analysis. Rarely has hypothesis received such decided confirmation, but Miss Clerke does not even mention the paper in which it is put forward. The history of several new stars is concluded with words to the effect that "the regular cycle had been run through: a planetary nebula replaced the faded star," but there is no reference to the analysis of spectroscopic records before Nova Aurigæ, which showed that the reversion to a nebular type is a common characteristic of new stars.

The case of Nova Persei is of even greater significance from the point of view of cosmogony than that of Nova Aurigæ, for its light revealed the existence of vast areas of dark matter in interstellar space. Miss Clerke describes the vicissitudes through which the object passed, and the apparent expansion of the nebula associated with it. With regard to this phenomenon we read:—

"An explanatory hypothesis of considerable plausibility was hit off independently by Prof. Kapteyn and Mr. W. E. Wilson.[1] It affirms the nebula to have been pre-existent, and to remain unchanged. But since we see it by the unchanged light of the Nova, its various spires and condensations have come successively into view as the flare of the explosion travelled outward in widening circles. Hence an illusory effect of radial expansion was produced, while in point of fact, the temporarily illuminated cosmic folds were as immovable as aligned snow-peaks, in turn set aglow by the setting sun."

In other words, cosmic dust, or meteoritic particles, or dark nebular matter—whatever you care to term it—existed in the part of space in which the new star made its appearance. The fundamental idea of the meteoritic hypothesis is here accepted, and its application to the phenomena of new stars acknowledged. Astronomers have, in fact, been driven to the belief in the existence of sheets or streams of non-luminous matter in space; and dark nebulæ, as Prof. Turner has termed them in an article in the *Fortnightly*

[1] NATURE, January 30, 1902.

Review, are no longer considered hypothetical, but as real as dark stars.

A new class of celestial bodies has thus been brought under notice, and Miss Clerke does not sufficiently appreciate its significance. This, however, is a matter of opinion, but surely for the sake of historical completeness she might have mentioned that the association of nebulæ with new stars was first put forward in the meteoritic hypothesis. She is careful to give credit in most cases, but in connection with Nova Persei no reference is made to the fact that Sir Norman Lockyer first suggested in these columns that the dark nebula existed before the star appeared. In the issue of December 12, 1901, he wrote:—

"It is impossible to think that the great nebula which has now been photographed while the new star is still in being did not exist there a few months ago; and it is important, further, to remark that the nebulous matter already photographed in the region round the Nova is very probably only a portion of the actual amount of matter existing there, and that if the disturbances continue, more of the remaining portion may become visible."

Here we have a definite statement of the pre-existence of the dark cosmic matter in the neighbourhood of Nova Persei before the new star became visible, but it has been overlooked by Miss Clerke. This is to be regretted because, a few years hence, astronomers will be just as interested in knowing how the idea of dark nebulæ passed from hypothesis to demonstration as we are in Bessel's discernment of the existence of dark companions of Sirius and Procyon before these bodies came within the sphere of astronomical discovery.

One other point connected with Novæ is worth mention. In the description of the spectrum of Nova Aurigæ it is stated that "an exceptional feature was the predominance of 'green' helium; D_3 and the rest of the lines belonging to the 'yellow' set were comparatively faint; while λ 4922, λ 5016 and their fundamental λ 6678, shone lustrously." An unnecessary difficulty is raised in the attempt to account for the appearance of these lines in the Nova spectrum; for the first two lines mentioned were really not due to helium, but were enhanced lines of iron at λ 4924 and λ 5018. This identification does not rest solely upon these two lines, for other enhanced lines of iron appeared in the spectrum of the Nova.

Other details upon which there are differences of opinion might be mentioned, but no useful purpose would be served by doing so. In directing attention to the various points referred to in the foregoing remarks, the object has been to show that, though Miss Clerke writes with exceptional facility and grace, she is not an infallible guide, and has a tendency to works of supererogation. Notwithstanding this, we do not hesitate to say that, by writing the record of astrophysics, she has done a great service to astronomers. Her book makes it possible to obtain a view of the chief fields in which astronomical inquiries are now being carried on, and of the achievements which have been reached. To readers interested in the progress of knowledge relating to the sun, stars and nebulæ, whether they are laymen, or men of science so deeply engrossed in other investigations that they have not been able to keep in touch with astronomy, the book will be a revelation. Those who are engaged in the work of astrophysics will be saved many hours of tedious research among scientific books and papers by this chapter from the history of science.

R. A. GREGORY.

THE GERMINAL LAYERS OF THE VERTEBRATA.

Furchung und Keimblattbildung bei Tarsius Spectrum. By A. A. W. Hubrecht. Pp. 115 + plates. (Amsterdam: Müller, 1902.)

EMBRYOLOGISTS will certainly unite to congratulate Prof. Hubrecht on the completion of this memoir. To have obtained and figured a complete series of developmental stages of any animal is in itself no mean achievement, but when this animal is one of the rarest of mammals, procurable only in a distant quarter of the globe, we may well wonder at the persevering patience which has succeeded in overcoming difficulties which, to an ordinary worker, would have been insurmountable.

Tarsius has always been regarded as a member, though a very aberrant member, of the Lemuroidea. The embryological evidence which has now been brought before us is practically conclusive in favour of its removal from this suborder. The placentation is most pronouncedly of the so-called "deciduate" type, while the arrangement of the fœtal membranes, with the diminutive yolk-sac, rudimentary allantois, and large extra-embryonic cœlomic space, is identical with that found in man and monkeys, but nowhere else.

The placenta, and the important changes leading to the formation of the "Bauchstiel"—so long a puzzle to human embryologists—have already been the subjects of two publications by Prof. Hubrecht. In the present treatise we are introduced to the processes of maturation, fertilisation, segmentation, the histology of the formation of the amnion, and, above all, to the germinal layers.

First to appear are the above-mentioned extra-embryonic cœlom and the yolk-sac. The material for the former springs from the posterior end of the blastoderm. In continuity with it is formed the primitive streak in the centre of which is the rudimentary blastopore or neurenteric canal. The mesoblast, however, is also formed from an anterior tract of hypoblast (as frequently in Amniotes) and from a peripheral ring (as described by the author in Sorex).

These facts, admirably illustrated by a very complete set of figures, form the basis for some very bold speculations. The germ layers of the Vertebrata have proved a stumbling-block to many an embryologist. The solution of the problem here proposed (due originally to van Beneden, and first expounded in Oxford) is one which cuts all the old ground from under our feet. We are taken back, not to Amphioxus, or even to an Annelid, but to a Cœlenterate, and asked to see in the gastrovascular cavity and stomodæum of this, the latest ancestor of all the Vertebrates, the forerunners of the blastopore and notochord respectively Such a theory involves the assumption that the

archenteron communicates with the segmentation cavity in all Anamnia, which is hardly the case; on the other hand, it seems to get over the difficulty of deriving the conditions found in the Amniotes from those observed in lower forms.

We imagine, however, that few morphologists will accept so imaginative an hypothesis. It is not difficult to explain the differences between these two great divisions of the Vertebrates more logically by reference to the Gymnophiona. But putting that aside, it is open to grave doubt whether it is possible to attach any phylogenetic significance, any morphological value in the determination of homologies, to the germ-layers of the Vertebrates, or, indeed, of any other group. Their significance is rather physiological, and can only be analysed by the ordinary physiological methods of observation and experiment.

PSYCHOLOGICAL STUDIES.

Harvard Psychological Studies. Vol. i. Edited by Hugo Münsterberg. Pp. 654. (New York: The Macmillan Company, 1903.)

THIS, the fourth volume of monograph supplements to the *Psychological Review*, consists of sixteen papers by the students of the Harvard School of Psychology, fifteen of which represent the principal results of the work done in the laboratory in the last few years. Most of the papers show, properly enough, the influence of Prof. Münsterberg's vigorous and original mind, and it is no doubt owing in part to his teaching and direction that each of the researches deals with a well-defined problem by appropriate and original methods. But the individual workers have preserved their independence, and the standard of treatment and achievement reached is in all cases a high one.

Of six studies in perception, Mr. Holt's explanation of the bands seen on passing a rod across the surface of a rapidly rotating disc bearing coloured, or black and white, sectors, is an admirable example of neat and convincing experiment. Of three studies in memory, those of Messrs. Meakin and Moore are interesting as achieving valuable results by systematically conducted introspective observation of the primary memory-image. Even the "purest" and most old-fashioned psychologist could hardly raise objection to their procedure. Their results suggest that much valuable knowledge is to be gained by those who have the patience to follow up this line of research, but the absence of all objective control of the results makes the method a dangerous one, unless subjects innocent of psychological theory can be found to carry out the introspective observations.

Of four studies in æsthetic processes, the principal are elaborate and ingenious researches on the constitution of objective rhythm-forms and on symmetry. In the case of the latter, the experimental conclusions are supported by analyses of pictorial compositions ranging from the ornamental designs of primitive people to the altar-pieces of Raphael. In two studies in animal psychology, Mr. Yerkes breaks new ground by registering accurately the reaction-times of the leg of the green frog in response to a variety of stimuli, and he shows that the frog and the crayfish are alike capable of learning by experience, of acquiring new associations, though but slowly; he thus refutes the view that they are but unconscious automata, a view that has been based on the belief that they are devoid of such capacity.

The volume is completed by a short paper in which Prof. Münsterberg briefly restates the main conclusions reached in his "Grundzüge der Psychologie" (Leipzig, 1900). He claims that under the term psychology two fundamentally different sciences are commonly confused together; the one treats of "the inner life as objective content of consciousness, as phenomenon, the other of the inner life as subjective attitude, as purpose." The former science is descriptive and explanatory, those who pursue it are "phenomenalists"; the psychical objects with which they deal are abstractions, comparable to the physical objects dealt with by the physicist. The other science, improperly called psychology, is "voluntarism"; it is teleological and interpretative, but not explanatory, it includes the normative and historical sciences, and gives "a more direct account of man's real life than psychology can hope to give." These remarks prepare the way for a comprehensive tabular classification of all the sciences, which, whether it be found acceptable or no, is certainly novel and extremely interesting.

W. McD.

OUR BOOK SHELF.

A Gloucestershire Wild Garden. By the Curator. Pp. xii+230. (London: Elliot Stock, 1903.) Price 6s. net.

GARDENING books are becoming noted for containing a small amount of gardening information largely diluted with something that has little or no relevance to horticultural pursuits. The diluting medium may be cookery or hygiene, tirades against vivisection, stale jokes, spiritualism, anything, in fact. In the present book gardening, or one phase of it, represents the slices of bread between which are inserted, sandwich-fashion, dissertations on the molecular structure of the brain and nerve centres, and discussions on the origin of thought and the nature of religious impressions.

The "Curator" is the gardener who evidently knows plants and loves them. To him appear when he is tired of work, or, at any rate, without preface or apology, a somewhat prosy "Professor," who supplies the anatomical details above mentioned, and explains them from the materialistic standpoint, and an orthodox "Padre," who is somewhat shocked at the views propounded by the professor. The Curator acts as moderator, and when discussion seems likely to become dangerous, suggests a pipe of tobacco or a cup of tea as effectual "shunters." At any rate, we pass abruptly from metaphysical subtleties either to the tea-table or to another chapter, in which we are told how to construct a "wild" garden. As if all this were not enough, a love story—a very short one—is introduced, and so the book has one quality which a garden should possess, and that is, variety.

The author tells us that he does not write for critics, but we hope he will not mind our saying that the gardening part of his book is on a higher level than that to which we are accustomed in similar books, and as for the remainder, we should prefer in this Journal not to express any opinion, but to leave the reader to form his own conclusions.

Geographen-Kalender. In Verbindung mit Dr. Wilhelm Blankenburg, Prof. Paul Langhans, Prof. Paul Lehmann, und Hugo Wichmann, herausgegeben von Dr. Hermann Haack. Erster Jahrgang, 1903–1904. (Gotha: Justus Perthes, 1903.)

THIS is the first issue of what is likely to prove an indispensable work of reference to geographers of all nationalities, as it gives in a compact form a mass of information on the yearly progress of geographical science in all its branches, besides containing much information of a statistical kind which will be of use to the general public no less than to the expert. Although, perhaps, as is but natural, the greatest amount of attention is given to German work, the book possesses a decidedly international character, account being taken of the most important work done by geographers throughout the world. A set of general tables, &c., for purposes of reference is followed by sections on the main events of the year with a bearing on political geography, on the progress of exploration, the geographical literature of the year, and so on.

A striking feature is the attention paid, in a special section from the pen of the general editor, to the progress of geographical education, though in this, more than any other section, the attention is focused on German work, hardly anything being said as to the steps lately taken in other countries to improve the position of geography in the school and college curriculum. Thus, when speaking of periodical publications devoted to this object, Dr. Haack makes no mention of the *Journal of Geography*, published in the United States, or of the *Geographical Teacher*, the organ of the Geographical Association in this country. From a purely practical point of view, a most useful section is the very complete "Adressbuch," which gives the names and addresses of geographers of all nationalities, with a brief statement of their special lines of study or research. The little book, which is most tastefully got up, concludes with an excellent series of maps illustrating the principal geographical events of the past year.

Biological Laboratory Methods. By P. H. Mell, Ph.D., Director of Alabama Experiment Station, Professor of Geology and Botany, Alabama Polytechnic Institute. Pp. xii+321; 127 figs. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1902.) Price 6*s*. 6*d*. net.

THIS is a well-conceived and eminently useful book, which within convenient compass and in clear language gives an account of microscope and microtome, staining and mounting methods, photomicrographs, and so on. It begins at the beginning, and expounds with simple accuracy the various instruments and methods of the well-equipped biological laboratory. After describing the microscope and the microtome and their accessories, the author discusses, in successive chapters, fixing, imbedding, staining, mounting, and drawing. Five chapters are devoted to photomicrography, and others follow on bacteriological methods, special methods (*e.g.* decalcification, injection, maceration and polarisation). The book ends with useful formulæ and tables, and with an appendix on laboratory furniture. We have tested the book as to various points, and have found it practical and lucid in every case. It is in part a compilation of hundreds of duly acknowledged useful hints and recipes from workers all over the world, but it also expresses the work of one who has faced detailed difficulties in actual practice and overcome them. We have come across many illustrations of American neatness and ingenuity which were fresh to us, and we confidently recommend the book as a worthy companion to Bolles-Lee's *vade mecum* and similar works.

Ijain; or, the Evolution of a Mind. Pp. ix + 207. *Isola; or, the Disinherited.* Pp. xv + 153. By Lady Florence Dixie. (London: The Leadenhall Press, Ltd.)

THESE are youthful productions of a versatile writer, whose object is to spread the truth about everything at whatever cost. "Ijain" traces the development of the mind of an unusually thoughtful child, and "Isola" is a drama, the object of which is to secure greater freedom and fuller opportunities of work for women.

LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Radio-active Gas from Bath Mineral Waters.

PROF. J. J. THOMSON has shown that the air extracted from Cambridge tap-water and from the waters of certain deep-level springs is mixed with a radio-active gas (NATURE, vol. lxviii. p. 90). It appeared of special interest to determine whether such a constituent existed in the hot mineral springs of Bath. Samples of water direct from the King's Bath Spring have been examined at the Blythswood Laboratory, and have been shown to contain a radio-active gas in solution. In the first experiments the gas was expelled from a flask containing a litre and a half of water by boiling under a pressure of about half an atmosphere. The amount of gas obtained after passing through a number of drying tubes was small, as was shown by the fact that the pressure only altered by a few centimetres. Yet this was sufficient to produce a marked increase in the ionisation in the testing vessel. The gas was also extracted from the water by exhausting the testing vessel and allowing a current of air to bubble through the water and a series of drying tubes into the vessel. In this case the ionisation current increased from four to five times.

Whichever method was employed for introducing the gas into the testing vessel, it was found that the effect did not assume its full value instantaneously, but gradually increased to a maximum and then diminished. The activity reached a maximum in rather more than one hour after the admission of the gas. About half an hour later the activity had diminished to one-half the maximum value. Rutherford (*Phil. Mag.*, v. p. 448, 1903) has observed a similar effect when the emanation from radium is introduced into a closed space. In this case the maximum activity is reached after five or six hours, and the activity decays to half value in 3·71 days. The gas from the Cambridge water lost from 5 to 10 per cent. of its activity in twenty-four hours. The gas from the Bath water appears to be intermediate in character between the radium emanation and the Cambridge gas on the one hand, and the thorium emanation on the other. The activity of the thorium emanation diminishes to one-half in one minute.

If the therapeutic action of the Bath waters is due in any degree to the radio-activity of the gases contained in them, the fact that the activity of the gas now being investigated begins to decrease so soon after the gas has been liberated acquires special significance. The opinion is commonly held that the waters of various spas possess greater efficacy when used on the spot. It is probable that this opinion, though doubtless fostered by interested individuals, has some basis in fact, and it is possible that the underlying fact may here find an explanation.

Prof. Dewar has shown that the Bath waters contain helium. The presence of a radio-active and of an inert gas in the same water is of interest from the point of view of the possible transmutation of such elements.

Blythswood Laboratory, Renfrew. H. S. ALLEN.

THE SOUTHPORT MEETING OF THE BRITISH ASSOCIATION.

SINCE the publication of the first article on the approaching meeting of the British Association (July 9, p. 224), the following additional arrangements have been made :—

Sir George Pilkington will give a garden party to 100 members at his residence, Belle Vue, Southport, on Monday, September 14. Mr. William Vernon will give a garden party to 100 members at Wyborne Gate, Birkdale, on Tuesday, September 15.

An exhibition of meteorological and magnetic instruments, diagrams, books, &c., will be held in the laboratory and lower corridor of the Science and Art Schools, immediately adjoining the reception room. The exhibition, owing to the presence of the International Meteorological Committee in Southport, is likely to be of unusual interest. Exhibits are promised by the Royal Observatory, Greenwich; the Solar Physics Observatory; the Meteorological Office; Kew Observatory; the Scottish Meteorological Society; the Royal Meteorological Society; Captain Wilson-Barker; the Scientific Instrument Co., Cambridge; Mr. W. H. Dines; Prof. Pernter; Dr. A. L. Rotch; Captain Creak; Dr. Mill; the Radcliffe Observatory, Oxford; Mr. C. T. R. Wilson; Mr. J. Aitken; Mr. Joseph Baxendell; and Mr. Halliwell.

A loan museum of objects of local scientific and archæological interest is being organised.

The printing of the "Handbook" is now complete. The contents are as follows:—(1) "Southport: Historical and Descriptive"; (2) "Southport as a Health Resort," by Dr. J. J. Weaver and Dr. A. V. Wheeler; (3) "The Meteorology of the Southport District," by Joseph Baxendell; (4) "The Geology of the Southport District," by Harold Brodrick and Edmund Dickson—(a) "The Ribble Estuary," by Edmund Dickson; (5) "The Botany of the District," by W. H. Stansfield and Henry Ball—(a) "A note on *Hypopitys Monotropa*," by Henry Ball, (b) "The Mosses of the District," by J. A. Wheldon, (c) "The Hepaticæ of the District," by J. A. Wheldon; (6) Zoology—(a) "Protozoa-Foraminifera," by Dr. G. W. Chaster, (b) "Lepidoptera," by F. N. Pierce and J. R. Charnley, (c) "Coleoptera," by Dr. G. W. Chaster and E. J. Burgess Sopp, (d) "Araneæ," by Dr. A. R. Jackson, (e) "Mollusca," by Dr. G. W. Chaster, (f) "Marine Fauna and Fisheries," by Prof. W. A. Herdman, F.R.S., and Isaac C. Thompson, (g) "A Note on the Vertebrate Fauna of the District"; (7) "Martin Mere and its Antiquities," by Harold Brodrick; (8) "Archæology," by Willis Brunt; (9) "Sketch of the Life and Works of the Rev. Jeremiah Horrocks," by G. Napier Clark.

The Cambridge Scientific Instrument Company will fix a Callendar temperature recorder in the reception room, the instrument being connected electrically with a thermometer suitably exposed to the air outside the building.

The committee of the British Association appointed at Belfast for the investigation of the upper atmosphere by means of kites will, if possible, show the working of the kite apparatus during the meeting of the Association at Southport, in illustration of the experiments carried out by Mr. W. H. Dines, under the auspices of the Royal Meteorological Society and of the British Association, with the aid of grants of money from the Association and from the Government Grant Committee of the Royal Society. The committee hoped to have the advantage of the services of an Admiralty vessel for a sufficient period to include the meeting at Southport, for, in compliance with the request of the Royal Society, the Lords Commissioners were good enough to assign a vessel for the experiments, but unfortunately she met with an accident at Devonport and sank in the harbour. She is consequently not available. The local committee of the British Association is trying to assist the committee to obtain a steamer for the purpose of carrying out the experiments at Southport.

The title of Dr. J. S. Flett's lecture to working men on Saturday, September 12, is "Martinique and St. Vincent: the Eruptions of 1902," with lantern illustrations.

The railway companies, as before stated, will issue tickets to Southport available from September 8 to 18 inclusive, but in the case of the Irish railways the tickets will be available from September 7 to 19 inclusive. The committees of the principal clubs have agreed to extend the privilege of honorary membership to non-resident members of the Association during the week of the meeting.

The Saturday afternoon excursion to Hoole and Rufford will take the form of a motor-car run. More than twenty cars have been placed at the disposal of the committee by their owners, and it is hoped that this excursion will be a popular one. Tea will be served at Rufford Old Hall. The excursion to the Wirral Peninsula is specially intended for geologists and botanists, and geological and botanical parties will be formed in connection with the Windermere excursion.

A specially prepared plan of the town in colours will be inserted in the local programme, and a plan of the Municipal Buildings, where most of the meetings of the Association will be held, will also be included.

A list of those members who had intimated their intention of being present at the meeting up to July 14 has been printed, and can be obtained at the local office. The following names of foreign and American corresponding members, and members of the International Meteorological Committee, are included in the list:—Prof. G. S. Atkinson, Cornell University, U.S.A.; Dr. Von. Bebber, Hamburg; Dr. R. Billwiller, Zurich; Prof. Ludwig Boltzmann, Vienna; M. Teisserenc de Bort, Paris; Captain Chaves, St. Miguel, Azores; Mr. W. Davis, Cordoba, Argentine; Prof. G. Gilron, Louvain; M. A. Gobert, Brussels; the Comte A. de Gramont, Paris; Prof. Hellman, Berlin; Prof. H. Hergesell, Strassburg; Prof. H. H. Hildebrandsson, Upsala; Prof. Lignier, Caen; Prof. C. Lombroso, Turin; Dr. T. P. Lotzy, Leyden; Mr. G. G. MacCurdy, Newhaven, Conn., U.S.A.; Prof. E. Mascart, Paris; Prof. H. Mohn, Christiania; Prof. Willis Moore, Washington, U.S.A.; Prof. Simon Newcomb, Washington, U.S.A.; Prof. L. Palazzo, Rome; Prof. Paulsen, Copenhagen; Prof. J. M. Pernter, Vienna; Dr. A. L. Rotch, Blue Hill Observatory, Mass., U.S.A.; General Rykatcheff, St. Petersburg; Prof. M. Snellen, Utrecht; Prof. R. H. Thurston, Cornell University, U.S.A.; Dr. H. C. White, University of Georgia, U.S.A.; Prof. E. Zacharias, Hamburg.

The Mayor of Southport (Mr. T. T. L. Scarisbrick) has issued more than a hundred invitations to members of the Association and to distinguished foreigners who will be present in Southport to a dinner at his residence, Greaves Hall, Banks, on Wednesday, September 16, to meet Sir Norman Lockyer, president of the British Association, and Prof. E. Mascart, president of the International Meteorological Committee.

The Southport Literary and Philosophical Society, which was responsible for the preliminary negotiations which resulted in the holding of this year's meeting of the Association at Southport, has arranged to hold the opening meeting of its winter session on Thursday, September 17. On this occasion Prof. A. R.

Forsyth, F.R.S., has consented to deliver an address on "Universities: their Aims, Duties, and Ideals." Invitations have been issued to many members of the British Association, as well as to others interested in educational work.

THE CENTENARY OF HEIDELBERG UNIVERSITY.

ON August 5–8 the University of Heidelberg celebrated the centenary of its re-establishment. The university, one of the oldest universities of the modern world, was originally founded in 1386 by the Palsgrave Ruprecht I. of the Palatinate. At that time Heidelberg was the seat of the princely residence and capital of this wealthy State of the middle ages, and the young university did good work from the point of view of those times. The "German Medici," Otto Heinrich (1556), delivered the university from the chains of scholastic pedantry and inspired in her the ideas of the Renaissance and of the Reformation. The thirty years' war had a disastrous effect on this town and its university, as, indeed, it had on all Germany; nevertheless, the Elector, Karl Ludwig (1650), again gave it a short period of prosperity. But with the year 1685 commenced for the Palatinate and the university a long period of sorrow and loss.

Soon the positions held by broad-minded inquirers and teachers were occupied by imperfectly educated members of Catholic Orders, and the university sank to a mere confessional school. Scientific research degenerated into the school-divinity of the middle ages, appointments were given by those in control to their relatives, and very strict tests in matters of faith were imposed.

The result was that, during the eighteenth century, scarcely any work of scientific value was done by the university, and the number of students sank to a minimum. The condition of affairs was made still worse by the loss of the income hitherto derived from the possessions on the other side of the Rhine, which were then in the hands of the French.

Though the Bavarian Prince, into whose hands Heidelberg had fallen in 1799, commenced to break the dominion of the monks, and though he sought to procure new incomes for the impoverished university, her renovation was really the work of the Badish Prince, Carl Friedrich.

By the division of Germany in 1803, Heidelberg came into the possession of the Elector, Carl Friedrich, who later became the Grand Duke of Baden. Without delay, he commenced to re-establish the Heidelberg University, to give to her a broad constitution resting on high ideals, and last, but not least, to procure the necessary money.

He endowed the university with an annual sum of 50,000 florins, which had to be raised by the State. He reserved to himself the office of "Rector" of the university, a charge which since that time has rested in the hands of the Grand Dukes. The essential principle of the reorganisation is to be found in the rule that "the professors' chairs shall be filled by the most worthy competitors, without any consideration of their religion."

The names of the first professors of that time are still well known. I only recall the names of the theologians Daub, De Wette, Paulus, the jurists Thibault and Zachariae, the physician Naegele, and the philosophers T. H. Voss, Creuzer, and Bökh. It is the centenary of this reorganisation that the university has just now celebrated.

Indeed, what these beginnings promised, the nineteenth century has seen fulfilled, and the university has taken her place among the foremost of the world. Excellent scientific laboratories, observatories, and hospitals have been built, a monumental library-building is in the process of construction, and the first modest annual endowment of 50,000 florins has grown to one of 800,000 marks, to which has been added a regular special grant, amounting in the budget of 1902–03 to almost exactly a million of marks, so that at the present time about 65,000 pounds sterling are expended annually upon the university.

If one remembers that Baden has about two millions of inhabitants, and that it possesses not only one, but three universities (Heidelberg, Freiburg, and the Karlsruhe Polytechnicum), it must be confessed that a great work has been accomplished. The number of professors and *docents* of the Heidelberg University is now 151, that of students 1884.

The work of the university during the nineteenth century has received the acknowledgment of educated men all over the world. The development of the history of Christianity is connected with the Heidelberg names, Hitzig, Ulmann, Rothe, Schenkel, and Holsten; lawyers and political economists appreciate fully the influence of Vangerow, Windscheid, Bluntschli, Mittermaier, Renaud, and Knies; physicians will remember the names of Chelius, Pfeuffer, Arnold, and Gegenbaur. The names of the philosophers Hegel and Zeller are known far and wide. Well known, too, are the philologists Koechly, Ribbeck, Wachsmuth, Zaugemeister, and Bartsch, and the historians Schlosser, Häusser, Gervinus, and Treitschke. The mathematicians Hesse and Fuchs, and the leaders in natural science, Hofmeister, Kekulé, Kopp, and above all, Bunsen, Kirchhoff and Helmholtz, have spread the glory of Heidelberg over the world.

The greatest credit for the success of the Heidelberg University in the past century must be attributed to the Grand Duke Friedrich, now seventy-six years old, who—during the fifty-one years in which he has been Rector—has made the university what she is to-day.

In the evening of August 5 the students formed a torch-light procession in honour of the Grand Duke. The next morning, after a festival divine service, the Actus was held in the Aula of the university, where the Grand Duke, the Minister, the deputations of other universities and corporations, and the acting Prorector of the university (Prof. Czerny) delivered addresses. After a banquet a reception was given by the city in the poetical ruins of the celebrated Heidelberg Castle.

On August 7 the historian of the university (Prof. Marks) gave a historical address, concerning the development of the scientific life of the university during the past century. In the evening the students held their great "Commers."

The announcement of the *honoris causa doctores* took place next morning. In the branch of medicine the following men of science were elected:—M. T. H. Dunant, Geneva; Prof. Sv. Arrhenius, Stockholm; Sir W. Ramsay, London; Prof. P. Lenard, Kiel; G. Schweinfurth, Riga; G. Moynier, Geneva.

In the branch of natural science the following were elected:—Mathematics, M. G. Darboux, Paris; physics, Dr. R. T. Glazebrook, London; astrophysics, Sir William Huggins, London; chemistry, Prof. S. Cannizzaro, Rome; mineralogy, Prof. F. Fouqué, Paris; astronomy, Prof. E. C. Pickering, Cambridge, U.S.A.; zoology, Prof. E. Maupas, Algiers; botany, A. Cogniaux, Nivelles.

In the evening of August 8 a reception was given by the Grand Duke and the Grand Duchess at their castle in Schwetzingen. Sunday, August 9, was devoted to excursions in the neighbourhood, and at night an illumination of the castle, and a great display of fireworks on the Neckar, brought the festivities to a close.

The present generation has expressed by these splendid meetings that it appreciates highly the benefit

resulting from the reorganisation of the university by Carl Friedrich, and the work done by the scientific men of past generations, and has indicated how it hopes that, in the century just begun, the development will not cease but continue, that new successes will be achieved by the more and more unrestrained unfolding of all intellectual forces, and that these successes may help to brighten the minds of the people, and to connect them more and more by the bridges of science, notwithstanding political boundaries. M. W.

BRITISH MEDICAL ASSOCIATION SWANSEA MEETING.

THE seventy-first annual meeting of the British Medical Association was concluded at Swansea on July 31. It will be remembered that last year the meeting was held at Manchester, and although as was *a priori* to be expected the numbers at Swansea fell short of those at Manchester, yet nevertheless the meeting will always live in the memory of those who attended it as an unqualified success.

The president this year was Dr. Griffiths, of Swansea, and in an excellent opening address he touched upon many points of interest and importance both to the profession and to the public. Not the least interesting of these to the readers of NATURE was the president's reference to the much discussed question of hospitals for paying patients. Sooner or later the very serious attention of the profession, and most probably also of the Government, will have to be directed to this question. An increasing number of patients requiring skilled medical or surgical treatment, such as they cannot obtain at their own homes, is occurring among a class the financial position of which, while being such as to render them the unethical recipients of charity, yet nevertheless is not adequate to meet the charges of private nursing homes. From the point of view of the economist, it seems truly absurd that this class cannot be catered for.

Another point of interest in the president's address was the repetition of the great want of complete remodelling of the Public Health Government Department. The need for something in this country corresponding to the German Gesundheitsamt has from time to time been emphasised in these columns. Numerous departmental committees appointed by various departments, the minutes of reference to which, however, have all borne directly upon the public health, have embodied in their reports a specific recommendation to this effect. Stress has also been laid upon the inadequacy of the present Governmental machinery for dealing with the important questions which modern technical industry and knowledge, using these terms in the widest sense, are apparently intermittently, but actually constantly, forcing into public hygiene. The policy adopted by the different departments of State concerned has heretofore been one of empirical opportunism. When a question has been sufficiently acute a Departmental Committee has been appointed and a report of this kind issued, often after considerable lapse of time; with the exception of notices at the time of its appearance in the Press, this report and its recommendations are often never heard of again. This policy, although it may have the effect of saving the salaries of permanent officials, cannot in the present state of the question continue long, and we are pleased to see that it was brought prominently before the greatest professional organisation which exists, viz. the British Medical Association.

The address in medicine was delivered by Dr. F. T. Roberts, the subject chosen being infective and infectious diseases. The lecturer dealt chiefly with the influence which new scientific method has exercised upon the diagnosis and treatment of disease. The scientific methods considered were essentially those which have been introduced as a result of increased knowledge of pathology, comprising under this term chemical pathology and bacteriology. These sciences, true to their name, have been without doubt most ancillary to medicine, but their very helpfulness may in itself be a source of danger in so far as concerns the progress of our knowledge of the treatment and diagnosis of disease. These new methods have a tendency, according to the lecturer, to be studied and pursued at the expense of the purely clinical ones. Students, in short, are apt to spend too much time in the laboratory and too little in the wards. An interesting part of the address was devoted to the question of the use of alcohol as a therapeutic agent; in this connection we heartily recommend the remarks of the lecturer to all interested in this question. There can be no doubt that under certain conditions therapeutics possesses no more valuable agent; most clinicians, as the result of their experience, are enabled to maintain that numerous lives have been saved by the skilful administration of alcohol; but, on the other hand, it is equally true that the seeds of future intemperance have not infrequently been sown by the indiscriminate and indefinite instructions, or rather want of instructions, which often accompany the ordering of alcohol by the practitioner of medicine. Too much care cannot be exercised in the prescribing of a remedy so potent both for good and evil.

The address in surgery was delivered by Prof. Mayo Robson, who took for his subject the evolution of abdominal surgery during the last third of a century. The address practically confined itself to the enormous development which has taken place in this branch of the healing art during the above time. In conclusion, the lecturer remarked that the future progress of surgery will probably be intimately bound up with the work of the physician, the pathologist, and the bacteriologist, and the time will come when preventive measures will save much operative work.

Much good work was done at the meetings in the different sections, though apparently no papers of very striking original interest were communicated. The social arrangements left little to be desired, the profession at Swansea and the neighbourhood extending a very hearty welcome to the visitors. Many, no doubt, made the Association meeting at Swansea the starting point of their holidays, and we have little doubt that the mental food ingested there will in many cases be assimilated on the charming holiday grounds of Wales. F. W. T.

VENTILATION OF FACTORIES AND WORKSHOPS.[1]

ABOUT three years ago, Lord Ridley, when Secretary of State for the Home Department, appointed a committee consisting of Dr. J. S. Haldane, F.R.S., and Mr. E. H. Osborn, engineering adviser to the Chief Inspector of Factories, to inquire into and report upon the means of ventilation in factories and workshops, with especial reference to the use of fans and the use and construction of respirators for the protection of workpeople exposed to dust or dangerous fumes.

In the report before us the committee deals with a portion only of the question upon which it was directed to make inquiry. It is for the present mainly concerned in the attempt to strengthen the

[1] "First Report of the Departmental Committee appointed to inquire into the Ventilation of Factories and Workshops; with Appendices." (London: Eyre and Spottiswoode, 1903.)

hands of the Secretary of State in prescribing a standard of sufficient ventilation for factories and workshops based upon what it deems to be an adequate objective criterion of what constitutes reasonably "sufficient" ventilation, viz. the proportion of carbonic acid in the air. Looked at from the point of view of the Inspecting Department of the Home Office, it was necessary, at the outset, to determine whether it was practicable to make use of this proportion as a legal standard of "sufficient" ventilation, or whether such estimations, if made with the requisite accuracy, might not prove to be both expensive and troublesome.

Determinations of atmospheric carbonic acid are mainly carried out on the principle first made use of by Dalton and worked out by Hadfield, that is, absorption of the carbonic acid contained in a known volume of the air by a suitable alkaline solution, the amount so absorbed being ascertained by volumetric analysis. This process was first extensively applied by Pettenkofer, and is generally known by his name. With proper precautions it is capable of a very high degree of accuracy, and, indeed, practically all our knowledge concerning the distribution of carbonic acid in the atmosphere, whether in the free air or in inhabited places, has been obtained by its means. The apparatus needed is somewhat bulky on account of the necessity of using large volumes of air in cases where the amount of carbonic acid is relatively small, as in ordinary atmospheric air. At the same time, when it is merely necessary to determine whether the air of an inhabited room or that of a factory or workshop contains an excess of carbonic acid over the quantity that could reasonably be prescribed as an official limit, vessels holding a couple of litres would suffice for most purposes. It would be readily possible to put together for the use of inspectors a Pettenkofer "kit" which should be light and not too bulky, and would enable the estimation of carbonic acid to be carried out rapidly and with approximate accuracy.

The committee recommends *inter alia* that the limit of carbonic acid should be fixed, except on very foggy days, when no tests should be made, on account of the vitiated state of the outside air, at 12 volumes of carbonic acid per 10,000 of air, and that when gas or oil is used for lighting, the proportion should not exceed 20 volumes after dark or before the first hour after daylight, the only exception to this rule to be in cases where the extra carbonic acid is produced in other ways than by respiration or combustion, as in breweries, &c. It is further recommended that arrangements be made by the Factory Department of the Home Office for the analysis, by a specially qualified person or persons, of samples of air collected by inspectors, and that any analysis on which a prosecution immediately depends should have been performed by such qualified person or persons, and also that arrangements should be made for inspectors of factories to have the use, when desired, of a properly tested portable apparatus for estimating on the spot the proportion of carbonic acid in air.

Dr. Haldane has devised an apparatus for the use of inspectors of factories, a specimen of which has been submitted to us for examination by Messrs. Müller, Orme and Co., of 148 High Holborn, and this seems to fulfil all the necessary conditions. A description of it constitutes appendix iii. of the report before us. The estimation of carbonic acid is made by measuring the contraction in the volume of the air to be tested by bringing the air in contact with a 10 per cent. solution of caustic potash or soda. As the volume of the air taken for the test is only about 20c.c., it is evident that special provision needs to be made, and great care in manipulation needs to be exercised if even approximate accuracy is aimed at. It is impossible in the absence of the diagrammatic representation of the apparatus which accompanies the report to explain the details of its construction, or to make clear the successive steps in its manipulation. We have had, however, an opportunity of making a number of experiments with it, and we are able to state that the amount of carbonic acid in the air of an inhabited room may be quickly ascertained, with sufficient accuracy, by means of it. An intelligent manipulator who understood the scientific principles involved would be able to obtain results accurate to within about one part in 10,000 with air containing ordinary proportions of carbonic acid, and to about two parts with air so highly vitiated as to contain, say, from 30 to 50 volumes of carbonic acid per 10,000. A trained gas analyst would, no doubt, obtain more accurate results. A determination is made in a few minutes when once the apparatus is put into working order.

Whether experiments of this kind should be entrusted to those factory inspectors who have had no training in physical science is perhaps open to question.

One possible source of considerable error was indicated during the experiments. After standing several days the potash solution used in the apparatus was found to be coloured yellow, doubtless from the action of the alkali upon the rubber tubing of the apparatus. Any sulphur thus dissolved would form alkaline sulphides which would absorb oxygen from the air under experiment, and so vitiate the result. As a matter of fact, the figures given when the apparatus was in this condition were wholly untrustworthy.

The following experiments may be cited in illustration of the degree of accuracy which may be obtained:—

GRAHAM BELL'S TETRAHEDRAL CELL KITES.

IN the June number of the *National Geographic Magazine* is a very interesting and instructive article by Dr. Graham Bell on the tetrahedral principle in kite structure. The article itself is so concise, and depends so much upon illustrations which are reproduced to the number of twenty in the text and seventy in an appendix, that an effective representation of the contents in an article of smaller dimensions is scarcely possible. Still the line of thought that runs through the work which the article represents is so clear and so suggestive that even an imperfect outline of it may be useful. Dr. Bell indicates certain stages in the development of his ideas as "milestones" of progress, and since the ultimate stage of the development is the possibility of building up very large kite structures by combining unit cells in such a way that the proportion of weight to wing area in the structure

is nearly the same as that of the constituent cell, the successive stages are noteworthy. They sketch out in a most interesting manner a reply to Newcomb's criticism of the limits of application of the aëroplane based upon the argument that increase of size means diminished efficiency because, for similar structures, the weight varies as the cube while the area, upon

FIG. 1.—A Winged Tetrahedral Cell.

which the lifting force depends, varies as the square of the linear dimensions.

The original stage, the ordinary kite, is a single plane structure. The first step in advance is the Hargrave box kite, with its upper and lower aëroplanes for its support, and side planes for stability. To stiffen the framework of the box kite it must be braced longitudinally and transversely; accordingly Graham Bell's development commences by replacing the rectangular framework of the box kite by a framework of triangular section which is by construction

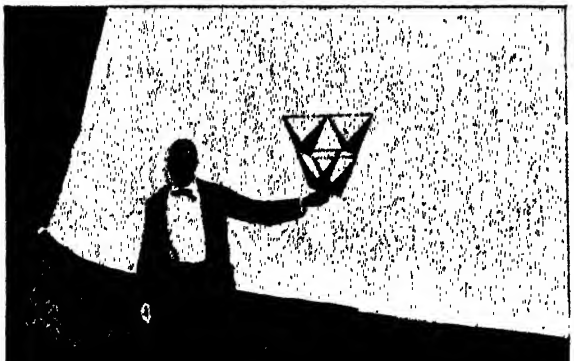

FIG. 2.—A Four-celled Tetrahedral Kite.

stiff so far as the cross section is concerned. The inclined sides are by the vector principle of resolution of forces regarded as equivalent to their geometrical projections, and, in so far as the principle applies, the inclined faces represent the combined effect of aëroplanes of the area of the projections.[1]

[1] This principle to be generally applicable would require the normal component of wind pressure to be uniform and independent of the angle between the plane and the wind. This is not the case with an aëroplane (see Rayleigh, NATURE, vol. xxv. p. 108); and for the principle to be applied approximately in the case of the kites some convention as regards the angle of exposure of the aëroplanes to the wind would be required.

The box kite of triangular section is, however, not stiff as regards longitudinal shear, and the next "milestone" marks the reduction of the triangular or prismatic form to the tetrahedron, an essentially stiff framework for all directions. A tetrahedron of rods with two adjacent faces covered with fabric forms a tetrahedral kite cell which, on the principle of projec-

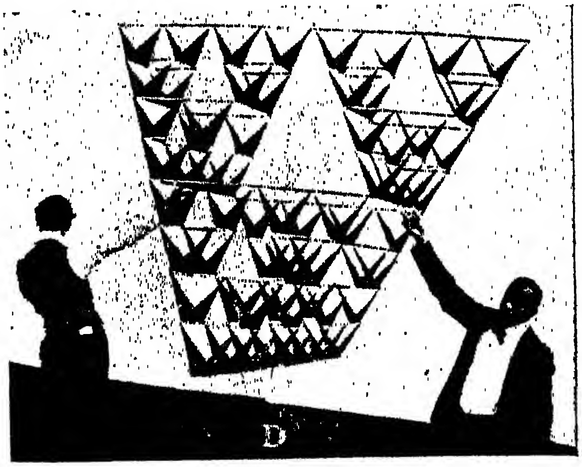

FIG 3.—A Sixty-four celled Tetrahedral Kite.

tion before referred to, is equivalent to three aëroplanes represented by the projections of the covered sides upon planes at right angles.

The further development of pure tetrahedral construction is obvious. Four cells can be combined to form a tetrahedron of double linear dimensions without additional framework; the weight and wing area are both simply proportional to the number of cells, and not to the linear dimensions. For each set of four cells thus combined there is an octahedral free space in the interior which corresponds to the free space between the two cells of the Hargrave kite. The tetrahedral

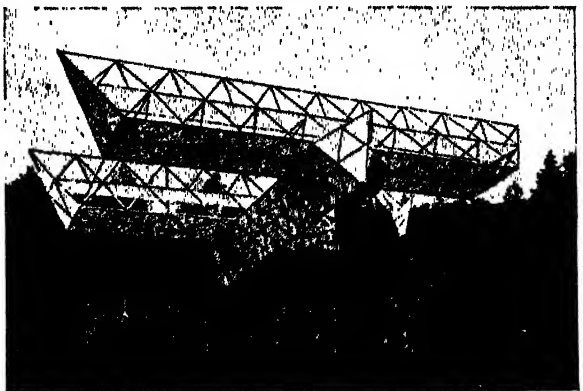

FIG. 4.—The Aërodrome Kite.

kites that have the largest central spaces preserve their equilibrium best in the air.

Combining four multiple cells to fill the outline of a tetrahedron of double size, again, we get a sixteen-cell kite, and repeating the process again a sixty-four cell kite, occupying a tetrahedron eight times the dimensions of a single cell. The building up of multicellular kites from the units is represented in the figures here reproduced from illustrations in Dr. Bell's article. Fig. 1 represents the unit cell, Fig. 2 a combination of four cells, Fig. 3 of sixty-four cells.

The kites fly with the points of the wings upward; the line of junction of the covered faces of the tetra-

hedron forms a kind of keel. No details as to the heights attainable are given. The most convenient place for the attachment of the flying end is said to be the extreme point of the bow. If the cord is attached to points successively further back on the keel, the flying end makes a greater and greater angle with the horizon, and the kite flies more nearly overhead; but it is not advisable to carry the point of attachment as far back as the middle of the keel. A good place for high flights is a point half way between the bow and the middle of the keel.

"Tetrahedral kites combine in a marked degree the qualities of strength, lightness, and steady flight; but further experiments are required before deciding that this form is the best for a kite or that winged cells without horizontal aëroplanes constitute the best arrangement of aëro-surfaces.

"The tetrahedral principle enables us to construct out of light materials solid frameworks of almost any desired form, and the resulting structures are admirably adapted for the support of aëro-surfaces of any desired kind, size, or shape."

The diagrams illustrating the article show various examples of the formation of complex kites from tetrahedral cells. One form suggested by Prof. Langley's aërodrome, but different in construction and appearance, is shown in Fig. 4, reproduced from an illustration in the article. That some of these complex kites are on a very large scale is evident from a case cited, in which an aërodrome kite, which was struck by a squall before it was let go, lifted two men off their feet, and subsequently broke its flying cord, a Manila rope of three-eighths inch diameter.

The simplicity of the construction of the cells, and the obvious possibilities of their combination, lend an additional fascination to a subject which is already full of interest.

BIBLE AND BABEL.

IN the number of the Johns Hopkins University *Circulars* for June (vol. xxii. No. 163), Prof. Paul Haupt has published an article entitled "Bible and Babel," referring to the somewhat heated controversy on Babel and the Bible which has raged recently in Germany, with which our readers are probably familiar. The line which he takes up is briefly that all the heterodox views which were expressed by Prof. F. Delitzsch in his famous lecture delivered in the august presence of the German Emperor had already been promulgated by himself, Prof. Haupt, at various periods during the last twenty-four years. Prof. Haupt claims to have made correct deductions in respect of the origins of the Biblical accounts of the Creation, the Deluge, &c., long before Prof. Delitzsch's lecture was delivered, but it must be clearly pointed out that, although such may be the case, he was not the first, even twenty-four years ago, to prove that the narratives, usually accredited to Moses are merely modified recensions which we owe to the prophets of the captivity in Babylon. Whatever credit is due either to Paul Haupt or Prof. Delitzsch in this matter, it must never be forgotten that all important statements made by them with regard to the Creation and Deluge tablets are derived from the works, writings, and oral remarks which were made by the late General Sir Henry Rawlinson, G.C.B., and the late Mr. George Smith, of the British Museum. Both Profs. Delitzsch and Haupt are skilled elaborators, but in our opinion they are not discoverers, and certainly neither of them can be placed side by side with such publishers and translators of text as the two famous Englishmen we have already mentioned. Still less can either be regarded as the author of the heterodox views and statements which so thoroughly shocked His Majesty the German Emperor.

NOTES.

IN connection with the tenth meeting of the Australasian Association for the Advancement of Science, to be held at Dunedin next January, particulars of which we gave in our issue for May 28 (p. 85), we learn from the *Otago Daily Times* that the colonial Government is rendering the Association material assistance. The New Zealand honorary secretary, Mr. G. M. Thomson, has received from Sir J. G. Ward, Colonial Secretary, a letter which states that the Government will assist the association in the following respects:—(1) A sum of 500*l.* will be placed on the Estimates of the present year towards the expenses of the January meeting; (2) the Government printer will be instructed to do all printing required by the association free of cost to the association; (3) railway passes will be issued to visiting members of the association; and (4) any assistance that it may be in the power of the permanent departments of the Government service to render to the association will be readily afforded on application being made.

AN entire skull (partially restored) of the remarkable Egyptian Eocene mammal *Arsinotherium zitteli* is now exhibited in the central hall of the Natural History Museum. This magnificent specimen was obtained by Dr. C. W. Andrews during his last trip to the Fayum district, and has been cleaned and restored in the museum. Behind the enormous nasal horns are placed a pair of quite small horns, recalling the rudimentary back-horns of the giraffe. The dentition, although including a full series of incisors and canines, recalls that of the Proboscidea. It is hoped that the skull of the Siberian rhinoceros (*Rhinoceros antiquitatis*) recently dug up in Salisbury Square, E.C., may ultimately find a home in the museum, since it is by far the finest example hitherto discovered in this country.

AT an extraordinary general meeting of the members of the Jenner Institute of Preventive Medicine, held on Friday last, the resolution recently passed on July 22 to alter the name of the institute to "The Lister Institute of Preventive Medicine" was unanimously confirmed.

THE fourteenth annual general meeting of the Institution of Mining Engineers will be held on Wednesday, September 2, in the University College, Nottingham.

THE Amsterdam Academy of Sciences has awarded its Buis-Ballot medal, given once in ten years, to Prof. Richard Assmann and Dr. Arthur Berson, of the Aëronautic Institute at Tegel, near Berlin.

REUTER states that a scientific expedition, to explore the northern parts of the Pacific Ocean, will leave Stockholm next April by railway for Port Arthur by way of Siberia. At Port Arthur the expedition will embark on a ship under the leadership of M. Kolthoff, who will be accompanied by five or six other Swedish naturalists.

SIR TREVOR LAWRENCE, president of the Royal Horticultural Society, has announced that Sir Thomas Hanbury, K.C.V.O., has purchased for presentation to the society the estate and garden of the late Mr. G. F. Wilson, F.R.S., at Wisley, near Woking. The total area of the estate is 60 acres.

AT the meeting of the Wilts County Council on August 4, a letter was read from Sir Edmund Antrobus, the owner of Stonehenge, to Lord Edmond Fitzmaurice, M.P. (chairman of the council), in which Sir E. Antrobus said he was willing to sell Stonehenge, and eight acres of land surrounding it, to the nation for the sum of 50,000*l.* The council decided to send the letter to the Chancellor of the Exchequer.

MISS DOROTHY BATE, whose investigation of the fossiliferous caves of Cyprus has recently created much interest among palæontologists, has also paid attention to the birds of that British dependency, and has written a paper on the subject which will appear in the next number of the *Ibis*. She has succeeded in making some good additions to the late Lord Lilford's "List of the Birds of Cyprus," which was published in 1889.

MR. R. C. L. PERKINS, who was employed for some years by the Sandwich Island Exploration Committee of the British Association to make zoological collections in the Hawaiian Archipelago, has received an appointment as economic entomologist in those islands, with the services of two assistants at his disposal. All the exertions that can be made will be required, as it is said that the crops in several of the islands are being completely ruined by introduced insects of various kinds and by fungoid diseases. No better selection could have been made for such a post, as Mr. Perkins is an expert on Hawaiian insects, and is still engaged in work upon them for the British Association committee.

THE manatee which has lately been added to the Zoological Society's living collection is an animal of much interest, as it does not belong to the ordinary species of the American coasts, but is a representative of the smaller form (*Manatus inunguis*) which is confined to the fresh waters of the Amazon. Here it was first discovered by the Austrian explorer Natterer, in the Rio Madeira, in 1830, and designated *inunguis* from the complete absence of nails on the hand, which are always present in *M. americanus*. A single living specimen of the same form was previously received by the Zoological Society in 1896, and its anatomy was described by Mr. Beddard in the *Proceedings* of the Zoological Society for 1897. The present manatee, which is a young animal about three feet long, has been placed in one of the tanks in the reptile house, and is fed principally upon lettuce. An excellent coloured figure of the marine manatee, based upon life-sketches made by the late Joseph Wolf, will be found in the mammal volume of Salvin and Godman's "Biologia Centrali-Americana."

ON the night of August 8 a destructive hurricane, which lasted five hours, swept over Martinique. The storm passed over Fort de France at 1 o'clock in the morning, taking a north-westerly direction. The barometer went down to 28.70 inches.

REPORTS of the following earthquake shocks on the Continent have appeared in the daily papers during the past few days:—*August* 9. Lisbon, 10.8 p.m. Three distinct shocks. Duration, three seconds, two seconds, and eight seconds respectively. Interval of two seconds between each shock.—*August* 11: Malta, 5.33 a.m. Duration, one minute. Naples, 5.35 a.m. Duration, two seconds. Syracuse, 5.38 a.m. Rumbling sounds heard. Canea, 6.9 a.m. Duration, thirty-two seconds. Direction, north to south. Walls of houses cracked. The shocks were felt in almost the whole of Eastern Sicily.

A LARGE party of delegates to the twenty-fourth annual meeting of French geographical and colonial societies, held at Rouen last week, is paying a visit to London, and on Monday was received by the council of the Royal Geographical Society, and entertained at luncheon. Twenty-four French geographical societies, nine kindred societies, and three foreign geographical societies were represented at the Rouen congress, and the members visiting England number eighty-two. At the luncheon, in responding to the toast of "The Geographical Societies of France," proposed by the chairman, Major Leonard Darwin, M. Zévort, rector of the University of Caen, and president of the congress, said his claim to speak in that assembly was that he was the rector of a university, French in its character, founded by an English king, that he represented a city which was visited every year by hundreds of English people, and he was, moreover, the nephew of Pasteur speaking to a son of Darwin. Wherever the French had worked and the English had followed there had been great progress in civilisation and in the peaceful development of the human race. That was the spirit in which the delegates came to this country, and it was in that spirit they were welcomed.

A REPORT by the director on the work in the engineering and physics departments of the National Physical Laboratory during the half year ended June 30 gives interesting particulars of the research work in progress. In the wind pressure research in the engineering laboratory, the case of flat surfaces exposed to a perpendicular current of air has been worked out, and a general relation established which is now being tested for the case of larger surfaces exposed to the natural wind. The case of parallel plates at varying distances apart has been treated, and experiments are also in progress on the pressure on inclined surfaces. Drawings have been prepared, and some preliminary tests made for the research into the constants of steam. In the physics department Dr. Harker has continued his comparison between the air thermometer, the platinum thermometer and the thermojunctions, and the work is now complete for temperatures between 0° C. and about 1050° C. The first part of the work for temperatures up to 500° C. was done with M. Chappuis, at Sèvres, and the results have been published. Dr. Harker has also constructed and subjected to stringent tests a set of platinum thermometers for the British Association. A small research on the specific heat of iron at high temperatures—700° C. to 1000° C.—is nearly complete, and promises to be of interest. Mr. F. E. Smith's research on the resistance of mercury and the construction of a standard mercury resistance is practically complete. The value of the specific resistance of mercury will probably prove to be very close to that determined by the director and Mr. Fitzpatrick in 1888. On the assumption that the absolute value of the wire standards in the laboratory is known, the length of the column of mercury, 1 sq. mm. in section, having a resistance of 10^9 C.G.S. units, is found to be almost exactly 106.29cm. The difference between Mr. Smith's results and those of the Reichsanstalt will not be more than some few parts in 100,000. An investigation of some importance into the changes in insulating strength of various dielectrics due to continued heating, by Mr. A. Campbell and Mr. Rayner, undertaken for the Engineering Standards Committee, promises to lead to results of value. In the metallurgical division the solidifying points and cooling curves of a series of pure iron carbon alloys have been determined, using platinum platinum-iridium and platinum platinum-rhodium thermojunctions. The range of carbon is from 0.15 to 3.55 per cent.; the range of temperature from 1502° C. to 1111° C. on the thermojunction scale. In addition to the above research work, nearly 600 tests have been made during the half year.

WE have received from Mr. E. Bohm two incandescent electric lamps which are specially designed to give good illumination vertically downwards. In both lamps the lower half of the bulb is made of fluted glass, which, acting as a row of lenses, serves to concentrate the light downwards;

one lamp has, in addition, opal glass for the upper half of the bulb, the filament being of the ordinary shape. The filament of the other lamp is fixed horizontally, and is zig-zag in shape; the upper half of the bulb in this case is of clear glass. The result of these designs is to give a distribution of light having the maximum candle-power in the vertical direction; in one of the lamps which we tested the vertical candle-power was 17·5, and the mean horizontal candle-power 10, thus practically reversing the values obtained with ordinary lamps. For situations in which good illumination directly below the vertical is specially required, these patterns of lamps should prove useful.

A VERY ingenious electrical type-setting machine is briefly described by M. Tavernier in a recent issue of the *Comptes rendus* of the Paris Academy of Sciences. The apparatus is similar in principle to the familiar linotype machines, but the operations of typing the copy and casting the type are separated; the operator works at an electrical typewriter, which produces a perforated tape, and at the same time an ordinary typed copy of the manuscript, which enables corrections to be made in the tape before the type is set up. The perforated tape is passed automatically through the type-setting machine, which is also operated electrically. The advantage of thus dividing the two operations is that the casting machine can be worked at a uniform maximum speed, and is independent of the skill of the typist. A further modification of the machine allows it to be used telegraphically; the perforated tape produced by the type-writer is passed through a transmitter, which sends signals over the line and reproduces in a receiving apparatus a duplicate of the tape, which can be used in the type-setting machine. The details of the various pieces of apparatus are not given, but there can be no doubt that the invention is likely to prove of great utility.

WE have received the forty-sixth volume of the "Year-book" of the Austrian Meteorological Service for 1901. The operations of the central office include the usual work of a normal observatory, the control of about 400 stations of various classes, and telegraphic weather forecasts. There are, in addition, a large number of stations dealing with thunderstorms and hail, but purely rainfall observations are now under the control of another department. An active part is taken in the international balloon ascents; we have frequently referred to some of the preliminary results obtained. Another feature of the Austrian service is the erection of a number of stations for "weather shooting" for the dissipation of thunder clouds and prevention of damage by hail, but the operations hitherto have not led to the hope of unqualified success. A separate appendix accompanies the "Year-book," which includes very valuable discussions on thunderstorm observations and on isotherms for Austria, both papers illustrated by charts. In the discussion of thunderstorms, some very interesting and instructive conclusions are drawn as to their connection with geographical features and the distribution of barometric pressure. It may be interesting to note here that out of 94 cases of damage to trees by lightning in 1901, 27 were pine or larch, 20 oak, 17 poplars, and 10 pear trees. The beech tree, which is generally supposed to be practically free from lightning strokes, was only struck once, but there were several other trees which similarly escaped damage.

AT the recent congress of the Royal Institute of Public Health, Prof. Moore, of Liverpool, read a paper upon a "Chemical Theory of the Transmission of Certain Infective Diseases." He pointed out that in many of the specific fevers no micro-organism has been isolated, and suggested that in these a chemical body of the nature of an enzyme may be the ætiological agent. To account for the reproduction of this chemical substance, which is necessary to explain the phenomenon of infection, Prof. Moore supposes that, by its action upon some of the cells, more of itself may be formed. He points out that there are analogies to this action in the case of certain "catalytic" reactions.

A SECOND report of the Special Chloroform Committee of the British Medical Association has just been issued. Mr. Vernon Harcourt, F.R.S., describes some experiments made to estimate the amount of chloroform which may be dissolved by the blood, and an apparatus for the limitation and regulation of chloroform vapour when administered as an anæsthetic. Dr. Dudley Buxton discusses the clinical use of certain inhalers (including Mr. Harcourt's form), and Mr. Walter Tyrrell reports upon the use of Mr. Harcourt's inhaler. Prof. Sherrington, F.R.S., and Mr. Sowton describe a number of experiments made to measure that dosage of chloroform under which the mammalian heart can, and cannot, work efficiently. They conclude that the heart muscle rapidly takes up chloroform offered to it in the blood-vessels of its vascular system.

CAPTAIN LAMB, I.M.S., has made a series of experiments upon the action of the venoms of the cobra and of Russell's viper (*Daboia Russellii*) upon the red-blood corpuscles and upon the blood plasma (*Scientific Memoirs of the Government of India*, New Series, No. 4). Both these venoms are shown to have a marked hæmolytic action, both *in vivo* and *in vitro*. Cobra venom never induces intra-vascular clotting; in fact, it rather diminishes blood coagulability, while Daboia venom causes extensive intra-vascular clotting. *In vitro* cobra venom prevents the clotting of citrated blood or plasma which ensues on the addition of a soluble calcium salt; Daboia venom, on the other hand, increases the tendency of citrated blood and plasma to coagulate. In conclusion, Captain Lamb considers that his experiments do not support Martin's hypotheses that all snake venoms contain at least two toxic proteids, one being a neurotropic, the other a hæmotropic, poison, and that the action on blood coagulability is due to a setting free of nucleo-proteids.

THE current issue of the *National Geographic Magazine* contains an article by Dr. H. W. Wiley, chief chemist of the Department of Agriculture, on "The United States; its Soils and their Products." Little is said about the special features exhibited by the soils of the country, the article being, in fact, a brief summary of the acreage, yield, and value of the main crops grown in the United States, useful to the student who has no opportunity of consulting the "Year-book" of the Department of Agriculture. The two facts that are most striking are the relatively low yield per acre and the enormous diversity of the agriculture; Dr. Wiley, indeed, asserts that "within the borders of the United States are grown every agricultural crop known to the world." The article is illustrated by several interesting photographs, calculated to impress the reader with the magnitude of the scale on which farming is practised in the United States.

A MOST interesting and remarkable instance of local adaptation to abnormal conditions on the part of a mollusc is recorded by Baron E. Nordenskjöld in No. 704 of the *Zool. Anzeiger*. It appears that in the "Chaco" districts of South America a species of fresh-water limpet (*Ancylus moricandi*) is found during the wet season in the pools which are then abundant in the country. During the dry season, however, these pools are completely desiccated, and

the whole country then becomes a practical desert, over which clouds of fine dust are swept by the wind. In order to exist during this season of drought, the Ancylus closes up almost the whole of the inferior aspect of its limpet-like shell by a growth of shelly matter continuous with the margin of the latter, leaving only a small circular mouth at one end. As is well known, many land molluscs, more especially *Helix pomatia,* are in the habit of sealing up the apertures of their shells during seasons of drought or heat, but in none of these is the substance with which the mouth is closed identical with that of the shell. In localities where there is no marked dry season, the Chaco Ancylus remains throughout the year in its normal condition.

In part i. of the general report and statistics relating to mines and quarries for 1902, issued by the Home Office, we note evidence of a general increase in production with regard to coal, fire-clay, ironstone, gypsum, rock-salt, &c. It is interesting to find that gold ore showed an increase from 16,374 tons in 1901 to 29,953 tons in 1902.

In a paper on the diffusion of granite into schists (*Geol. Mag.*, May), Mr. E. Greenly suggests that the granitoid matter that has been injected *lit par lit* was intruded while the surrounding rocks were at a high temperature, and this view would help to explain the occurrence of lenticles of granite in complete isolation from the parent mass.

A useful map of Peru, on the scale of 1 : 3,000,000, or an inch to a little more than forty miles, has been issued by Mr. Eduardo Higginson, Consul of Peru, Southampton. It shows the various ports and havens, railways completed and in progress, telegraphs, roads, forests, petroleum deposits, &c. On the back of the map are printed numerous particulars relating to the country, such as climate, agriculture, artesian wells, mineral wealth, manufactures, and various statistics. Of the industries, that of indiarubber is especially described.

To the *Proceedings* of the Geologists' Association for June (vol. xviii. part ii.), Dr. Catherine A. Raisin contributes an article on the formation of Chert, with especial reference to the bands and nodules in Jurassic strata. In some cases the silica may have originated from hot springs aided by the action of algæ; in other cases silica may have been directly derived from the sea water, but more often through the agency of siliceous organisms. Molecular changes that subsequently took place in the rocks have led to the dispersal and concentration of the silica in patches or layers. Mr. Jukes-Browne gives an account of the zones of the Upper Chalk in Suffolk.

In a paper on "The Marl-Slate and Yellow Sands of Northumberland and Durham," Prof. G. A. Lebour (*Trans.* Inst. Mining Eng.) remarks that these Permian strata rest on the stained edges of eroded Carboniferous rocks. Discussing the origin of the yellow sands which occur at the base of the Permian group, he is disposed to agree with R. Howse that they were wind-blown, and that consequently the overlying Marl-slate may rest somewhat irregularly upon them. Some of the inequalities observable between the divisions are, however, due to the fact that springs carry away portions of the sands, and this subterranean erosion leads to subsidence of the overlying Marl-slate or Magnesian Limestone. The Marl-slate is made up of thin limestones and shales, with marine shells and remains of land-plants, as well as amphibia, and numerous fishes the nearest existing analogues of which inhabit rivers and lakes. The organic remains thus indicate estuarine or lagunal conditions.

A German Bohemian Archæological Expedition to Asia Minor, conducted by Drs. J. Jüthner, K. Patsch and H. Swoboda, and Architect F. Knoll, left Konia (Iconium) on April 4 on a roundabout journey to Isaura, to link on with the work of the Vienna Academy. They visited various towns and villages between Konia and the Lake of Bey Schehir, and investigated the interesting Hittite temple at Fassiler previously discovered by the American explorer Sterrett. In Kyzyldschakiöj they made their most valuable epigraphical discovery of two fragments of a limestone stele, which is important since it bears on the history of the second century B.C., and illustrates certain aspects of Greek public law. An illustration is given of the ruined gate of the acropolis of ancient Isaura which confirms the statement that very little now remains. More than three hundred inscriptions were found, and numerous photographs were taken of monuments and landscapes; the map accompanying the report in *Deutsche Arbeit* (vol. ii. Heft 10, p. 784) was drawn by Prof. Jüthner.

Prof. James Walker's "Elementary Inorganic Chemistry," published by Messrs. Geo. Bell and Sons, and reviewed in our issue for June 19, 1902, has been translated into German by Margarete Egebrecht and Emil Bose. The translation has been published by Messrs. F. Vieweg and Son, of Brunswick.

A second edition of the "Guide to the Search Department of the Patent Office Library, with Appendices," has been published at the Patent Office, Chancery Lane. The first appendix is a descriptive list of unofficial class-lists, and digests of English and foreign patent specifications, and the second contains a select dictionary of words and phrases associated with inventions introduced under letters patent.

We have received copies of the *Compte rendu* of the proceedings of the 1901 meeting of the Société Helvétique des Sciences Naturelles, held at Zofingen, and that of the 1902 meeting held at Geneva. The two volumes of *Verhandlungen* and *Actes,* containing the papers presented and addresses delivered in connection with the same meetings, have also reached us.

Subjects of scientific interest take a prominent place in the current issue of the *Century Magazine.* Mr. Frank W. Stokes, who accompanied the Swedish South Polar Expedition under the leadership of Dr. Otto Nordenskjöld, contributes an article entitled "An Artist in the Antarctic," which is accompanied by three beautifully coloured plates by the author, and these give a vivid impression of the region described. M. J. Deniker writes of Lhasa, under the title "New Light on Lhasa, the Forbidden City." Miss A. K. Fallows explains, in a well illustrated paper, the means adopted to secure for New York a supply of pure milk.

The first part of vol. ii. of "The Fauna and Geography of the Maldive and Laccadive Archipelagoes: being an Account of the Work carried on and of the Collections made by an Expedition during the Years 1899 and 1900," which is being edited by Mr. J. Stanley Gardiner, has been issued by the Cambridge University Press. The first part of vol. i. of this work was reviewed in our issue of April 3, 1902, and the remaining volumes will be dealt with after the publication of the concluding part. The present fasciculus contains reports by Prof. S. J. Hickson, F.R.S., and Miss E. M. Pratt on the Alcyonaria of the Maldives, by Sir Charles

Eliot on Nudibranchiata, by Mr. L. A. Borradaile on the sponge-crabs, and by Sir John Murray, F.R.S., and the editor on lagoon deposits.

THE *Proceedings* of the Washington Academy of Sciences for July 18 is made up of a full account of a meeting held in Columbia University, under the auspices of the Washington Academy, to commemorate the distinguished services to knowledge of the late Major John Wesley Powell, together with a list of the 251 papers and articles written by him during the years 1867 to 1903. Major Powell's work as director of the Bureau of American Ethnology is well known to anthropologists, and his services to science as an explorer, geologist and organiser are of the same high value. As an observer in many fields of natural science, and as one who exerted great influence on scientific progress, Major Powell's memory will long be held in honour.

MESSRS. CHARLES GRIFFIN AND CO., LTD., have now published a tenth edition of Mr. Bennett H. Brough's "Treatise of Mine-Surveying." The book was first published in 1888, and was reviewed at length in our issue of August 2 of that year. The prediction made on that occasion—"as soon as the book becomes known, no English-speaking mine-agent or mining student will consider his technical library complete without it"—has been fully justified, as the issue of a tenth and revised edition shows. Descriptions of appliances invented since the ninth edition appeared at the beginning of last year have now been inserted in the book, and among these additions will be found accounts of Sir Howard Grubb's new sight for mining dials, of Gothan's instrument for surveying bore-holes, and of the Dunbar-Scott mine tacheometer. Besides these improvements, references to important papers lately published and recent examinations questions have been added.

THE current number of the *Popular Scientific Monthly*, in addition to other articles of general scientific interest, reprints the Romanes lecture delivered last June by Sir Oliver Lodge, F.R.S., and publishes the third of a series of papers on Hertzian wave wireless telegraphy by Prof. J. A. Fleming, F.R.S. Other papers are on the bird rookeries on the island of Laysan, and bacteria in modern economic agriculture. From the columns headed the progress of science we learn there are now somewhat more than 100,000 students in the colleges, universities, and technical schools of the United States, and somewhat more than 50,000 in the professional schools of theology, law and medicine. In 1901, 16,513 students graduated from colleges and technical schools, and of these 5050 were women. The number of pupils in secondary schools was in 1901 upwards of 600,000, as compared with less than 100,000 in 1878.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. — Townshend; two Malayan Bears (*Ursus malayanus*) from Malacca, presented by the Right Hon. Earl of Crawford; two Norwegian Lemmings (*Myodes lemmus*) from Norway, presented by Major-General C. S. Sturt; two Dwarf Chameleons (*Chamaeleon pumilus*) from South Africa, presented by Mrs. Mainwaring; four Tuberculated Iguanas (*Iguana tuberculata*) from Venezuela, three Elephantine Tortoises (*Testudo elephantina*) from the Aldabra Islands, two Radiated Tortoises (*Testudo radiata*) from Madagascar, deposited; a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

BORRELLY'S COMET (1903 *c*).—The following elements and ephemeris for Borrelly's comet have been computed by Dr. Aitken, of the Lick Observatory, from observations made on June 22 and 30, and July 10 (Lick Observatory *Bulletin*, No. 47):—

Elements.

T = 1903 August 27·6056 G.M.T.

$$\left.\begin{array}{rl} \omega = & 127^\circ\ 19'\ 25''\cdot5 \\ \Omega = & 293\ \ 32\ \ 55\cdot0 \\ i = & 84\ \ 59\ \ 45\cdot3 \end{array}\right\} 1903\cdot0$$

$$\log q = 9\cdot518126$$

PROJECTION ON MARS.—In the first *Bulletin* issued by the Lowell Observatory, Flagstaff, Arizona, Mr. Percival Lowell describes the observations of a projection which was discovered on the terminator of Mars by Mr. Slipher at 15h. 34m. (G.M.T.) on May 25. Messrs. Lowell and Slipher afterwards alternately observed the projection, which lasted for about thirty-one minutes; the position angle varied from 204°·0 to 199°·8, and the projection was variously estimated as being removed from the terminator by a perpendicular distance of 0·067–0·075 of the radius of the disc; its length was 1″·58, and it disappeared at 16h. 8m.

The projection was "suspected" again at 15h. 58m. on May 27, and, if really seen, had moved 7° in latitude and 8° in longitude during the twenty-four hours' interval. The observations lead to the conclusion that the projection was probably a cloud of *dust* about 300 miles long, travelling at about 16 miles an hour in a north-easterly direction, and dissipating as it went.

THE SATELLITE OF NEPTUNE.—Using the Crossley reflector, Prof. Perrine has obtained a series of photographs of Neptune's satellite which cover one complete revolution, January 4–January 16, 1902.

The measurements of forty-five plates show that a correction of +0°·55, with a probable error of ±0°·09 in position angle, and of −0″·006, with a probable error of ±0″·020 in distance, must be applied to Hall's elements as published in No. 441 of the *Astronomical Journal*.

The observations are recorded in *Bulletin* No. 39 of the Lick Observatory, which also contains a series of determinations of the position of the planet itself, at certain times, as determined from the same photographs.

THE ESTIMATION OF STELLAR TEMPERATURES.—The question of the relative temperatures of the different types of stars is one of the most important in astrophysics, and has lately been the subject of much discussion in consequence of the discovery that spark lines appear in the arc spectrum under certain special conditions. In *Astr. Nach.* (No. 3882), after reviewing the recent contributions to the discussion, Prof. Kayser suggests a method of estimating the temperatures of stars which is based on an idea put forward in 1876 by Sir George Stokes in a note appended to a paper by Sir Norman Lockyer (Roy. Soc. *Proc.*, vol. xxiv. pp. 352–4). In the case of an incandescent solid body the proportion of the more refrangible radiations increases with the temperature, and Stokes suggested that a line spectrum might behave in the same manner, so that at different temperatures different lines would be most persistent. Prof. Kayser thinks that, while this may not hold for the whole spectrum, it may be true for the lines of a definite series, such as those of hydrogen, or one of the series of lines of helium. On this supposition he has recently undertaken a preliminary investigation for the

detection of such variations in the spectra of hydrogen, helium, and lithium, and has obtained indications that the energy of the shorter waves is relatively increased with increase of temperature, assuming that the temperature in Geissler tubes rises with increased potential and current strength. It is considered probable that further laboratory experiments combined with photometric or photographic estimates of the intensities of the stellar lines may result in a fairly accurate knowledge of the temperatures of some of the stars; great progress will have been made if the temperatures can only be ascertained within one or two thousand degrees.

OBSERVATIONS OF THE MINIMA OF MIRA.—In No. 3888 of the *Astronomische Nachrichten*, Prof. A. A. Nijland records his observations of the last minimum of Mira, which took place during December. Plotting his observations on a curve, he found that the actual minimum occurred on December 17, 353 days after the minimum of December 29, 1901, the magnitude on that date being 8·70 on the Harvard photometer scale.

The following table shows the differences between the dates of minima as predicted by Guthnick (*Astronomische Nachrichten*, No. 3745) and those actually observed:—

Observed		Guthnick		O–G
1901 Feb. 16	...	1901 March 6	..	−18 days
„ Dec. 29	...	1902 Jan. 31	...	−33 „
1902 „ 17	...	„ Dec. 28	...	−11 „

THE SIZE OF STELLAR SYSTEMS.—In an editorial article in the *Observatory* for August, a table is given which compares the dimensions of various stellar systems with those obtaining in the solar system. As the writer states, these are not generally known or not remembered, therefore he has tabulated a few of the more interesting and approximately known data, which must, however, only be taken as approximations owing to the uncertainty of the original data from which they are computed.

Object	Separation of components		Motion across the line of sight, in millions of miles per annum
—	In astronomical units	In millions of miles	—
Earth	1·0	93	—
Saturn	9·5	883	—
Procyon	17·3	1,608	372
Uranus	19·2	1,782	—
Sirius	21·1	1,962	316
α Centauri	23·3	2,167	465
Castor	27·5	2,557	140
Neptune	30·1	2,792	—
o_2 Eridani (B and C)	34·5	3,207	2,000
η Cassiopeiæ	44·7	3,947	580
θ Ursæ Maj.	63·0	5,860	1,300
61 Cygni	68·0	6,324	1,116
Polaris	250	23,250	133
Aldebaran	282	26,226	170
θ_2 Eridani (A and B)	455	42,315	2,000

RECENTLY DETERMINED STELLAR PARALLAXES.—No. 10 of the *Publications* of the Groningen Astronomical Laboratory contains the details of the observations and reductions of parallax for the stars and clusters "*h* and χ Persei," "745 Groombridge," and "61 Cygni and the surrounding stars." The photographs from which the parallactic values were determined were obtained by Prof. A. Donner, and have been reduced by Prof. J. C. Kapteyn and Dr. W. de Sitter.

In the summary given for the cluster *h* and χ Persei, 178 stars are included, and it will be possible, when it has been decided, from observations of their proper motions, whether or not the individual stars actually belong to the cluster, to determine the parallax of this cluster with extreme accuracy.

The parallax of 745 Groombridge relative to stars of the mean magnitude 9·0 was found to be $+0''.083 \pm 0''.024$, and on consideration of the star's magnitude (8·2) and its annual proper motion (0″·64), +0″·068 was accepted as the most probable value of this parallax.

The final value of the parallax of 61 Cygni relative to the four comparison stars (mean magnitude =7·4) is given as $+0''.326 \pm 0''.035$; the plates from which this result was obtained do not confirm the existence of any real difference of parallax between the two components.

No. 11 of the same *Publications* contains a discussion on "The Luminosity of the Fixed Stars" by Prof. J. C. Kapteyn.

EXPERIMENTS IN RADIO-ACTIVITY, AND THE PRODUCTION OF HELIUM FROM RADIUM.[1]

(1) *Experiments on the Radio-activity of the Inert Gases of the Atmosphere.*

OF recent years many investigations have been made by Elster and Geitel, Wilson, Strutt, Rutherford, Cooke, Allen, and others on the spontaneous ionisation of the gases of the atmosphere and on the excited radio-activity obtainable from it. It became of interest to ascertain whether the inert monatomic gases of the atmosphere bear any share in these phenomena. For this purpose a small electroscope contained in a glass tube of about 20 c.c. capacity, covered in the interior with tin-foil, was employed. After charging, the apparatus if exhausted retained its charge for thirty-six hours without diminution. Admission of air caused a slow discharge. In similar experiments with helium, neon, argon, krypton, and xenon, the last mixed with oxygen, the rate of discharge was proportional to the density and pressure of the gas. This shows that the gases have no special radio-activity of their own, and accords with the explanation already advanced by these investigators that the discharging power of the air is caused by extraneous radio-activity.

Experiments were also made with the dregs left after liquefied air had nearly entirely evaporated, and again with the same result; no increase in discharging power is produced by concentration of a possible radio-active constituent of the atmosphere.

(2) *Experiments on the Nature of the Radio-active Emanation from Radium.*

The word emanation originally used by Boyle ("substantial emanations from the celestial bodies") was resuscitated by Rutherford to designate definite substances of a gaseous nature continuously produced from other substances. The term was also used by Russell ("emanation from hydrogen peroxide") in much the same sense. If the adjective "radio-active" be added, the phenomenon of Rutherford is distinguished from the phenomena observed by Russell. In this section we are dealing with the emanation, or radio-active gas obtained from radium. Rutherford and Soddy investigated the chemical nature of the thorium emanation (*Phil. Mag.*, 1902, p. 580) and of the radium emanation (*ibid.*, 1903, p. 457), and came to the conclusion that these emanations are inert gases which withstand the action of reagents in a manner hitherto unobserved except with the members of the argon family. This conclusion was arrived at because the emanations from thorium and radium could be passed without alteration over platinum and palladium black, chromate of lead, zinc dust, and magnesium powder, all at a red-heat.

We have since found that the radium emanation withstands prolonged sparking with oxygen over alkali, and also, during several hours, the action of a heated mixture of magnesium powder and lime. The discharging power was maintained unaltered after this treatment, and inasmuch as a considerable amount of radium was employed it was possible to use the self-luminosity of the gas as an optical demonstration of its persistence.

In an experiment in which the emanation mixed with oxygen had been sparked for several hours over alkali, a minute fraction of the total mixture was found to discharge an electroscope almost instantly. From the main quantity

[1] By Sir William Ramsay, K.C.B., F.R.S., and Mr. Frederick Soddy. Received at the Royal Society July 28.

of the gas the oxygen was withdrawn by ignited phosphorus, and no visible residue was left. When, however, another gas was introduced, so as to come into contact with the top of the tube, and then withdrawn, the emanation was found to be present in it in unaltered amount. It appears, therefore, that phosphorus burning in oxygen and sparking with oxygen have no effect upon the gas so far as can be detected by its radio-active properties.

The experiments with magnesium-lime were more strictly quantitative. The method of testing the gas before and after treatment with the reagent was to take 1/2000th part of the whole mixed with air, and after introducing it into the reservoir of an electroscope to measure the rate of discharge. The magnesium-lime tube glowed brightly when the mixture of emanation and air was admitted, and it was maintained at a red-heat for three hours. The gas was then washed out with a little hydrogen, diluted with air and tested as before. It was found that the discharging power of the gas had been quite unaltered by this treatment.

The emanation can be dealt with as a gas; it can be extracted by aid of a Töpler pump; it can be condensed in a U-tube surrounded by liquid air; and when condensed it can be "washed" with another gas which can be pumped off completely, and which then possesses no luminosity and practically no discharging power. The passage of the emanation from place to place through glass tubes can be followed by the eye in a darkened room. On opening a stopcock between a tube containing the emanation and the pump, the slow flow through the capillary tube can be noticed; the rapid passage along the wider tubes; the delay caused by the plug of phosphorus pentoxide, and the sudden diffusion into the reservoir of the pump. When compressed, the luminosity increased, and when the small bubble was expelled through the capillary it was exceedingly luminous. The peculiarities of the excited activity left behind on the glass by the emanation could also be well observed. When the emanation had been left a short time in contact with the glass, the excited activity lasts only for a short time; but after the emanation has been stored a long time the excited activity decays more slowly.

The emanation causes chemical change in a similar manner to the salts of radium themselves. The emanation pumped off from 50 milligrams of radium bromide after dissolving in water, when stored with oxygen in a small glass tube over mercury turns the glass distinctly violet in a single night; if moist the mercury becomes covered with a film of the red oxide, but if dry it appears to remain unattacked. A mixture of the emanation with oxygen produces carbon dioxide when passed through a lubricated stopcock.

(3) *Occurrence of Helium in the Gases Evolved from Radium Bromide.*

The gas evolved from 20 milligrams of pure radium bromide (which we are informed had been prepared three months) by its solution in water and which consisted mainly of hydrogen and oxygen (*cf.* Giesel, *Ber.*, 1903, 347) was tested for helium, the hydrogen and oxygen being removed by contact with a red-hot spiral of copper wire, partially oxidised, and the resulting water vapour by a tube of phosphorus pentoxide. The gas issued into a small vacuum-tube which showed the spectrum of carbon dioxide. The vacuum tube was in train with a small U-tube, and the latter was then cooled with liquid air. This much reduced the brilliancy of the CO_2 spectrum, and the D_3 line of helium appeared. The coincidence was confirmed by throwing the spectrum of helium into the spectroscope through the comparison prism, and shown to be at least within 0·5 of an Ångström unit.

The experiment was carefully repeated in apparatus constructed of previously unused glass with 30 milligrams of radium bromide, probably four or five months old, kindly lent us by Prof. Rutherford. The gases evolved were passed through a cooled U-tube on their way to the vacuum-tube, which completely prevented the passage of carbon dioxide and the emanation. The spectrum of helium was obtained and practically all the lines were seen, including those at 6677, 5876, 5016, 4932, 4713, and 4472. There were also present three lines of approximate wave-lengths, 6180, 5695, 5455, that have not yet been identified.

On two subsequent occasions the gases evolved from both solutions of radium bromide were mixed, after four days' accumulation which amounted to about 2·5 c.c. in each case, and were examined in a similar way. The D_3 line of helium could not be detected. It may be well to state the composition found for the gases continuously generated by a solution of radium, for it seemed likely that the large excess of hydrogen over the composition required to form water, shown in the analysis given by Bodländer (*Ber., loc. cit.*) might be due to the greater solubility of the oxygen. In our analyses the gases were extracted with the pump, and the first gave 28·6, the second 29·2 per cent. of oxygen. The slight excess of hydrogen is doubtless due to the action of the oxygen on the grease of the stopcocks, which has been already mentioned. The rate of production of these gases is about 0·5 c.c. per day for 50 milligrams of radium bromide, which is more than twice as great as that found by Bodländer.

(4) *Production of Helium by the Radium Emanation.*

The maximum amount of the emanation obtained from 50 milligrams of radium bromide was conveyed by means of oxygen into a U-tube cooled in liquid air, and the latter was then extracted by the pump. It was then washed out with a little fresh oxygen, which was again pumped off. The vacuum tube sealed on to the U-tube, after removing the liquid air, showed no trace of helium. The spectrum was apparently a new one, probably that of the emanation, bur this has not yet been completely examined, and we hope to publish further details shortly. After standing from July 17 to 21, the helium spectrum appeared, and the characteristic lines were observed identical in position with those of a helium tube thrown into the field of vision at the same time. On July 22 the yellow, the green, the two blues and the violet were seen, and in addition the three new lines also present in the helium obtained from radium. A confirmatory experiment gave identical results.

We wish to express our indebtedness to the research fund of the Chemical Society for a part of the radium used in this investigation.

ON THE INTENSELY PENETRATING RAYS OF RADIUM.[1]

RADIUM is known to emit three types of radiation. These are:—

(1) The α rays, very easily absorbed by solids, and carrying a positive electric charge.

(2) The β rays, more penetrating than these, and negatively charged.

(3) The γ rays, intensely penetrating, and not conveying an electric charge at all.

In a paper published in the *Phil. Trans.* for 1901, I investigated the relative ionisations of gases by the α and β rays. The present communication may be regarded as a sequel to that one, and deals with the γ rays.

The radium employed was of activity 1000 (uranium = 1), and was contained in a glass cell, over which was cemented a piece of thin aluminium. The cell was placed in a cavity in a block of lead, and over it was placed a disc of lead 1 cm. in thickness. This it was considered would suffice to suppress all but the γ rays, which are much the most penetrating.

In measuring the electrical leakage, the electroscope method was employed. The apparatus was that described in a paper published in the *Philosophical Magazine* for June, p. 681.

The radium, covered by the thick lead, was placed under the apparatus, and the rate of leak determined when the different gases filled the testing vessel.

The conditions were, of course, arranged so as to use a saturating E.M.F. The γ rays are so penetrating that there can be no question of their being appreciably absorbed in a moderate thickness of gas.

For the methods of preparation of the gases I must refer to the former paper (*Phil. Trans.*, A., vol. cxcvi., 1901, p. 508).

[1] By Hon. R. J. Strutt, Fellow of Trinity College, Cambridge. Communicated to the Royal Society by Lord Rayleigh, F.R.S. Received August 5.

The results were as follows; the rates of leak are given in scale divisions per hour, and are corrected to 30 inches pressure:—

Gas	Rate of Leak	Mean
Hydrogen	10·4, 10·5, 10·4, 11·2, 10·4, 11·2, 9·86, 10·1, 10·2 ...	10·5
Air	65·2, 66·6, 66·6, 60·0, 57·0, 61·5, 60·2, 63·0, 58·2, 58·3, 56·6, 56·2	62·1
Oxygen	75·0, 74·2, 71·0, 74·1	73·6
Carbon dioxide	96·0, 95·4, 94·5, 95·1, 94·1, 94·7	95·0
Cyanogen	107, 104, 106, 106	106·0
Sulphur dioxide... ...	132, 126, 134, 135	132·0
Chloroform	297, 298, 290, 327	303·0
Methyl iodide	298, 292, 310, 291	298·0
Carbon tetrachloride ..	363, 351, 344, 349	352·0

The following table gives the relative ionisations, referred to air as unity. The values of the same constants for the α and β rays formerly found are included, and also measurements of relative ionisation under Röntgen rays. These latter form part of an investigation not hitherto published.

Relative Ionisations.

Gas	Relative density	Relative Ionisation			
		α rays	β rays	γ rays	Röntgen rays
Hydrogen	0·0693	0·226	0·157	0·169	0·114
Air	1·00	1·00	1·00	1·00	1·00
Oxygen	1·11	1·16	1·21	1·17	1·39
Carbon dioxide	1·53	1·54	1·57	1·53	1·60
Cyanogen	1·86	1·94	1·86	1·71	1·05
Sulphur dioxide	2·19	2·04	2·31	2·13	7·97
Chloroform	4·32	4·44	4·89	4·88	31·9
Methyl iodide	5·05	3·51	5·18	4·80	72·0
Carbon tetrachloride ...	5·31	5·34	5·83	5·67	45·3

The determinations for the γ rays are less accurate than the former ones for the α and β rays, on account of the very much smaller rates of leak which have to be measured. I think, if this be taken into account, there is no reason to doubt that, within the limits of experimental error, the γ rays give the same values as the β rays. These values are nearly proportional to the density of the gas, except in the case of hydrogen. The law which holds in the case of Röntgen rays is totally different.

This conclusion throws some light on the nature of the β rays. The view seems to be gaining ground that these are Röntgen rays, produced by the impact of the β rays on the radium itself.[1] This theory seems to have much to recommend it. The β rays should, by analogy with the kathode rays in a vacuum tube, produce Röntgen rays when they strike a solid obstacle, and these Röntgen rays should be much more penetrating than the β rays themselves. The γ rays seem at first sight to be just what should be expected. But the present paper shows that in one respect, at all events, the γ rays behave quite differently from Röntgen rays, while, on the other hand, they resemble the α and β rays. There seems to be a possibility that they too are of a corpuscular nature, though uncharged with electricity. This would account for the absence of magnetic deflection.

I do not think that the absence of conspicuous Röntgen radiation is very hard to understand, if we consider that the current emitted in kathode rays by a square inch of intensely active radium is only 10^{-11} amperes; the current through a focus tube is of the order 10^{-3} amperes, and probably a great part of this is carried by the kathode rays.

[1] See, for instance, Madame Curie, "Thèses presentées à la Faculté des Sciences," 1903, p. 83.

THE COLORATION OF THE QUAGGAS.

IT is well known that, in different districts of their range, the zebras of the type commonly known as Burchell's, but which, for reasons elsewhere given, I propose to call "quaggas," present distinct and easily determinable colour variations, sufficiently constant in character to be worthy of nominal recognition. Grant's quagga occurs in North-East Africa, Crawshay's quagga in Nyasaland, Selous's quagga in Rhodesia, and Chapman's quagga in Angola. Still further south came Burchell's quagga, and south of this again the two or more extinct types which, as Mr. Lydekker has shown, pass currently as the quagga proper.

The first and last of this category are the extremes in pattern variation. Grant's quagga may claim to rank as one of the most completely striped of existing horses. Apart from the ears, which are sometimes nearly white, and the muzzle and fetlocks, which are usually black, he is a mass of stripes from head to tail, from hoof to spine; and in sharpness of contrast between the blackness of the stripes and the whiteness of the interspaces, he rivals the Abyssinian race of Grévy's zebra and the Angolan race of the mountain species, while surpassing both in the inferior extension of the stripes to the middle line of the belly. Place him alongside Gray's quagga, with his pale stripeless limbs, underside and hind-quarters, his brown and confusedly banded body and fawn-lined neck and head, and you will hardly believe them to be the same species. Yet there is no avoidance of the conclusion, since all intermediates have been seen either as living specimens or mounted skins. And one of the chief interests centred in the existence of these intermediates lies in the progressiveness of the change this species undergoes as it passes from north to south over its geographical area. Even in British and German East Africa the pale interspaces on Grant's quagga begin to be washed with brown, and to be filled in with narrower intervening stripes. It will be difficult, perhaps impossible, to distinguish such forms from the quagga of the Mashonaland plateau. The latter, indeed, may be taken as illustrative of the first step in the change above alluded to leading from Grant's to Gray's quagga. From it may be traced a series of gradations represented by the local races named after Chapman, Wahlberg, and Burchell, in which the stripes gradually disappear and thin out upwards from the fetlocks to the shoulders and haunches, while those on the body lose their connection with the mid-ventral band, and, becoming shorter, leave the belly unstriped. Concomitantly the intervening "shadow" stripes increase in number and definition as they extend forwards towards the neck, the normal stripes themselves turn brown, and the ochre-stained ground colour deepens in hue. In the typical form of Burchell's quagga the "shadow" stripes reach the head, and the last of the complete stripes is the one that extends backwards from the stifle to the root of the tail, the hind-quarters and legs being practically, and the belly actually, stripeless. It is but a step from this to the extinct Gray's quagga, in which the stripes of the body were fused together and blended to a great extent with the brown of the intervening areas, those on the neck being exceedingly broad and broken up by paler tracts of hair.

The tendency of these modifications is to convert a striped and conspicuously parti-coloured animal into one which, even at a short distance, must have appeared to be an almost uniform brown, paling into cream on the underside, limbs and back of the haunches. What is the meaning of this change? Inferentially we may conclude it was protective in the sense of subserving concealment.

The testimony of observers in the field has established the truth that the coloration of the coat renders a zebra invisible under three conditions, namely, at a distance on the open plain in midday, at close quarters in the dusk and on moonlit nights, and in the cover afforded by thickets. The procryptic result is achieved by the cooperation of several factors. The white stripes blend with the shafts of light sifted through the foliage and branches and reflected by the leaves of the trees, and in an uncertain light or at long range they mutually counteract each other and fuse to a uniform grey. It is probable, too, that the alternate arrangement of the black and white bars contributes something to the effect produced, by imparting a blurred appear-

ance to the body and destroying the evenness of its surface owing to the difference in light-reflecting power between hairs of these hues to which domestic horses bear witness. Moreover, the extension of the stripes to the very edge of the body and legs breaks up the continuity of the outline, and this, I believe, is the reason for the alteration in their direction on the hind-quarters and limbs, so that, except on the forehead, the whole animal is barred transversely with reference to its spinal and appendicular axes.

We have also the positive assurance of observers that the asses of the deserts of North-East Africa are perfectly adapted to their surroundings in colour, and no one can doubt that the assimilation is equally perfect in the case of the kiang and Prjevalsky's ponies[1] of Central Asia. In the matter of colouring the kiang forcibly recalls the typical quagga, despite a decided difference in the deepness of the brown pervading the upper parts in the two species. Notwithstanding this difference, there can, I think, be no question that the explanation to be given of the significance of the colours of the kiang applies with equal truth to the quagga. This explanation is the hypothesis of the counteraction of light and shade put forward by the American artist, Thayer.

It would be hard to find a better and simpler instance of this style of coloration than the kiang. The upper parts on which the light falls are of a rich ruddy hue, darker than ordinary sand, while the muzzle, the lower side of the head, the throat and the belly are creamy white. Surely no one with a knowledge of the truth enunciated by Thayer will

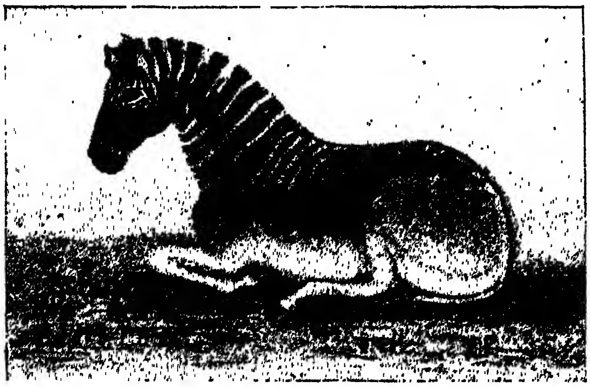

FIG. 1.—Gray's Quagga lying, to show the unbroken continuity of the white on the underside.

dispute that the arrangement and nature of the colours in the kiang must render it practically invisible when standing in the desert at a distance. But this is not all. Why are the legs, or at least the greater part of them, and the backs of the thighs up to the root of the tail also white? This is doubtless the reason. When the kiang rests on the ground in the attitude characteristic of ungulates, with the hind-quarters depressed, the fore-legs folded and the hind-legs tucked in close to the body, the white on the back of the thighs is brought into line with that of the belly, and a continuous expanse of white, obliterating the shadow, extends all along the underside from the knee to the root of the tail. So, too, with the quagga. This, then, is the meaning of the change in pattern presented by the African species as it passed southwards into Cape Colony. In correlation with the adoption of a life in the open, a new method of concealment by means of shadow counteraction was required, and was gradually perfected by the toning down of the stripes on the upper side and the suppression of those on the hind-quarters, belly and legs.

The same alignment of the white on the rump and belly may be seen in many antelopes, like gazelles, and the co-operation of the legs in increasing the underlying area of white is especially well shown in the bonte-bok.

Now the rump-patches, be it noted, only subserve the purpose here suggested when the animals that possess them are lying on the ground. This, however, is the time, as they drowsily rest or chew the cud, when concealment is of the greatest importance to ungulates, which are, for the most part, clumsy risers, and slow at getting under way. When standing and on the alert, their need for concealment, though seldom absent, is certainly less, and when they are on the run all idea of it is thrown to the winds. It is then that the rump-patches act, as Mr. Wallace suggested, as danger signals and "follow-the-leader" marks, showing the young and inexperienced which way to go, and helping the members of a herd to foregather in the dark when dispersed by the panic of a night attack.

The pattern of a zebra, in its entirety, is also believed by Mr. Wallace to have a double significance analogous to the above. It is known to be procryptic; but he holds that it acts as a badge of recognition, enabling the zebras to distinguish their own kind amongst the herds of other beasts that may be feeding in the same place. It may be so; for although seemingly contradictory, the two explanations are not mutually exclusive. The procryptic effect of the pattern is largely a matter of distance and light. At close quarters in broad daylight a zebra is conspicuous unless under cover, and the colouring is strikingly unlike that of other animals. On the other hand, it must be remembered, as I have elsewhere pointed out (NATURE, October 11, 1900), that the species, like wildebeests, zebras, spring-buck, or even ostriches, which formerly at all events fed together upon the veldt,[1] are so dissimilar in size and shape that the need for a distinctive type of coloration to prevent the postulated likelihood of specific confusion can hardly have been a sufficiently important factor in survival to have guided the evolution of the colour for the purpose supposed. And since we have evidence of the best kind that the pattern of zebras and quaggas is procryptic, it seems unnecessary to look further for its explanation.

R. I. POCOCK.

1 A suspicious inconstancy about their coloration inclines me to the opinion that these ponies are the descendants of "runaways."

1 These odd friendships are a great puzzle; but perhaps the following suggestions may throw some light upon their occurrence and use. It is unlikely in the extreme that all the species concerned have their sense organs developed to an equal pitch of excellence. In one the sense of smell, in another the sense of sight, in a third the sense of hearing will be pre-eminently keen. Hence the sensory imperfections of one species will be made good by the proficiencies of the others; and each will be benefited by the association. Ostriches, for instance, in virtue of their stature and long sight, will see an enemy in open country at a much greater distance than will zebras or gnus, and will give the alarm by starting to run. Zebras, on the other hand, will scent a lion creeping up under cover long before the ostriches will see him; and by making off will warn these birds and other duller scented members of the incongruous assemblage that danger is afoot.

AGRICULTURAL NOTES.

IN the recently published number of the *Journal* of the South-eastern Agricultural College, Wye, Mr. Theobald gives an account of some injurious flea-beetles (Halticæ) which he has recently studied. He finds that the damage ascribed to the turnip "fly" (*Phyllotreta nemorum*) is very often due to related genera. A troublesome attack of the "fly" at the College farm drew attention to a new culprit, *Haltica oleracea*, and in observations made in Yorkshire, Cambridge, Huntingdon, Surrey, Kent and Devon, this species was found to be much more destructive than *P. nemorum*. The characteristics of five injurious genera are described, and observers are asked to collect and report upon these very destructive insects. Mr. Theobald's experience leads him to remark that "The present economic entomologist relies on the past economic entomologist, and so errors go on until they really seem facts. . . . John Curtis wrote the most excellent article on the turnip flea that can be imagined, and we have all copied it." Mr. Theobald's request for "serious reporting and collecting" should appeal to a wider circle than is reached by the College *Journal*. The entomologist is not the only worker who relies on the achievements of the past, nor is economic entomology the only branch of applied science that may learn something from this study of the Halticæ.

In the same number Principal Hall, until recently head of the College, summarises the results of manurial experiments on the hop, which have been carried on at various centres for from three to eight years. He concludes that the hop plant is "an all-round feeder," in this respect differing from such crops as swedes, which depend mainly on phosphates, and from potatoes, which must be liberally dressed with potassic manures. No one special manure can

be recommended to hop-growers; the first point in successful management must be to ascertain and make good the manurial deficiencies of the particular soil. In some cases phosphates, and in others potash, may be found profitable as an addition to a dressing of a nitrogenous manure. Specific instructions are given for the manuring of the Farnham hop soils.

To part i. vol. v. of the *Journal* of the Khedivial Agricultural Society, one of the editors, Mr. E. P. Foaden, contributes an article on "Manures in use in Egypt." With the rapid advances made in the material welfare of the country, and the increased use of irrigation, there has been "an extraordinary increase in the value of land," and the subject of suitable manures for use in intensive cultivation is a pressing one. Nile mud, upon which the cultivators have so largely depended in the past, has been proved by experience to be insufficient, and by analysis to lack nitrogen, though supplying an abundance of potash for most, and of phosphate for many, crops. The supply of farmyard manure is very inadequate. In Egypt as in India, the lack of wood leads to the use of dried cow-dung cakes for fuel. Pigeon manure forms a concentrated fertiliser extensively used in Upper Egypt, and dried sewage is becoming popular. Two interesting natural products are mentioned; one, *Coufri*, is a manure collected on ancient village sites, but it is of low quality, seldom containing more than 0·5 per cent. of nitrogen; the other, known as *Marog* or *Tafia*, is a blue clay or a marl found in hills in the deserts in Upper Egypt. This is an important manure in common use in parts of Upper Egypt, and of great value to the country. Analyses of seven samples are quoted, and these show that *Marog* contains notable quantities (from 2·5 to 24 per cent.) of nitrate of soda, associated with which is common salt. The percentage of salt in the analyses quoted varies from 6·8 to 21·5, but there is no constant relation between the salt and nitrate of soda. It is suggested that *Marog* might be treated so as to yield commercial nitrate of soda. In its present crude form the heavy cost of transport prevents the use of *Marog* in Lower Egypt. The article deals briefly with common artificial manures such as nitrate of soda, sulphate of ammonia and superphosphate, all of which are now being imported into Egypt for application to cotton, sugar-cane, and the more valuable cereal and market-garden crops.

When the "Sale of Milk Regulations" came into force in September, 1901, the standard of 3 per cent. fat and 8·5 per cent. non-fatty solids required by the Board of Agriculture was regarded as being very low, and the opinion was freely expressed that the milk of well-fed, healthy cows was rarely so poor in quality. It has since been shown that milk is more variable in composition than was formerly supposed, and that a sample representing a single milking may frequently contain a smaller percentage of solids than is required by the Board's regulations. When milk is drawn at equal intervals, the mixed milk of a herd of cows will usually be satisfactory, but if the milk of the individual cows be tested, it will be found to show wide, and at present inexplicable, variations. On this question some experiments have recently been made by Messrs. Dymond and Bull at Chelmsford, under the auspices of the Essex Technical Instruction Committee. The experiment consisted in testing, twice daily, the milk of six shorthorn cows which were housed, fed and milked under careful supervision and under favourable conditions. Two of the cows were under observation for short periods only. The following figures show the number of times on which the milk of the others failed to reach the standard:—

	Average daily yield lbs.	No. of milk analyses	Fat deficient	Non-fatty solids deficient
Cow I. ...	30·8 ...	206 ...	8 times ...	68 times
,, II. ...	28·8 ...	206 ...	117 ,, ...	52 ,,
,, III. ...	16·6 ...	156 ...	1 ,, ...	0 ,,
,, IV. ...	18·8 ...	206 ...	0 ,, ...	0 ,,

The first two animals were in full milk, having calved six weeks before the test began; the other cows had calved eight months, and were beginning to go dry. The feeding was varied in the course of the experiments, and on several occasions the animals were exposed to low temperatures, but the milk was little, if at all, influenced. The quality depended on the cow, not on the conditions under which she was kept. The mixed milk did not fall below standard during the experiments, but the analyses given indicate that when a herd is largely composed of newly-calved cows the milk *may* frequently fall below standard.

An illustrated article in a recent number of the *Scientific American* describes scientific poultry raising as practised on the largest poultry farm in the States (at Sidney, Ohio). On this farm 3000 Leghorns supply on an average 200 dozen unfertile eggs for culinary purposes *per diem*, and 900 Plymouth Rocks produce 450 eggs daily, which the hatchery—a building 480 feet long—converts into 300 healthy chicks. The chicks, when a day old, pass to the "nursery," and spend a month in this building, which is capable of holding 6000 at a time. They then pass to a second building, where they remain until three months old. The chickens are not allowed to mix, but are divided up into small colonies, so that if anything goes wrong the mischief is prevented from spreading. The hens are provided with automatic nests, so constructed that the egg is removed as soon as it is laid; the new-laid eggs are thus collected at once, and are washed, dated, and placed in refrigerators for transport, so that they reach their destination absolutely fresh. Electric light is employed in the testing of eggs, and the progressive poultryman, assisted by the researches of the U.S. Department of Agriculture, feeds his fowls on the most approved principles. The net result of science in the poultry yard is a "marvellous development of the incubator industry" and of the poultry business. It is stated that one town in Illinois turns out more than 50,000 incubators a year. Among leading poultry farms are mentioned those of ex-President Cleveland and of President Diaz, of Mexico.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Royal Commissioners for the Exhibition of 1851 have made the following appointments to science research scholarships for the year 1903, on the recommendation of the authorities of the several universities and colleges. The scholarships are of the value of 150*l.* a year, and are ordinarily tenable for two years (subject to a satisfactory report at the end of the first year) in any university at home or abroad, or in some other institution approved of by the Commissioners. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country. The nominating institutions and the scholars are as follows:—University of Glasgow, A. W. Stewart; University of St. Andrews, D. McLaren Paul; University of Birmingham, N. L. Gebhard; Yorkshire College, Leeds, R. Gaunt; University College, Liverpool, J. F. Spencer; University College, London, H. Bassett; Owens College, Manchester, L. Bradshaw; Durham College of Science, T. P. Black; University College, Nottingham, G. Tattersall; University College, Sheffield, Catherine Radford; University College of North Wales, Bangor, K. J. Thompson; Royal College of Science, Dublin, S. A. Edmonds; Queen's College, Belfast, T. B. Vinycombe; McGill University, Montreal, H. L. Cooke; University of Sydney, A. Boyd. The following scholarships granted in 1902 have been continued for a second year on receipt of a satisfactory report of work done during the first year:—University of Edinburgh, J. K. H. Inglis; University of Glasgow, A. Wood; University of Aberdeen, A. C. Michie; University of Birmingham, J. A. Lloyd; Yorkshire College, Leeds, H. D. Dakin; University College, Liverpool, F. Rogers; University College, London, E. P. Harrison; Owens College, Manchester, G. C. Simpson; Durham College of Science, C. R. Dow; University College, Sheffield, G. B. Waterhouse; Queen's College, Galway, W. Goodwin; University of Toronto, W. C. Bray; Dalhousie College, Halifax, Nova Scotia, T. C. Hebb; University of Melbourne, R. Hosking; University of New Zealand, M. A. Hunter. The following scholarships granted in 1901 have been exceptionally renewed for a third year:—Yorkshire College, Leeds, R. B. Denison; University College, London, G. Owen; University College of London, Dr. G. Senter; University College of North Wales, Bangor, Alice

E. Smith; McGill University, Montreal, R. K. McClung; Queen's University, Kingston, Ontario, Dr. C. W. Dickson.

THE August number of the *Fortnightly Review* contains the ninth of the series of essays by Mr. H. G. Wells, entitled "Mankind in the Making," the subject being the organisation of higher education. Among many other important considerations, the suggestions made for "suitable arrangements of studies that can be contrived to supply the essential substantial part of the college course" are of particular interest. The first such course proposed is an expansion of the physics of the school stage, which may be conveniently spoken of as the natural philosophy course. "Its backbone will be an interlocking arrangement of mathematics, physics, and the principles of chemistry, it will take up as illustrative and mind-expanding exercises, astronomy, geography, and geology conceived as a general history of the earth. Holding the whole together will be the theory of the conservation of energy in its countless aspects and a speculative discussion of the constitution of matter." The second course "is what one may speak of as the biological course. Just as the conception of energy will be the central idea of the natural philosophy course, so the conception of organic evolution will be the central idea of the biological course. A general review of the whole field of biology—not only of the natural history of the present but of the geological record—in relation to the known laws and the various main theories of the evolutionary process will be taken, and in addition some special department, either the comparative anatomy of the vertebrata chiefly, or of the plants chiefly, will be exhaustively worked out in relation to these speculations." The other two college courses proposed are named classical and historical respectively. Of a purely mathematical course Mr. Wells writes, "few people, however, are to be found who will defend the exclusively mathematical 'grind' as a sound intellectual training, and so it need not be discussed here." Educationists who study the paper will find in it much material for thought.

THE Home Counties Nature-Study Exhibition will be held at the offices of the Civil Service Commission (formerly the buildings of the University of London), Burlington Gardens, London, W., on October 30–November 3.

MR. ANDREW CARNEGIE has presented to Dunfermline, his native town, the sum of half a million sterling in Steel Trust bonds, to be employed, among other purposes, for the advancement of technical education in the district, which is the centre of the linen industry in Scotland.

M. ANDOYER has been appointed professor of physical astronomy, and M. Painlevé professor of general mathematics, at the University of Paris. M. Padé, of the University of Poitiers, has been appointed professor of mechanics at the University of Bordeaux, and M. Lebœuf professor of astronomy at the University of Besançon.

THE opening address of the Edinburgh summer meeting was delivered on August 4 by Sir John Murray, who reviewed the history of the meetings, and explained that this year the special subject for study was Edinburgh and its region. The chief object of the course of study arranged was to train teachers of nature-study in accordance with the present requirements of English and Scottish schools. Sir John Murray gave it as his opinion, at the conclusion of his address, that "the great battles of the future would be not between man and man, but a struggle for possession of the forces of the earth; and no nation could hope to keep in the forefront if it were not continually making additions to the sum total of human knowledge."

AN Agricultural Education Bill was introduced in the House of Commons by Mr. Collings on August 6. It is similar to the one which passed the second reading in 1895. The object of the Bill is to provide for the teaching in elementary schools of agricultural and horticultural subjects, to give facilities for nature-studies, and generally to cultivate habits of observation and inquiry on the part of the pupils. To this end the Bill provides for school gardens and such collections of objects as may be necessary for practical illustration. The education specified in the Bill is to be compulsory in all schools in rural and semi-rural districts. The Bill cannot be proceeded with this session.

THE prospectus of the Department of Education at Owens College, Manchester, for the session 1903–4, has now been published, and gives full particulars of the courses of training provided for teachers in primary and secondary schools. The instruction received by primary school teachers is for the most part of an undergraduate standard, while that for teachers in secondary schools is of a post-graduate character. Special lectures are provided for those who are already engaged in teaching, and opportunities will be offered of individual study and research in education without reference to any preparation for a diploma or certificate. Among the public lectures arranged in connection with the department are one by the new Sarah Fielden professor—Dr. Findlay—on training for the teaching profession, and one by Prof. M. E. Sadler on the need for scientific investigation in education.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 18.—"Separation of Solids in the Surface-layers of Solutions and 'Suspensions.'" Preliminary Account. By W. **Ramsden**, M.A., M.D., Oxon., Fellow of Pembroke College, Oxford.

In this paper it is shown that the free surfaces of a large number of colloid solutions become coated with solid particles derived from the solutions under conditions excluding evaporation, or chemical change due to the gases in contact with the free surfaces. This is the case not only with proteid solutions of every kind, but also with solutions of certain aniline dyes, soaps, saponin, methyl orange, colloid ferric hydrate, &c. These surface coatings give rise to an intense viscosity confined to the surface layers and absent from the bulk of the solutions. In some cases the solid particles become mutually coherent to form a solid membrane, and then cause an intense superficial resistance to "shear." A magnetised needle floating on the surface of a colloid solution as limpid as water may be in some cases so rigidly fixed that it rotates the vessel containing the solution if this be suspended by a thread and a magnet be brought near.

By simple mechanical means, adapted to produce heaping up of any surface coatings, masses of solid material can be separated from all these solutions—in some cases when they contain only one part of dissolved solid in a million. Various solids can in this way be completely removed from solution without filtration, addition of chemicals, or necessary alteration of temperature. The "mechanical coagula" described by the author some years ago are simply heaped-up surface membranes of solid proteid.

These accumulations at the free surfaces are explained by the observation that the dissolved substances are always such as possess the property of diminishing the surface-tension of the free surface of water. The most stable mechanical arrangement of such solutions must involve a relative concentration of the dissolved substance at any surfaces the surface-tension of which can be thereby diminished, and in some cases the formation of a coating of de-soluted solid completely separating the solution from the adjacent medium.

Every limpid solution capable of forming unusually persistent thin films or bubbles yields solid or highly viscous "mechanical surface aggregates," and is therefore regarded as having a surface coating of solid or highly viscous matter. On some of these bubbles the presence of a coherent surface membrane can be directly demonstrated by their behaviour on collapse. Unusual persistence of a thin film derived from a limpid solution is invariably associated with the presence of solid or highly viscous particles on its free surfaces. Particles of this nature and in this situation would act partly by serving as *points d'appui*, partly by offering mechanical resistance to deformation of the surface, and partly, in virtue of their effect upon the "surface energy," by calling out resistance to such deformation as would expose a fresh surface of greater "surface-tension."

Precisely similar phenomena are met with at the interfaces of certain immiscible liquids one of which is a solution, and the great persistence of many emulsions is due mainly to the accumulation of solid or highly viscous particles at the interfaces of the two liquids.

Superficial resistance to "shear," the capability of yielding "mechanical surface aggregates" and "coagula," the possession of marked bubbling-power, and the formation of very persistent emulsions by certain limpid liquids, are all explained as due to the accumulation of certain substances in a solid or highly viscous condition at the surfaces concerned, and to the physical properties of the matter thus accumulated.

PARIS.

Academy of Sciences, August 3.—M. Albert Gaudry in the chair.—The relations between multi-fluid batteries, by M **Berthelot.**—Remarks concerning the relations between batteries formed of the same liquids, between two different or identical electrodes, by M. **Berthelot.**—On a double carbide of chromium and tungsten, by MM. Henri **Moissan** and A. **Kouznetzow.** A double carbide of chromium and tungsten of the formula $CW_2.3C_2Cr_3$ has been prepared by two different methods. It is similar to analogous compounds indicated by MM. Carnot and Goutal as existing in metallurgical products. The carbide is very stable, not attacked by acids or by ordinary reagents, and is remarkable for its extreme hardness, scratching quartz and topaz with ease. It is possible that this compound may be formed by the addition of tungsten to chrome steels, and may be the cause of some of the special properties of these steels.—Does arsenic exist in all the organs of the animal economy? by M. Armand **Gautier.** A review of the work done on this question since the author's first memoir in 1899, together with a minute study of the influence of arsenic in the reagents on the results.—The addition of hydrogen to aldehydes and ketones by catalysis, by MM. Paul **Sabatier** and J. B. **Senderens.** The direct action of hydrogen in presence of reduced nickel at a low temperature readily transforms aldehydes and ketones into the corresponding alcohols. The method possesses the advantage of furnishing the alcohols free from secondary products, and in high yields.—The residue of secular perturbations, by M. Jean **Mascart.**—On quasi-periodic functions, by M. **Esclangon.**—On the functions of *n* variables represented by series of homogeneous polynomials, by M. H. **Dulac.**—On the integrals of S. Lie, by M. N. **Saltykow.**—On the changes in phase resulting from the normal reflection in quartz on silver, by MM. J. Macé **de Lepinay** and H. **Buisson.**—A description of an instrument designed to measure accurately the optical constants of microscope objectives and eye-pieces, by M. V. **Legros.**—On telekine, by M. L. **Torres.** The name telekine is applied by the author to a system of a spring and governor, controlled from a distance by wireless telegraphy. Among the applications suggested by the author as possible are the direction of submarine torpedoes and of balloons.—New laws of tonometry, deduced from Raoult's experiments, by M. E. **Wickersheimer.**—Pressure curves of univariant systems containing one gaseous phase, by M. A. **Bouzat.** Four groups of univariant systems are distinguished, for which it is found that the ratio of the absolute temperatures corresponding to a given pressure in any two systems of the same group is constant for any value of the pressure. This is equivalent to the proposition that the variation of entropy resulting from the liberation of one molecule of gas under a given pressure has the same value for all systems in one group.—The estimation of pyridine in aqueous solution, by M. Maurice **François.** The method is based on the formation of the chloroaurate, $C_5H_5N.HCl.AuCl_3$, and its insolubility in ether. The chloroaurate is ignited, and the amount of pyridine deduced from the weight of gold left.—On secondary amides, by M. **Tarbouriech.** By the action of acid chlorides upon primary amides in sealed tubes at 110°–115°, several mixed secondary amides have been prepared, the physical and chemical properties of which are given.—The reduction of the ethereal salts of acids of complex function, by MM. L. **Bouveault** and G. **Blanc.**—The action of phenyl hydrazine on alkyl bromides and iodides, by M. J. Allain **Le Canu.**—Thermochemical researches on colouring matters. Rosaniline and pararosaniline, by M. Jules **Schmidlin.**—On the estimation of ammonia in wine and its use in differentiating *mistelles* from liqueur wines, by M. J. **Laborde.**—On the salol ferment present in certain samples of milk, by M. A. **Desmoulière.** Remarks on a paper on the same subject by MM. Miele and Willem.—On the properties and chemical composition of the phospho-organic reserve material of plants containing chlorophyll, by M. S. **Posternak.** It is shown that the phospho-organic reserve material of green plants possesses characteristic properties by means of which it can be easily differentiated from other phosphorus compounds already known.—Excretion in hydroids, by M. A. **Billard.**—The mechanical laws in the development of the skull of Cavicornes, by M. U. **Duerst.**—The digestive apparatus of the Silphidæ, by M. L. **Bordas.**—On the Heteropods collected during the voyages of the *Hirondelle* and the *Princesse Alice*, made under the direction of the Prince of Monaco, by M. A. **Vayssière.**—Sections of the Tertiary strata of Patagonia, by M. André **Tournouër.**—On the geological constitution of the district of Mirsa Matrouh, by M. D.-E. **Pachundaki.**—The sensitisers of the tubercle bacillus, by MM. J. **Bordet** and O. **Gengou.**

NEW SOUTH WALES.

Royal Society, June 3.—Mr. F. B. Guthrie, president, in the chair.—Language of the Bûngandity Tribe, South Australia, by Mr. R. H. **Mathews.** The paper dealt with the grammatical structure of the aboriginal tongues of the tribe. The author also briefly referred to the social organisation of South Australian tribes from the Lake Eyre basin to Port Lincoln and Mount Gambier.—Notes on tide gauges, with description of a new one, by Mr. G. H. **Halligan.** The author gave a brief history of the development of the automatic tide recorders, and exhibited a new gauge of his own design.

RIVER IMPROVEMENT.

The Improvement of Rivers. A Treatise on the Methods Employed for Improving Streams for Open Navigation, and for Navigation by means of Locks and Dams. By B. F. Thomas and D. A. Watt, U.S. Assistant Engineers, Members Am. Soc. C.E. Pp. xiv+356. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 25*s*. 6*d*. net.

IN their preface the authors state that they know of no recent book which treats of the improvement of rivers except in a general way, possibly because they seem not to be aware of the existence of a book, "Tidal Rivers," published in 1893, and have not apparently heard of the issue of a second edition in 1896, rewritten and enlarged, of "Rivers and Canals," from the first edition of which, published in 1882, they quote a long extract on the principles which should govern the improvement of tidal rivers. Undoubtedly, if the authors of these two books had confined their attention to the rivers of the United Kingdom, there would have been little matter in them properly applicable to American practice, owing to great differences in the physical conditions of the two countries; but both these books range over a very wide field, and deal with the improvement of rivers in various parts of the world, including, of course, rivers in the United States. Though, however, there is not such a complete dearth of books describing the methods of improvement of rivers with extensive basins, as the authors intimate in their preface, and on account of which they express the hope that their book will supply a much needed want, it is certain that the detailed descriptions of American methods and experience relating to the regulation and canalisation of large non-tidal rivers, will be of great service, not merely to those engaged in such works in the United States, but also to all engineers who have to deal with large problems of river improvement in countries containing vast drainage-areas, as met with in eastern Europe, Asia, Africa, and Australia, as well as in North and South America.

The largest river-basin of the United Kingdom, that of the Thames, with an area of only 5244 square miles, owing to the comparatively restricted extent of the British Isles, sinks into insignificance when compared with the Mississippi, having the largest drainage-area of the rivers of North America, amounting to 1,244,000 square miles, which, in its turn, is exceeded by two river-basins in South America, namely, the La Plata with a basin of 1,600,000 square miles, and the Amazon with a basin of about 2,250,000 square miles, the largest in the world. Accordingly, there is little scope in the United Kingdom for regulation works, and even for canalisation, which have enabled inland navigation to be considerably improved and extended along the large rivers of North America. On the other hand, there have not been the same opportunities in America for the great increase in depth of small tidal rivers, by dredging and training works, affording access to seaports, as has been effected in Great Britain in the Tyne, the Clyde, and the Tees, though access for sea-going vessels has been extended from Quebec to Montreal by dredging in the St. Lawrence; whilst the most important works carried out in the United States at the outlet of a river, are the parallel jetties which were constructed several years ago in extension of the South Pass of the tideless and deltaic Mississippi, across the bar encumbering its mouth, in order to concentrate the scour over the bar and thus deepen the outlet channel.

The authors deal very briefly with the improvement of river outlets in a single chapter of only ten pages, stating that this important subject would require a volume; and after quoting at full length the principles laid down by an English engineer for the improvement of tidal and non-tidal river outlets, and alluding to the experiments with working models, carried out by the same engineer, on the effects of training works in tidal estuaries, they refer to the method of improvement by jetties, and conclude with a short account of the jetty works completed at the outlet of the South Pass in 1879, and those authorised last year for obtaining a navigable depth of 35 feet at the outlet of the South-West Pass of the Mississippi. The book, accordingly, really relates to the improvement of the inland portions of large rivers for navigation by regulation works or canalisation, in which the authors, as assistant engineers in the Government Department of the United States, which has control of all the rivers, have wide practical experience, and for which the book furnishes a very valuable guide. This large quarto volume, with 349 pages of text, and illustrated by numerous pages of drawings, diagrams, and photographic reproductions dispersed throughout the book, and eighteen plates of detailed drawings at the end, together with a few blocks in the text, deals with the improvement of rivers in three distinct parts; the general characteristics of rivers and their surveys being considered in the first part, the improvement of open rivers in the second part, and the improvement of rivers by canalisation in the third part.

The first part is divided into five short chapters, occupying only forty pages altogether, treating respectively of introductory matters, the characteristics of rivers, preliminary examinations and surveys, topographical surveys and levelling, and hydrographic surveys. This part is mainly concerned with the preliminary data which require to be obtained before undertaking works of improvement, namely, the physical features of the river, consisting of the amount of the rainfall and the size of the river-basin, the fall and nature of the river-bed, the sediment brought down, shoals, bars, and changes in water-level; next, surveys of the course of the river; and, lastly, cross-sections of the channel, and measurements of the discharges over weirs and in the unimpeded channel.

The second part is divided into seven chapters, and covers ninety-one pages, dealing successively with the "Removal of Bars and other Obstructions," "Regularisation," "Dykes and their Effects," "Protection of Banks," "Levees," "Storage Reservoirs," and "Improvement of River Outlets." The first of these chapters relates to the various devices attempted

for stirring up the materials of bars and shoals so as to effect their removal by the current, the different types of dredgers and their capabilities, and the clearing away of trunks of trees, termed snags, and wrecks from the navigable channel. The most interesting work in this respect is the formation each year, during the low stage of the Mississippi, of a channel for navigation, about 250 feet wide and 9 feet deep, across sandy shoals in certain places by suction dredgers, the efficiency of which is increased by stirring up the sand with water-jets; and in 1899 five of these dredgers cut about 62 miles of channel at the average rate of 105 lineal feet per hour. The second chapter of this part lays down the general principles on which the regulation of river channels is based, with the object of obtaining greater uniformity of depth; whilst the following chapter describes the construction of spur and longitudinal dykes, which are sometimes submerged, by which the regulation is effected, a system which has been successfully applied to several of the larger rivers of Europe, as well as in America.

The protection of banks aims mainly at the prevention of prejudicial changes in the course of a river by the erosion of the concave banks in flood-time; and it is accomplished by pitching, rubble stone, fascines, brush mattresses, or occasionally submerged spurs. Levees, consisting of earthen embankments, formed along the banks of a river to prevent the river from inundating the riparian lands in flood-time, are rather works for the protection of property than for river improvement; but to effect their purpose they must be watertight, continuous, and have their tops above the highest floods, which necessarily have their water-level raised by being confined within the banks. Several rivers in Europe have been controlled by embankments, notably the Po, the Loire, and the Theiss; and levees have been extensively carried out on the Mississippi below Cairo and some of its tributaries, the total expenditure on these works in the United States being estimated at about 10,000,000*l*., up to the present time, for a length of 1436 miles; whilst considerable additions to the Mississippi levees are projected. These embankments, however, are liable to be occasionally overtopped and breached by an exceptional flood; and in alluvial plains, as in the case of the Mississippi, they are exposed to undermining by changes in the course of the river, in spite of regulating works; and the rush of water through the gap formed in the bank produces considerable devastation over the adjacent low-lying lands. Rivers bringing along large quantities of detritus in their torrential flow down steep mountain slopes, and abruptly emerging into flat plains, are liable to raise their beds by the deposit of sediment, owing to loss of velocity, when confined within embankments, a result which occurs in the Yellow River of China and some Japanese rivers; and under such conditions, when the embankments are successively raised to compensate for the rising of the river-bed, a terrible catastrophe is a mere question of time, due to the precipitation of the raised and imprisoned river through a weak place in the embankments, with irresistible force and rapidity, into the plains below.

The chapter on "Storage Reservoirs" consists almost entirely of extracts from a report by Captain Chittenden on "Reservoir Sites in Wyoming and Colorado," a method of compilation employed in several of the earlier chapters, though to a minor extent, and also in the following chapter on river outlets, already referred to. Reservoirs would be valuable in river valleys in serving, like lakes, for regulating the flow of rivers by reducing the flood discharge and augmenting the low-water flow. It is, however, only under exceptional conditions that reservoirs can be formed extensive enough, at a reasonable cost, to increase materially the flow of a river at its low stage; but this has been accomplished by damming the outlets of some lakes near the sources of the Volga and Msta in Russia, extending the navigable period of those rivers by nearly three months; whilst a similar improvement has been effected in the Upper Mississippi by raising the water-level of several lakes near the head-waters of the river, a system which might be considerably extended in this case, owing to the immense number of lakes existing near its sources. The formation of reservoirs at intervals along a river valley would greatly reduce the flood discharge by impounding the flood-waters, but the conditions are rarely favourable; and the cost of construction, and the extent of land submerged, present insuperable obstacles to the adoption of this system, merely for the mitigation of floods, in the great majority of cases. Several reservoirs, however, have been constructed in Europe for storing up water for water-power for industrial purposes, as well as for the mitigation of floods, with successful results, as, for instance, the Furens and Ternay reservoirs in France, and the Dahlhausen reservoir on the Wappen in Germany, the provision for floods being effected by keeping the reservoir drawn down to a definite extent below its full water-level for their reception.

The third part, relating to the canalisation of rivers, occupies one hundred and forty-one pages, or rather more than half the regular text of the book, and is divided into ten chapters, the three first dealing with locks and lock gates, the fourth with fixed dams on rivers, and the remainder with the various types of movable weirs, which constitute the more novel and most interesting portion of the subject. Though the first movable weir appears to have been the bear-trap weir erected in 1818 across the Lehigh River in the United States, consisting of two gates or shutters turning on horizontal axes on the sill, and one resting on the edge of the other, the principal types of movable weirs were gradually introduced in France between 1834 and 1885; and most of these French forms have been reproduced, on a larger scale, on some of the rivers of the United States; whilst the American bear-trap weir was adopted, with improvements, at Laneuville-au-Pont on the River Marne, in France, about the middle of the nineteenth century.

The object of these movable weirs is to leave the channel of a river quite unimpeded in flood-time for the passage of the flood discharge, and occasionally of vessels when the lock is submerged, whilst retaining the water-level of the river above it at a sufficient height for navigation in dry weather; and the three chief French types are the Needle Weir, the

Chanoine Shutter Weir, and the Drum Weir. The needle weir consists of a series of wooden spars resting against a bar at the top across the weir, carried on a row of iron frames providing a foot-bridge, and against a sill at the bottom, though of late years sliding panels or rolling-up curtains have been often substituted for the spars or needles; and this type of weir has been adopted for the first time in the United States for a weir across the Big Sandy River at Louisa, in Kentucky, with large inverted V-shaped frames placed 8 feet apart, and lying one inside the other when lowered on the apron in flood-time, and closed by needles having the exceptional dimensions of 12 inches width, 14 feet length, and 8½ inches thickness at the bottom and 4½ inches at the top, which are handled by a floating derrick. The frame weir suspended from an overhead bridge, so that all the movable parts can be raised out of the river in flood-time, as resorted to on the Lower Seine at Poses and Port-Mort, and the barriers substituted for needles, are described and illustrated in the book, but have not hitherto been adopted in the United States.

The Chanoine shutter weir is composed of a series of shutters supported centrally on a trestle, and turning on a horizontal axis, the trestle being maintained in an upright position by a prop, resting at its lower extremity in a cast-iron shoe fixed to the apron when the river is closed; and the weir is opened by withdrawing the props from their shoes, causing the trestles to fall flat on the apron, with the shutters on top of them in a horizontal position. Owing to the rapidity with which it can be opened, this type of weir is advantageous for rivers subject to sudden floods; and it has been adopted in the United States across the deep navigable passes on the Ohio and Kanawha Rivers, where shutters somewhat larger than the biggest in France have been erected.

The drum weir consists essentially of an upper and an under paddle revolving on a central horizontal axis, the row of upper paddles forming the weir; and the under paddles, revolving in the quadrant of a horizontal cylinder forming the drum, are made to close or open the weir by altering the water-pressure on their two sides in the drum, so that when the head of water from the upper pool presses on the upstream side of the under paddles, the upper paddles rise against the current of the river. In spite of the perfect control of this weir which the under paddles afford, the deep foundations required for these paddles below the sill, exceeding the height of the weir above it, have hindered its general adoption; and since the completion, in 1867, of a series of these weirs in the canalisation of the Marne, a tributary of the Seine, they have only been used in Europe for timber passes at the side of the weirs erected across the River Main for canalising it in 1883–6, and across the navigable pass, 9 feet in depth, of the Spree at Charlottenburg. A modified form of drum weir has been quite recently constructed in timber across the Osage River in Missouri, in which the paddles are replaced by a sector of a cylinder which fits exactly in the drum when lowered, and closes the weir when raised. The old bear-trap weir fell into oblivion for many years in America; but within the last few years some weirs of this type, of improved design, have been constructed; and two, placed alongside a new weir near Beaver on the Ohio River, each 120 feet long and 13 feet high, serve for the passage of drift and for regulating the discharge.

Another peculiar, novel type of weir, also forming part of the new weir across the Ohio, consists of a series of A-shaped frames, which, as in other frame weirs, can be lowered flat on the bed of the river in flood-time; but it differs from ordinary frame weirs in the frames themselves forming the barrier for closing the weir, by being constructed with a widened plated upstream leg touching the plates of the legs of the adjacent frames when standing upright, besides furnishing a support for the foot-bridge along the top of the weir.

The book concludes with three appendices, giving the dimensions of various locks and weirs in the United States, the standard specifications adopted for certain river works and materials, and laws for protecting the waterways in the United States. Altogether, the book affords a large amount of information about works carried out on rivers under Government in the United States; whilst in some of the chapters, such as those on levees, storage reservoirs, and more especially those on movable weirs, interesting particulars are also given of European works.

THE FISHERMAN IN AMERICA.

Bass, Pike, Perch, and Others. By James A. Henshall. Pp. xix+410. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 8s. 6d. net.

Big Game Fishes of the United States. By Chas. F. Holder. Pp. xiv+435. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 8s. 6d. net.

THESE two volumes of the "American Sportsman's Library" deal with the fishes of the United States, other than salmon, trout, and char, from the sportsman's point of view. Although the same ground is to a certain extent covered by both, Dr. Henshall has to deal with numerous species inhabiting both fresh and salt water, while Mr. Holder's volume confines itself to a comparatively small number of marine species, and this naturally results in the adoption of a different method of treating the subject by the two authors; this much they have in common, that both have produced books which give the angler information as to the tackle to be employed for each species and the places in which to employ it, and at the same time illustrate their remarks with excellent personal observations on the habits of the fish with which they deal.

The first book under notice combines in a greater degree than almost any other work of which we are aware, systematic ichthyology and directions to the fisherman; the author has adopted the classification of Jordan and Evermann's "Fishes of North and Middle America," and his specific descriptions and most of his nomenclature are taken from that standard work, with the addition of useful observations of his own upon the

specific differences between allied species. While welcoming the restoration of Esox as a generic name for the pike—in consonance with Jordan and Evermann's own most recent work—one rather regrets that the author has not reconsidered the reasons which have caused American writers to separate the graylings from the Salmonidæ as a separate family, and to substitute Stizostedium for the Lucioperca of European authors.

The reader of this book is immediately struck by the great difference between the American and European fish fauna as viewed by the fisherman; among fresh-water forms the only Cyprinoid fish considered in any other light than as prospective bait is the introduced *Cyprinus carpio*, while the place occupied in England by Cyprinoids is taken by numerous species of Percidæ and Centrarchidæ, the only representatives of which in our waters are the common perch and the ruff. From the angler's point of view this is no slight gain, especially as some of the Centrarchidæ, notably the two species of "Black Bass," attain a large size and rise freely to an artificial fly. Justice is also done to the merits of the grayling, but hardly, we think, to the views of either English anglers or poets respecting it. Among the marine fishes, again, our American friends have very many Serranoid and Sciænoid fishes to set against our bass, and numerous Sparoids where we have but one sea bream that can be considered an "angler's fish," but we find the grey mullets only mentioned as bait for other fish, and no species of Gadoid even mentioned. Mr. Holder is surely right, and the coalfish (the "pollack" of American writers) has not yet met with the recognition it deserves as a sporting fish.

It is, perhaps, hypercritical and unfair to complain of such a matter, but Dr. Henshall's language, especially in dealing with technical descriptions of tackle and gear, is not very intelligible to an Englishman, more especially when the great differences between English and American rods and lines are taken into account; it is a little startling to find an eight ounce rod recommended for pike fishing and puzzling to find no details as to the length and build of such a rod. A "chlorinated sea breeze" is apparently a special product of the western Atlantic, like the author's Bahama negro, for whose observations on fishes and their ways all Dr. Henshall's readers will be grateful.

We are reminded of a certain traveller's tale about a "mixed bag of wild fowl and hippopotami" when dealing with Mr. Holder's "Big Game Fishes," almost on the same line with Dr. Henshall's work; we pass from the grayling and the perch to the huge Serranoids of the Florida and California reefs, the tarpon, and the pelagic Scombridæ, the weights of which are reckoned by the hundredweight, and we pass, too, to descriptions of some of the most exciting fishing man can want. Unfortunately, the English sea fisherman must content himself with smaller game (unless he chooses to fish for the blue sharks, which are common enough off our western shores in the late summer), but a work like this should find readers outside the United States; the tunny and the albacore are within reach of British fishermen in the Mediterranean, the American tarpon has its counterpart in the Indian Ocean, and huge Serranoids are not confined to American waters. If English or colonial readers should feel encouraged to try their hands at "big game fishing," they will find in Mr. Holder's book all the information they can desire as to the necessary tackle and baits to use, and the kind of place in which to use them, and if Mr. Holder's descriptions of this exciting form of sport do not encourage them to try their hands at it, we really do not know what will.

In marked contrast to Dr. Henshall, Mr. Holder gives no specific descriptions of the fish he deals with, and his only attempt at systematic or anatomical detail in his introductory chapter is not very happy; no reason is given for terming the shark "not a true fish," and to dismiss so important a structure from a systematic point of view as a fish's pectoral arch by saying that "many of the corresponding bones among higher animals are seen, as a pectoral arch, scapula, clavicle, ulna, and radius," is neither useful nor accurate.

The printing and get up of both books is excellent, and both are well illustrated, the one in black and white, the other in colours; the only fault to be found is that the process blocks of fishes have lost in clearness by being printed on rather too rough a paper, and that the figure of Pseudopleuronectes in Dr. Henshall's book is printed upside down; there are also in Mr. Holder's book certain references to a non-existent Fig. 9, which are apparently due to an oversight. The index in each case is very good. L. W. B.

TECHNICAL PHYSICS.

Lehrbuch der technischen Physik. By Prof. Dr. Hans Lorenz. Erster Band. Technische Mechanik Starrer Systeme. Pp. xxiv+625. (Munich: Oldenbourg, 1902.)

THIS book is interesting as the work of an engineer who is also a professor in one of the leading universities of Germany, where it is generally conceded that the science and practice of technical education are best understood, and have led in modern times to the most striking practical and commercial developments. The author rightly considers the fundamental principles of mechanics to be the groundwork of all physics, and has chosen mechanics as the subject of his first volume.

The most striking features of the book, as a whole, are the rigorous mathematical method of treatment adopted, the generality of the principles discussed, and the logical order of the arrangement. In an English "technical" text-book we should rather expect to find the practical applications in the foreground, and the general mathematical treatment of the principles either absent, or introduced only so far as was necessary for purposes of calculation, and not as the groundwork of the whole arrangement. Owing to the difficulty which many students find in appreciating general mathematical reasoning, we are inclined to make the mathematics as concrete and "practical" as possible, and to restrict it to the immediate applications required for illustrations. No doubt this may produce the best results, on the whole, in the case of

students whose abilities and opportunities are limited; but such students will probably not possess sufficient grasp of the mathematical principles to enable them to apply their knowledge to any new problem. Their training is "technical" in the English sense of the term. It may be questioned whether the German view of technical physics, as understood by the author of the present work, is not really the wiser and the more likely to lead to sound educational and commercial progress in the end.

The book begins with a general chapter on the geometry of motion. The idea of time is introduced in the next chapter on velocity and acceleration. This is followed by a chapter on relative motion, treating the usual examples, such as projectiles, planets, pendulum, oscillations, &c., in a very general manner. In chapter iv. we have mass and force introduced together with friction, damped oscillations, impact, work, and kinetic energy. In chapters v. and vi. we have a general discussion of the equations of motion in a plane, and in three dimensions, respectively, with a number of important applications, such as the theory of the precession of the earth's axis, the centrifugal governor, and the theory of models and dimensions.

The book concludes with a historical survey of the evolution of mechanical science divided into three sections:—(1) before Newton, (2) from Newton to Lagrange, (3) the later development of technical mechanics. This historical excursus would be unnecessary, from the teacher's point of view, for the mere inculcation of the principles of the subject, and would interfere with the logical order of ideas. But from the student's point of view such a historical survey is not only extremely interesting, but also most instructive. Correct ideas can only be appreciated in their true significance by contrast with incorrect conceptions, such as abound in the earlier history of the subject; and the methods and principles at which we have arrived at the present stage of progress are not in all probability the best expression of the science, but are the outcome of an intricate process of evolution along certain lines. To appreciate them fully it is necessary to know something of the manner in which they have been evolved.

It is probable that the English engineer would hesitate before devoting much time to the study of a foreign text-book which at first sight is of so "unpractical" a nature. But the mere existence of the book in its present form suggests a lesson which our technical educators may have yet, in some cases, to learn. H. L. C.

OUR BOOK SHELF.

An Introduction to Botany. By W. C. Stevens. Pp. 428; with preface and index and key, 121 pp. and index. (New York and London: D. C. Heath and Co., 1903.) Price 6*s*.

AMONG the numerous works professing to guide the elementary student through the mazes of botanical science, this may claim several advantages, inasmuch as the greater part of the book is based on a sound conception of the method best suited for the purpose of training the beginner to observe and think for himself. It is the method which Huxley worked so hard to introduce into this country many years ago, namely, that of encouraging the student to investigate first, and then telling him more about the things he has seen, keeping the opinions and records of others in the background until he has acquired a stock of his own knowledge to work upon.

On the whole the purpose of the book is carried out, but the figures are often very poor, and the part dealing with systematic botany frankly returns to the old lines, and is, moreover, only suited to American students. Why this part should be separately paged is not clear; it necessitates a second index, and makes the book somewhat cumbrous. English students will find far better exercises in the use of analytical keys and floristic work generally in Hooker and Bentham's well-known "Flora."

Kant's Lehre vom Glauben. By Ernst Sänger. Pp. xvii+170. (Leipzig: Verlag der Durr'schen Buchhandlung, 1903.) Price 3 marks.

KANT'S philosophy has found, and continues to find, various application and still more various interpretation. The diversity of commentaries has led, in some quarters especially, to a feeling that Kant has received enough development, that in some cases the development has been too much controlled by the ideas of later systems, that, in fact, we must go back to Kant and define more clearly our ideas of what he really said. The present essay is obviously designed to assist that process. If we except the last section, which makes reference to the relation between Kant's doctrine and theology, the entire essay is confined to collecting Kant's statements and piecing together his doctrine of belief from the original sources. The author has clearly spared no pains to make his collection of passages complete, nor has he failed to point out the significance of Kant's distinctions or his variations in the use of terms. For the purpose indicated, it was necessary to follow the historical order; the result is a monograph not, perhaps, eminently readable, but deserving study. Though the author's reference seems to be especially to that scientific theology which ever finds it a primary duty to accept or answer Kant, his essay cannot fail to be of value to all interested in philosophy. His remarks on the various passages show clearly how the doctrine of belief runs through all Kant's work, and how its elucidation throws light on the structure and purpose of all his writings. An introduction by Prof. Dr. Hans Vaihinger will doubtless appear to many an adequate recommendation. G. S. B.

Elementary Physics. Practical and Theoretical. Second Year's Course. By John G. Kerr, M.A., LL.D., and John N. Brown, A.R.C.Sc. (Lond.). Pp. 169. (London: Blackie and Son, Ltd., 1903.) Price 2*s*.

THE practical exercises here brought together are intended for young students who have already had a year's work in experimental physics. Dynamics, heat and light are the only branches of the subject drawn upon, and presumably the learner is expected to wait until his third year before he may hope to become acquainted, from his own experiments, with the fundamental principles of sound, electricity, and magnetism. The exercises are well arranged and the instructions given are sensible and helpful, and show that the authors are teachers of experience. The student is more likely to obtain good results if a simple sighting apparatus is used in counting vibrations of the pendulum, but no instructions appear to be given as to the use of one. On p. 64 the student is told to hang a 50-gram weight to a thread for use in his experiment, which necessitates handling the weight, a bad habit which the teacher should discourage as much as possible. A want of uniformity in the spelling of gram should be corrected in the next edition. But, on the whole, the book is likely to prove useful.

Among the Night People. By Clara Dillingham Pierson. Pp. xi+221. (London: John Murray, 1903.) Price 5s.

THIS is an American book, for American children, and about American nocturnal animals; but, if we are not mistaken, it will interest English children too, and may be of no small value in letting them into some of the secrets of the life of "the Night People" of the world in general. It consists of a series of stories or sketches of the doings of raccoons, musk-rats, skunks, mice, weasels, foxes, moths, fireflies, &c., told without any affectation in simple language, and with an evidently real knowledge of the habits and characteristics of these creatures, and with a gentle humour which aptly conceals the instruction conveyed. The animals are, of course, humanised to some extent, and talk the language of human beings, but this is managed with such skill, that the animal characteristics are quite adequately retained. A good example is the story of the inquisitive weasel, where a phlegmatic black-tailed skunk is made to play with most amusing effect on the lively curiosity of these little animals, which are the same all the world over. The illustrations of scenes in the dark, by Mr. F. C. Gordon, are very happily conceived and executed.

Qualitative Chemical Analysis. By John B. Garvin, B.S. Pp. viii+241. (Boston: Heath and Co., 1902.) Price 3s. 6d.

IT is rare in these degenerate days to find an enthusiast for the teaching of qualitative analysis, who regards it as "a source of joy to the majority of normal minds," and as affording "the keenest delight and satisfaction." For analysis, as it is taught, is usually an arid tract, which the student is compelled to traverse on the way to earning a grant or receiving a degree, not a fertile country which he can cultivate with profit and pleasure. Yet one is bound to confess that these pages reflect the author's interest in his subject, and leave the impression that, in the hands of such a teacher, analysis might possess the attributes he describes. This is effected by making the student discover and tabulate the reactions for himself. Thus, the mere mechanical following of directions is, to a great extent, avoided, and the student is freed from the burden of making his own observations correspond with the printed information in his text-book. For an elementary book the subject is very fully treated. It is not intended to be used without some assistance from the demonstrator, and consequently many details of manipulation are suppressed.

J. B. C.

British Rainfall, 1902. Compiled by H. Sowerby Wallis and Dr. H. R. Mill. Pp. lxxvi + 250. (London: E. Stanford.) Price 10s.

THIS valuable work, which has appeared yearly since 1860, is perhaps better known to the scientific world than any other work on meteorological subjects; it has become a unique and indispensable epitome of reference on all questions relating to the distribution of rain over the British Islands. Each year adds to its importance, owing to the longer period over which the averages extend, and the nearly constant addition to the number of stations dealt with. These now amount to about 3500, and have increased 40 per cent. during the last fifteen years. It is highly creditable to the compilers that they have been able to issue the volume six months after the close of the year, within which time every record has been carefully revised prior to publication. In addition to the usual tables, the present volume contains an exhaustive discussion of the rainfall at Camden Square for the forty-five years 1858–1902, by Mr. H. Sowerby Wallis. Illustrations and notes upon the unusual occurrences of the year 1902 greatly enhance the usefulness of the volume.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Amount of Emanation and Helium from Radium.

IN connection with the very striking experiments described by Sir William Ramsay and Mr. Soddy in NATURE of August 13, in which they have observed the presence of helium in the gases obtained from radium bromide and also the production of helium by the emanation of radium, it may be of interest to give some calculations of the probable amount of emanation and of helium produced by radium on the disintegration hypothesis, recently put forward by Mr. Soddy and myself to explain the phenomena of radio-activity.

A method of calculation has already been indicated by us (*Phil. Mag.*, May), but the data on which it was based are somewhat imperfect. A more accurate estimate can be made from the data of the amount of heat liberated by radium, recently measured by Curie and Laborde.

I have shown that the α or easily absorbed rays from radium consist of a stream of positively charged bodies, of mass about twice that of the hydrogen atom, projected with a velocity of about $2{\cdot}5\times10^9$ cm. per sec. These results have been recently confirmed by Des Coudres. These α bodies are expelled from every part of the mass of radium, but in consequence of the ease with which they are absorbed, only a small proportion of them escapes into the air. This self-bombardment of the radium probably gives rise to a large proportion of the heat which keeps the radium at a temperature above that of the surrounding atmosphere. Assuming for the moment that all of the heat is supplied by this continuous bombardment, an estimate can readily be made of the number of α bodies projected per second from one gramme of radium.

The kinetic energy of each projected body is 5×10^{-6} ergs. Since this energy is transformed into heat in the mass of radium, the number of bodies projected to give an emission of heat of 100 gr. cals. per hour—the amount determined by Curie and Laborde—can be shown to be $2{\cdot}4\times10^{11}$ per second. Now Townsend has shown from experimental data that $Ne=1{\cdot}22\times10^{10}$, where N is the number of atoms in 1 c.c. of gas at standard pressure and temperature, and e is the charge carried by an ion. The latest value of e, found by J. J. Thomson, is $3{\cdot}4\times10^{-10}$, so that $N=3{\cdot}6\times10^{19}$.

If the α bodies after expulsion can exist in the gaseous form, the volume of the gas produced (at standard pressure and temperature) is thus $\frac{2{\cdot}4\times10^{11}}{3{\cdot}6\times10^{19}}=6{\cdot}7\times10^{-9}$ c.c. per sec. or 0·21 c.c. per year. Allowing a wide margin for the possibility that only one-tenth of the heat emitted by radium is due to the kinetic energy of the projected bodies, the volume of the α particles should lie between 0·021 c.c. and 0·21 c.c. per year for each gramme of radium.

The determination of the mass of the α body, taken in conjunction with the experiments on the production of helium by the emanation, supports the view that the α particle is in reality helium. In addition, the remarkable experiment of Sir William and Lady Huggins in which they found that the spectrum of the phosphorescent light of radium consisted of bright lines, some of which within the limit of error were coincident with the lines of helium in the ultra-violet, strongly supports such a view. For as a consequence of the violent expulsion of the α particle, it

is to be expected that it would be set into powerful vibration and give its characteristic spectrum.

In the experiments of Sir William Ramsay and Mr. Soddy 30 milligrammes of radium bromide, probably about four months old, were used. If the α body is helium, the amount of helium liberated by solution of the radium in water must have been between 0·00017 and 0·0017 c.c., assuming that all of the helium produced was occluded in the mass of the substance.

There is evidence of at least five distinct changes occurring in radium, each of which is accompanied by the expulsion of an α particle. One of the products of these changes is the radium emanation. It is of interest to calculate the volume of the emanation occluded in radium when in a state of radio-active equilibrium. Taking as the simplest hypothesis that one α particle is projected at each change, the number of atoms of the emanation produced per second is 1/5 of the number of α particles, *i.e.* $1{\cdot}3\times10^{-9}$ c.c. When radio-active equilibrium is reached, it has been shown that 463,000 times the amount of emanation produced per second is stored up in the radium. This corresponds to 6×10^{-4} c.c. The maximum amount of emanation to be obtained from one gramme of radium thus probably lies between 6×10^{-5} c.c. and 6×10^{-4} c.c.

The radium emanation is the active principle of radium, for about $\frac{3}{4}$ of the activity of radium is due to it. Thus a large proportion of the radiations from radium is a direct result of the changes occurring in the very minute amount of matter constituting the radium emanation. If ever 1 c.c. of the radium emanation can be collected at one spot, it will exhibit some remarkable properties. The powerful radiations from it would heat to a red heat, if they would not melt down, the glass tube which contains it. This very rapid emission of energy, in comparison with the amount of matter producing it, would continue for several days without much change, and would be appreciable after a month's interval. The very penetrating rays from it would light up an X-ray screen brilliantly through a foot of solid iron.

E. RUTHERFORD.

Bettws-y-Coed, August 15.

Summer Lightning.

ALTHOUGH a good deal has been written on the subject of "summer lightning," it may not be superfluous to describe a display of the phenomenon which occurred here last evening on a scale far surpassing anything which it had been my good fortune to witness before. There had been several thunderstorms in the district during the previous five or six days, and a few peals were heard and heavy rain fell in the early afternoon of the day before (August 13). But the sky cleared rapidly thereafter, and the evening and night of that day were cloudless, every peak and crest standing out sharply defined in the clear air. Yesterday was still fine, but warmer and less bracing than visitors here expect. Late in the afternoon wisps of white mist began to gather round the summit of the Jungfrau, and streaks of thin cloud took shape in the higher air above the great mountain ridge that extends from the Silberhorn to the Breithorn. About 8 p.m. I noticed a faint quivering light overhead, supplemented by occasional flashes of greater brilliance and different colour. These manifestations rapidly increased in distinctness, and continued to play only along the opposite mountain-ridge, not extending into the regions beyond, so far as these could be seen from here, though I have since learnt that an independent series of flashes was seen around the Schilthorn on this side of the valley. Not a single peal of thunder was at any time audible. A long bank of cloud formed at a higher level than the summits of the mountain-ridge, and at some distance on the further side of it, so that the stars, elsewhere brilliant, were hidden along the strip of sky above the crest.

As one watched the display it was easy to distinguish more definitely the two kinds of discharge. One of them took the form of a faintly luminous reddish or pink light, which shot with a tremulous streamer-like motion in horizontal beams that proceeded apparently from left to right, as if their starting point lay somewhere about the back of the Jungfrau. These streamers so closely resembled the *aurora borealis* that, had they appeared alone, one would have been inclined to wonder whether the "northern lights" had not here made an incursion into more southern latitudes. So feeble were they when they sped across the clear sky that the stars were clearly visible through them. Sometimes they quivered on the far side of the cloud, lighting up its edges and shooting beyond it across the still unclouded blue. At other times they appeared on this side of the cloud, and showed the dark outline of the mountains in clear relief against the luminous background. They so rapidly succeeded each other that they might be said to be continuous, a faint pinkish luminosity seeming to remain always visible, though pulsating in rapid vibrations of horizontal streamers.

The brighter discharges were not only far more brilliant, but much more momentary. They had a pale bluish-white colour, and came and went with the rapidity of ordinary lightning. But they were clearly connected with the mountains, and not reflections from a series of distant flashes. Sometimes they arose on the other side of the great ridge, allowing its jagged crest to be seen against the illuminated surface of the cloud beyond, but leaving all the precipices and slopes on this side in shade. In other cases they clearly showed themselves on this side of the mountains, lighting up especially the snow-basins and glaciers with the dark crags around them. Nothing of the nature of forked lightning was observed among them. In one instance the flash or horizontal band of vivid light, a mile or two in length, seemed to shoot upward from the slope at the base of the precipices of the Silberhorn, as if it sprang out of the ground, having a sharply defined and brilliant base, rapidly diminishing in intensity upward, and vanishing before reaching half-way up to the crest.

But the most singular feature of the more brilliant white discharges was to be seen when one of the great couloirs of snow or a portion of a glacier remained for a minute or two continuously luminous with a faint bluish-white light. After an interval the same or another portion, perhaps several miles distant, would gleam out in the same way. My first impression was that this radiance could only be a reflection from some illuminated part of the cloud. But I could not satisfy myself of the existence of any continuously bright portions of the cloud. Moreover, the luminosity of the snow and ice remained local and sporadic, as if the beam of a search-light had been directed to one special part of the mountain declivity, and then after a while to another. While watching one of these patches of illumination, I noticed a bright point of light at the top of one of the basins of *nevé* on the slopes of the Mittaghorn. It quickly vanished, but soon reappeared, and then as rapidly was lost again. I thought that it was probably a star briefly exposed through rifts in the cloud, though its position seemed rather below that of the mountain-crest. Half an hour later, however, a similar bright light appeared about the same place, more diffused than the first, and having a somewhat elongated shape. Whether it was really a star seen through the distorting medium of a wreath of mist, or a form of St. Elmo's fire clinging to some peak on the precipice, could not be ascertained from its momentary visibility.

I learnt this morning that other observers who could watch at the same time the mountain ridges on each side of the Lauterbrunnen valley noticed that sheet-lightning was also playing about the Schilthorn, but quite independently of that on the Jungfrau range, the one mountain being dark, while the other was illuminated. The distance of the two electric centres from each other is between five and six miles. The whole display last evening afforded an admirably complete demonstration of the erroneousness of the notion formerly prevalent that summer lightning is only the reflection of distant ordinary lightning, and of the truth of the more recent views as to the nature of the phenomenon.

I may add that, as the lightning increased, the air, which

had previously been nearly calm, freshened into a strong breeze, which blew from the south-west down the valley, but died down after the illumination faded away. The cloud above the mountain began to assume irregular dark cumulus shapes, and the sky became generally overcast. Early this morning rain was falling heavily. The mountains have been all day shrouded in dripping cloud, and the deluge still continues. ARCH. GEIKIE.

Mürren, August 15.

A Mirage at Putney.

PERHAPS the phenomenon of mirage is not sufficiently rare in England to make its occurrence noteworthy, but I should like to mention a singularly beautiful example that I noticed on Sunday last (August 16). I was riding on my bicycle along the Upper Richmond Road towards the west, and against a fairly steady breeze, and had arrived at that part of the road lying between the railway bridge and the Putney High Street—about opposite house No. 110—when I noticed that the road beyond, some fifty yards in front of me, was apparently flooded ankle deep in water. I was somewhat disconcerted at the prospect of riding through such a quantity of water, but I found to my astonishment that when I arrived at the supposed lake the road was perfectly dry. I thereupon turned and rode back to my previous station, and, dismounting, watched the phenomenon for some while. To assure myself that it was no personal illusion upon my part, I directed the attention of a passing stranger to the scene, and he was impressed as I had been. I should mention that the road sloped slightly downhill from me, and the sun was high (12.50 p.m.) above on my left. The line of sight must therefore have met the dividing surface between the layers of hot and cold air lying above the wooden paving almost at grazing incidence. The surface of the "water" was still, and the reflection of the gay dresses and sunshades of the ladies just from church was remarkably and beautifully clear. H. E. WIMPERIS.

London, S.W., August 17.

THE SOUTHPORT MEETING OF THE BRITISH ASSOCIATION.

SECTIONAL ARRANGEMENTS.

THE arrangements of the various sections of the British Association for the forthcoming meeting at Southport have now been practically completed. The following summary shows the chief points of the programmes, so far as they are at present known:—

Mathematical and Physical Sciences.—The physical portion of Section A will be mainly occupied in discussing three questions of considerable interest to physicists at the present time. The nature of the emanations from radio-active substances will be introduced as one of the subjects for discussion by Prof. Rutherford, of Montreal, and it is expected that several visitors from the Continent will take part. Mr. Swinburne will introduce a discussion of the method of treatment of non-reversible processes in thermodynamics, in which Prof. Perry and others will have something to say, and Prof. Henrici will direct attention to the desirability of introducing vectorial methods into physics to a much larger extent than has been done hitherto. The fact that the International Meteorological Congress meets at Southport under the presidency of Prof. Mascart, of Paris, at the same time as the Association, will make the work in the department of Section A devoted to meteorology and astronomy of special importance this year. Contributions to the proceedings of the department have been promised by several of the members of the congress, including Hildebrandsson, Paulsen, and Pernter, and Sir Norman Lockyer will discuss the agreement in time between certain solar and terrestrial phenomena. Papers have been promised by Prof. Turner, Dr. W. J. S. Lockyer, the Rev. A. L. Cortie and Mr. Hinks, and there will be an exhibition of photographs from the Yerkes Observatory.

Chemistry.—In his opening address to the section, the president, Prof. W. N. Hartley, F.R.S., proposes to give a brief account of twenty-five years' work in spectroscopy applied to the investigation of the composition and constitution of terrestrial substances, both organic and inorganic, and to review the present position of spectroscopy chiefly in relation to chemical theories, indicating where it may be usefully and profitably extended. The following papers will be read:—"Dynamic Isomerism," by Dr. T. M. Lowry; "Hydroaromatic Compounds," by Dr. A. W. Crossley; "The Cause of the Lustre produced during the Mercerising of Cotton," by Mr. J. Hübner and Prof. W. J. Pope, F.R.S.; "Mutirotation, and the Glucoside Formula of Glucose," by Dr. E. F. Armstrong; "A Contribution to the Constitution of the Disaccharides," by Mr. T. Purdie, F.R.S., and Dr. J. C. Irvine; "Some Derivatives of Fluorine," by Miss Ida Smedley; "Fluorescence as Related to the Constitution of Organic Substances," by Dr. J. T. Hewitt; "The Cholesterol Group," by Dr. R. H. Pickard; "On Essential Oils," by Dr. O. Silberrad; "Freezing Point Curves of Binary Compounds," by Dr. J. C. Philip; "Action of Diastase on the Starch Granules of Raw and Malted Barley," by Mr. A. R. Ling; "Action of Malt Diastase on Potato Starch Paste," part i., by Mr. B. F. Davis and Mr. A. R. Ling; "Action of Malt Diastase on Potato Starch Paste," part ii., by Mr. A. R. Ling; "Some Properties of Sodium Hydride," by Mr. A. Holt; "On a Method of Separating Cobalt and Nickel and the Volumetric Determination of Cobalt," by Mr. R. L. Taylor; "The Influence of Small Quantities of Water in bringing about Chemical Reaction between Salts," by Dr. E. P. Perman; "Sur le Spectre du Silicium" and "Sur les Procédés de Photographie Spectrales applicables à la Pratique des Laboratoires de Chimie," by M. le Comte Arnaud de Gramont. Dr. W. A. Bone will open a discussion on the general subject of combustion by a paper on the combustion of methane and ethane.

Geology.—The following papers have been promised in this section:—"On the Disturbance of Junction-beds from Differential Shrinkage during Consolidation," by Mr. G. W. Lamplugh; "On the Igneous Rocks of Weston-super-Mare," by Mr. William Boulton; "On the Igneous Rocks of the Berwyn Mountain," by Mr. T. H. Cope and Mr. J. Lomas; "On the Recent Work of the Geological Survey," by Dr. J. J. H. Teall, F.R.S.; "Lower Ordovician Rocks in the Neighbourhood of Snowdon and Llanberis," by Mr. W. G. Fernsides; (1) "On the Origin of Certain Quartz Dykes at Foxdale, Isle of Man," (2) "On some Glacial Lakes in Switzerland," (3) "On the Geology of the Country Around Southport," by Mr. J. Lomas; "On the Porosity of Rocks," by Mr. C. C. Moore; "Notes on Sarsen Stones, with Special Reference to the Stones at Stonehenge," by Mr. H. W. Monckton; "On the Geology of Martin Mere," by Mr. H. Brodrick; (1) "On the Origin of Eruptive Rocks," (2) Observations on the Metalliferous Deposits of the South of Scotland," by Mr. J. G. Goodchild; (1) "On the Origin of the Drift Deposits of Lancashire and Cheshire," (2) "On the Striation of Boulders on Modern Beaches," (3) "Observations upon the Evidences for the Former Existence of Glacier-Lakes in N. England and S. Scotland," by Mr. P. F. Kendall. Dr. A. Smith Woodward, F.R.S., has promised a paper, but the title is not yet known. There will also be the first report of the committee appointed at Belfast to report upon the fauna and flora of the Trias of the British Isles. The greater part of this first report is furnished by Mr. Beasley, and deals with footprints.

Zoology.—There is promise of an interesting meeting in Section D. The most important event will be the open discussion on certain problems of fertilisation, in which it is anticipated that some prominent botanists will take part. Several papers dealing with the morphology of Cœlenterata have been promised, including one by Mr. Duerden on corals, and one on the physiology of digestion in Alcyonarians by Miss Edith Pratt. Mr. Crossland has promised an address on his dredging experiences in Zanzibar; Prof. McIntosh will read papers on a comparison of the terrestrial and marine fauna and on variation in Ophiocoma. Among other papers that will probably prove to be of considerable interest, there is one, by Mr. M. D. Hill, on the nuclear changes in the egg of Alcyonium. The president's address will deal partly with the question of the influence of the environment in the production of variations.

Engineering.—In this section, after the president's address on Thursday, September 10, a paper by Mr. T. Clarkson on steam driven motor-cars will be dealt with. Friday, September 11, will be mostly devoted to a discussion on the problem of modern street traffic, which will be opened by Colonel Crompton, R.E. If time permit, other papers will be taken on Friday. On Monday and Tuesday, September 14 and 15, the following papers will be discussed:—Refuse destructors, by Mr. W. F. Goodrich; natural gas in Sussex, by Mr. R. Pearson; water supply of south-west Lancashire, by Mr. T. Parry; balancing of Manchester engines, by Prof. Perry; balancing of alternators, by Mr. B. Hopkinson; gas engine explosions, by Mr. H. L. Wimperis; rainfall at Seathwaite, by Dr. Mill; and (1) cast iron used for springs; (2) alloys cast in water-cooled moulds; (3) effect of varying stresses on steel, by Captain H. R. Sankey. Several other papers will also be taken, but the final arrangements are not yet completed for these.

Anthropology.—The address of the president, Prof. J. Symington, F.R.S., will deal mainly with the significance of variations in cranial form, and will discuss the view recently revived by Prof. Schwalbe that the Neanderthal skull belongs to a distinct species of Homo, not *Homo sapiens*. It will also consider the relation between the external and internal form of the cranial wall. Among the papers accepted in physical anthropology are the following:—A study of the skulls from Round Barrows, in Yorkshire, by Dr. W. Wright; papers on skulls from the Malay Peninsula, by Mr. N. Annandale; and on the physical character of the Andamanese, by Dr. Garson; a note on Grattan's craniometrical methods, by Prof. Symington; a paper on the papillary ridges of the hand, by Dr. E. J. Evatt; another, by Mr. D. MacRitchie, on a Mongoloid type in N.W. Europe; and important reports on Dr. C. S. Myers's work on the rank and file of the Egyptian Army, on Dr. W. H. R. Rivers's researches among the Todas, and on Mr. Duckworth's investigations among the ancient and modern populations of Crete. The committee on anthropometric methods has a valuable report, and that on the teaching of anthropology will probably report *ad interim*. Archæology is unusually well represented. Mr. Arthur Evans, Mr. R. C. Bosanquet, and Mr. J. L. Myres offer reports on this year's excavations in Crete; Prof. Flinders Petrie and Mr. J. Garstang on recent work in Egypt; Mr. G. Clinch on a megalith at Coldrum, in Surrey, which illustrates certain points in Stonehenge; Mr. Annandale on stone implements from Iceland; Dr. C. S. Myers on the ruins of Kharga in the Great Oasis; Mr. T. Ashby on Roman work at Caerwent; and Mr. Garstang on Ribchester; while the usual report on Silchester excavation may be expected to lead to some discussion. Prof. R. S. Conway offers an analysis of ancient Italian place-names, as illustrating the early languages. Prof. Ridgeway has a paper on the origin of jewellery, and Mr. E. Lovett on the origin of the brooch. General ethnography (with the exception of Dr. Rivers's work on the Todas), and folklore and comparative religion (apart from Mr. W. Crooke's paper on Islam in modern India) are as yet poorly represented, but this defect will probably be made good before long.

Botany.—In the botanical section the address of the president will deal with the nature and geographical distribution of floras subsequent to the Coal period; the gradual progress of vegetation from the Lower Carboniferous period through the Coal age up to the Lower Cretaceous formations will be discussed, greater prominence being given to the Mesozoic floras. Miss Ethel Sargant will open a discussion on the evolution of the Monocotyledons, and Prof. J. B. Farmer will give a semi-popular lecture on Epiphytes. Mr. W. Bateson will give an account of the new discoveries in heredity, Miss E. R. Saunders will describe the results of some cross-breeding experiments with plants, and Mr. C. C. Hurst will describe some recent experiments on the hybridisation of orchids. Other papers will include an account of important recent advances in our knowledge of algæ, by Messrs. Tansley and Blackman; the sandhill and saltmarsh vegetation of Southport, by Dr. Otto V. Darbishire; on the seedlings of some grasses, by Miss Sargant and Miss Robertson; on willow canker, by Prof. T. Johnson; and on some experiments with the staminal hairs of Tradescantia, by Mr. Harold Wager. It is expected that a number of foreign botanists will be present at the meeting.

Educational Science.—The organising committee of this section has decided to continue the procedure adopted at previous meetings, namely, to confine the discussions to a few broad subjects. It is proposed to devote two days (September 10 and 11) to an organised discussion of school curricula, based on a series of short papers contributed by Prof. John Adams, Prof. H. E. Armstrong, F.R.S., Miss S. A. Burstall, Mr. G. F. Daniell, Mr. W. E. Fletcher, Mr. T. E. Page, Mr. J. L. Paton, and Prof. Michael E. Sadler. A joint meeting with the Geographical Section will be held to discuss the "Teaching of Geography." The discussion will be opened by Mr. H. J. Mackinder, and he will be followed by several gentlemen who have devoted special attention to this important branch of school work. In addition to these subjects, there will also be discussions on the reports of committees on:—(*a*) "The Conditions of Health Essential to the Carrying on of the Work of Instruction in Schools"; (*b*) "The Teaching of Natural Science in Elementary Schools"; (*c*) "The Influence Exercised by Universities and Examining Bodies on Secondary School Curricula, and also of the Schools on University Requirements"; (*d*) "The Teaching of Botany in Schools."

NATIVES AND CUSTOMS OF CHUTIA NAGPORE.[1]

THIS bright and picturesque book, which should be widely read, gives in its text and illustrations a vivid picture of the eastern side of Chota, called by the natives Chutia Nagpore, the motherland (Chut) of the Nagas, who were Naga-Kushikas, sons of the Naga Cobra and the tortoise. But I hope that its interesting description of the country, its inhabitants and their festivals, and its glimpses into the traditional history of the past, especially those given in chap. v. of the Santal birth legends, are only a prelude to works

[1] "Chota Nagpore: a little known Province of the Empire." By F. B. Bradley Birt. Pp. xiv+310. (London: Smith, Elder and Co., 1903.) Price 12s. 6d. net.

of deeper research, in which the present author and others living in Chutia Nagpore may try to disentomb from below the present surface the ancient history of the country which was once the treasury of the Naga rulers of India, and will undoubtedly be in the future its richest manufacturing province. It contains about 5000 square miles of coal-fields, only worked on its eastern rim, inexhaustible supplies of iron ore, red and brown hæmatite, magnetite and limestone, immense wealth in other minerals, and in the remote past the gold of its gold-bearing river-sands and its diamonds filled the coffers of the Naga-Kushika kings. The central mountain of their realm was Parisnath, described in chap. vi., which was first the Marang Buru or Great Mother Hill of the Mundas and Santals. The Kushikas called it Mandara, the revolving mountain, and it was finally consecrated as the sacred mountain in the east of the trading Jains of the west, who gave it its present name of the Lord (nath) of Traders (Pañris).

The history of the country told in the legends, ritual and customs of its numerous tribes, takes us back through layer after layer of deposit beneath the surface of to-day to the first age of Indian village life surviving in Jushpore and Sirgoojya among the Korwas, who are nomad agriculturists living in rude huts of tree branches in forest encampments, vacated every two or three years. Their women add to the tribal food they collect in the woods and the animals killed by the men of the tribe, the produce of the crops they sow in their clearing until the soil is exhausted. Their successors were the Mundas and Marya or tree (marom) Gonds, living in permanent villages under the shade of the Sarna or village grove of old forest trees left standing in the ring of cleared rice land, the Gond tribal sacred snake. Beside the Sarna is the Akhra or dancing-ground, well depicted in the illustration here reproduced of Girls and Musicians at a Santal dance (p. 128). There the seasonal dances are held, a separate step and figure being set apart for each season, and thither in the primitive age the women of each village invited to these dances the men of one adjoining it in the same province or Parha, and there the children of each village were begotten as the offspring of the mother trees of the sacred grove. Their Spartan education, in separate establishments for each sex, by the women and men of each village to whom their mothers were sisters, still exists among the Ooraons of Chutia Nagpore, the Nagas of Assam, the islanders of Melanesia in the Indian Archipelago, and other races. They were taught to repeat the national educational and historical stories, and made thorough proficients in all their tribal duties.

We can trace in Chutia Nagpore the stages of advance from the simple primitive villages of the Mundas and Marvas to the elaborate Ooraon villages with allotments for village servants, in which the lands are divided into Manjhus or Lord's land, the Bhuinhiari land of privileged tenants eligible as Headman, Pahn or Village Priest, and Mahto or Accountant and the land of ordinary tenants, whose duty it is to till the landlord's Manjhus land. We can further study local history in the ritual customs and traditions of the laughter-loving and indomitably independent Mundas and Ho Kols, the Irish of India, of the silent and dogged Bhuyas, the musical Ooraons, forming a mixture of these two types, in the farming skill of the Kaurs and the feudal customs of the Chiroos and Kharwars, the ancestral rulers of Magadha, who attached Chutia Nagpore to their confederacy and ended the chain of aboriginal rulers, in which Mundas, Bhuyas, Gonds, Ooraons, and Kaurs were the successive links.

FIG. 1.—Girls and Musicians at a Santal Dance.

The three last, Ooraons, Kaurs, and Chiroo-Kharwars, were the sons of the barley as their predecessors were sons of the rice. Their national birthday is the

July-August festival of the Kurum, when they dance round the national mother, the kurum almond tree (*Nauclea Parvifolia*), wearing barley shoots in their hair, and the festival corresponds to the Hindu Nag Punchami, the five mother snakes held in the same month. The union of the rice-eating sons of the south with the northern eaters of barley is marked by the Magh festivals of January-February (p. 102) in Chutia Nagpore, and the Magh festival of Puryag at the junction of the Jumna and Ganges, where the union with the men of the south of the Kushika Gonds, who came down the Jumna, is celebrated by the offering as sacrifices of living victims brought in by the northern people as additions to the southern ritual, in which the only sacrifices had been the first fruits of the soil offered by the primitive villagers, and the fowls slain by the Munda sun worshippers.

It was the castes who form the northern stratum of the community who began the custom of wedding brides and bridegrooms to mahua and mango trees, while almost all castes still retain the leafy marriage bower in which weddings are celebrated as a reminiscence of their ancestors, who were sons of the tree before the northern growers of oil-seeds, barley, and other crops of Asia Minor substituted individual marriages for village unions.

The last stage in primitive national history is that of the race of the trading Jains of the Bronze age, and its length is marked by the vast excavations they have made in the copper hills of Lando in Seraikela and Baragunda, under Parisnath. They formed the port of Tamluk, called Tamra-lipti or Copper-port, and have left lasting memorials of their rule in the ruins of their capital at Dalmix on the Subanrikha, their temples at Telkupi (p. 177), and along the ancient road to Orissa, and in the establishment of the brass-ware industry of Manbhum, which supplied the brass vessels looked on as sacred in modern Hindu domestic ritual.

J. F. HEWITT.

THE SEISMOLOGICAL CONGRESS IN STRASSBURG.

IN July of last year the British Government received an official invitation from Germany to take part in a conference the object of which was to establish an international inquiry about earthquakes. The meetings of this conference, which took place in Strassburg—July 23 to 28—usually commenced at 9 or 10 a.m., and concluded at about 5 or 6 in the afternoon. The proceedings were reported at length in the *Strassburger Korrespondenz* and other papers.

At the opening ceremony the chair was occupied by His Highness Prince Hohenlohe-Langenburg, his supporters being representatives of the Imperial Government and other officials. Twenty-five States or countries were represented, but the total number of delegates and guests who were at liberty to take part in the proceedings up to the time when final votes were demanded seems to have been exactly one hundred. As sixty-two of these were Germans, it can be easily imagined that German language and German influence preponderated in debates, and although ultimate results were arrived at by the single voices of separate countries, when Great Britain and her colonies, like the German Empire, had each one vote only, it is difficult to suppose that these results are entirely free from German bias.

France was not officially represented. When we consider the powerful influence exercised by this country upon the progress of science, the impetus given to seismology by Perrey, Montessus and other workers, together with the desirability of establishing stations in French colonies, a feeling of regret arises that so important a State was unable to assist the congress. Whether this would have been the case had the same been held in some other town than Strassburg is a matter for conjecture. The chief results arrived at were as follows:—

A central association is to be formed with its headquarters in Strassburg. Each contributing country will be represented by one member on a governing committee which elects a president, a chief for the central office, and a general secretary. The chief will reside in Strassburg, but it was decided that the president and secretary should be elected from outside Germany. Although it is desirable that these officers should represent different nationalities, it is also desirable that the chief of the central office and his secretary should reside at the central office.

It was suggested that the work of the association should be as follows:—

(1) To make observations after a common plan approved by the association. Inasmuch as there now exists in connection with the British Association, in Italy, in Japan, and in other countries established systems for seismic observations, which on account of the expenditure it would involve and for other reasons could not be reduced to a common plan, and further, that as direction from a centre would destroy incentive to investigation, this proposition was abandoned.

(2) To carry out experiments on important matters.

(3) To establish and support observatories.

(4) To collect, study, and publish reports or *résumés* of the same.

The detailed investigations referred to in the second suggestion are not unlike headings for chapters in a treatise on seismology. This work, and that embodied in the third and fourth proposals, are for the first twelve years to be carried out at a cost of 1000*l.* per annum, and this sum is to include a salary for the general secretary. The contributions to this inadequate sum are to be apportioned amongst the cooperating States according to population, the British contribution to be 160*l.* per year. Whether the British and other Governments will take part in the scheme remains to be seen. Assuming that they do, inasmuch as 1000*l.* per year is far too small an amount to meet expenses connected with the proposed programme, it seems likely that the central office at Strassburg, in its early days at least, will become a depôt from which reports are issued and a distributing centre for earthquake registers and other materials bearing upon recent seismological research. This in itself is a work of a magnitude not generally realised, a mere catalogue of earthquakes which have been recorded during ten years in Japan, for example, making in itself a volume of 1000 pages. To reduce publications of this description, written in Chinese characters, to a form in which European investigators might wish to see them would be a labour which but few would undertake. Yet Germany offers men who are willing to face such labours, whilst her Imperial Government asks the civilised world to cooperate in carrying out the gigantic task. Now at the eleventh hour, in the name of science and because other nations are apparently unprepared or indifferent to the advantages of centralisation, it seems likely that the seismological work of all countries is to be swept into one great net.

Germany has but few observing stations and no organised system for seismological investigations of her own, yet she is willing to take beneath her ægis the organisations of the world. Whether it be in the relief of a beleaguered city or in the study of an obscure science, Germany desires to take the lead. To turn the eyes of the world towards Berlin as the centre of

all learning turns the steps of students in the same direction, and a Government which fosters such a policy is deserving of its country. Germany has offered to take upon her shoulders a burden which others shirk, and if this can be achieved to the satisfaction of those concerned, she deserves great praise.

While this no doubt is one view of the situation, it must not be overlooked that Governments, particularly those that do not feel justified in giving support to seismological investigation within their own territory, may hesitate in offering support to such investigation in a foreign State. To suggest that a powerful empire needed 1000*l.* a year to carry on the proposed work would be wanting in good taste. Neither can it be suggested that delegates at the conference have carried away with them the impression that they are to receive something greater than a *quid pro quo.* Should the proposed convention be ratified, what they may possibly discover is that a birthright has been exchanged for a mess of pottage, and for a period of twelve long years a suzerainty has to be acknowledged. Truly enough the movement is called international, but at the same time it bears the character of absorption and crystallisation at a centre, and it is not every country that will care to add to its neighbour's prestige at the expense of its own, play second fiddle, and pay for the privilege. That seismology will benefit by cooperation there is but little doubt, but whether Germany can carry out what has been proposed, and whether the scheme has been presented in its best form are matters open to discussion.

NOTES.

WE are informed that Mr. A. S. le Souef has been appointed director of the zoological garden at Sydney in succession to the late Mr. Catlett. Mr. Dudley le Souef, his elder brother, has been director of the gardens of the Zoological and Acclimatisation Society at Melbourne for several years, and a younger brother is director of the newly established garden at Perth, in Western Australia, so that the three brothers occupy three corresponding positions in the three Australian capitals.

FOR the study of bird migration, Mr. W. Eagle Clarke, assistant keeper in the Natural History Department of the Edinburgh Museum of Science and Art, has obtained permission from the Elder Brethren of Trinity House to spend a month upon the Kentish Knock Lightship, situated off the mouth of the Thames, and about twenty-one miles from the nearest point of land. The position of the vessel affords exceptional opportunities for observing the east to west autumnal movements of birds across the southern waters of the North Sea.

THE meeting this year of the French Association for the Advancement of Science was held at Angers under the presidency of M. Émile Levasseur, who, in his presidential address, dealt with one of those economic questions around which, at the present time, many controversies are being raised. "Wages," said M. Levasseur, "have furnished the material for hundreds of volumes and millions of fugitive leaflets which daily discuss the subject in all civilised countries," and he went on to devote his address to a consideration of three main questions affecting the wage-earner. These may be stated in the following words. "What causes determine the rate of wages?" "Have wages increased?" "Is the wage-earner a permanent factor in the organisation of labour?" In discussing the first question, the president recognised a number of causes for the variations in the rate of wages; among these factors are the productivity of the worker, the cost of living for the workman and his family, the general prosperity of the country, the special abundance of capital in each industry, the opposition between workers and employers, and political institutions and customs. After examining his second question, M. Levasseur concluded that wages have risen in France and in other civilised countries, and that the cause of it is the growth of riches, the progress of industry, the development of machinery, and the greater individual and collective value of the worker. The grants for scientific research made by the association amount this year to about 760*l.*, and this sum was divided among some fifty recipients, including certain scientific associations as well as men of science.

A REUTER telegram from Buenos Ayres states that severe shocks of earthquake were felt on August 12 at Mendoza. A number of houses and the tower of a church were destroyed.

VESUVIUS is in a state of active eruption. The Rome correspondent of the *Daily Chronicle* says a stream of boiling lava is flowing in a north-easterly direction towards San Giuseppe and the village of Ottajano, and has already reached a length of 800 metres.

A SEVERE hurricane passed over the island of Jamaica during the night of August 10–11, causing serious damage and loss of life. On August 8 the U.S. Weather Bureau notified its local agent at Kingston that a disturbance north-east of Barbados was moving to the north-west over the Windward Islands, and would probably develop a dangerous strength. Little notice, however, was taken of the warning. The storm was most severe in the early morning hours of August 11, and the whole of the eastern and north-eastern half of Jamaica has been desolated by it.

THE preliminary international conference on wireless telegraphy came to an end on August 13. The results of the conference have been embodied in draft regulations for the control of wireless telegraphy which it is proposed to submit to the various Governments concerned. A further conference may then be summoned to enter into an international convention based on these regulations; it is said that Germany intends before long to invite the European sea Powers and the United States to take part in a more general conference with this object. The conclusions at which the delegates at the preliminary conference arrived have not yet been made public.

AN instance of the practical advantages of wireless telegraphy at sea was given by the *Observer* last Sunday. A gentleman crossing to New York by the *Campania* discovered in the middle of the voyage that he had not sufficient money to pay his customs dues on arrival, nor did he know anyone on board from whom to borrow. He remembered, however, that his mother was crossing from New York by the *Lucania*, and the two vessels having got into communication by wireless telegraphy, he transmitted a request to her to pay the purser 10*l.*, asking him to advise the purser of the *Campania* to pay the sum to him. The transaction was successfully accomplished within an hour; it seems that with the spread of wireless telegraphy on ships, all the business that we are accustomed to transact on land will be able to be carried on with equal facility at sea.

AN account of some further experiments on the heat radiating power of radium, carried out by M. Curie in conjunction with Prof. Dewar at the Royal Institution at the time of M. Curie's lecture last June, is given in the *Times* of August 13. The facilities for accurate research at low

temperature which Prof. Dewar has developed at the Royal Institution laboratories enabled some careful experiments to be made. It was found that the heat radiating power of radium bromide is not diminished at the temperature of liquid air, and is actually greater at the temperature of liquid hydrogen. It is stated that the experiments leave no room for doubt that the rate of emission of heat by radium is greater at the temperature of liquid hydrogen than at any temperature from that of liquid air up to that of an ordinary room. The experiments also showed that the radiating power of a salt, or solution of a salt, of radium increases for about a month after its preparation to a maximum at which it then apparently remains stationary.

THE fire which occurred last week on the Paris Metropolitan Railway is probably the most disastrous which has taken place in connection with electric traction. In addition to the sympathy one feels for the unfortunate victims and their relatives, the accident is to be especially regretted as tending to discredit a system of transit which was becoming increasingly popular in this country. But although the fire was apparently started by the fusing of an electric wire, the terrible results which followed can in no way be charged to the account of electric traction, nor indeed to the system of underground railways. So far as one can judge by what is as yet known, there seem to have been serious mistakes made after the fire had been first noticed, and finally a panic resulted with its attendant dangers. But for this the accident might have been followed by little serious result; it is safe to say that in all accidents of this kind the best that any system can do is to safeguard, as far as possible, against the occurrence of a panic, for once this occurs the result is in no way commensurable with the original accident, and whatever precautions for safety may exist they are rendered inoperative.

THE Antarctic relief ship *Terra Nova* will leave Dundee on August 21. The vessel will proceed to Hobart, where she will be joined by the *Morning*. Captain McKay will command the *Terra Nova* and Captain Colbeck the *Morning*. Each vessel will carry instructions in duplicate for Captain Scott, upon whom the supreme command will devolve when communication has been established. A *Globe* correspondent states that the French Antarctic Expedition has sailed from Havre under the leadership of Dr. Charcot. The first task to be undertaken by the expedition will be that of finding the Swedish Antarctic Expedition under Nordenskjöld, which, it is supposed, is fast in the ice off Graham's Land. If Nordenskjöld should be found, then a voyage will be made into the Antarctic Ocean, mainly for purposes of scientific research, as the expedition will not try to establish an "Antarctic record." Dr. Charcot is taking out five men of science, and provisions for twenty-eight months, as the expedition will be absent nearly two years. A Reuter message from Stockholm reports that the Swedish expedition for the relief of Dr. Otto Nordenskjöld's South Polar Expedition sailed from there on August 17 on board the *Frithjof*.

THE recent serious floods in Silesia have raised an interesting point as to the relation between them and deforestation. The rivers which inundated Silesia have their origin in Austria, and it appears from a Berlin message in Monday's *Morning Post* that the Prussian authorities are informed by experts that the overflows are due principally to the deforestation of the Austrian highlands, which have become so barren of timber that the rivers no longer lose the large quantity of water which the trees formerly absorbed. Prussia has concluded, therefore, that until the Austrian highlands are retimbered the flood danger in Silesia cannot be eradicated, and heavy relief expenditure, such as the 500,000*l*. just granted, will be wasted.

WE learn from *Science* that it is proposed to celebrate the seventieth birthday of Prof. August Weismann, which will occur on January 17, 1904. The committee has decided to have prepared for that time a portrait bust of Prof. Weismann, which shall be deposited at the Zoological Institute of the University of Freiburg with appropriate festivities. It invites cooperation in this undertaking, not only from those who owe scientific stimulus to Prof. Weismann and have been guided by him into zoological activity, but also from all colleagues who desire to join in honouring Prof. Weismann for his work. Contributions may be sent to the Deutsche Bank, Leipzig, for the account of Prof. Zur Strassen, who is treasurer.

THE first International Exhibition of Industrial Art for Metal or Stone Products will be held at St. Petersburg in November next. The exhibition has the object of making the public acquainted with the progress attained by Russian and foreign industry in the artistic finish of metal and stone products.

THE Liverpool School of Tropical Medicine has decided, with the cooperation of the Government of the Congo Free State, to dispatch a trypanosoma expedition to the Congo Free State in September. The objects of the expedition will be to report on the sanitary conditions of Boma, Leopoldville, and other centres visited, and to recommend improvements of existing sanitary conditions; to continue the work of trypanosomiasis, human and animal, including the occurrence and distribution of trypanosoma in the Congo, the carriers of the parasite, and the relation of trypanosoma to sleeping sickness. Major Ross, of the Liverpool School, has received a letter from Major Penton, the principal medical officer of the Sudan, testifying to the success of the measures taken against mosquitoes for the prevention of malaria. Ismailia has been found by Major Penton to be practically free from mosquitoes, and to show a striking improvement as regards malarial fever.

THE committee of the National Physical Laboratory announces that it is prepared to test the accuracy of the pipettes, measuring glasses, and test-bottles used in the Lister-Gerber and other methods of testing milk. The fees charged are very moderate, and in view of the increasing attention that is being bestowed upon our milk supplies, these facilities should be largely made use of.

IN addition to the usual circulars respecting the close seasons for the salmon and other fisheries, the Fishmongers' Company has issued a notice with regard to the opening of the oyster season. It is pointed out that the various oyster beds, pits and layings round the coasts have been inspected, and all those proved to be polluted with sewage have been closed, and no oysters from these places will knowingly be allowed to be sold until they have been proved to be safe and wholesome. The coöperation of the medical and sanitary authorities in this matter is invited.

THE July number of the *Journal of Hygiene* (No. 3, vol. iii.) contains several papers of considerable interest. Drs. Newsholme and Stevenson describe the graphic method of constructing a "life table," and Mr. Hayward gives a new "life table" for England. Dr. Meredith Richards discusses the factors which determine the incidence of infantile diarrhœa, and concludes that artificial feeding and in-

sanitary milk supply are the most important. Dr. Fremlin describes the cultivation of the nitroso-bacterium, and Dr. Durham a new diluting pipette. Dr. Haldane finds that the presence of sulphur in coal-gas is the principal factor in vitiating the air, and Dr. Savage has investigated the relation between the pathogenicity of *bacillus coli* in drinking water and purity. Dr. Graham-Smith describes further researches upon factors which may modify the biological or precipitin test for blood.

DR. ROBERTO BOROLA, of Pavia, contributes to the Lombardy *Rendiconti*, xxxvi. 12, a note on the metric properties of quadric surfaces in non-Euclidean geometry, dealing with circular sections, foci, and confocal and concyclic systems of quadrics.

AN interesting extension of the use of Green's functions to the mathematical theory of conduction of heat is given by Prof. H. S. Carslaw, of Sydney, in the *Proceedings* of the Edinburgh Mathematical Society, xxi. The use of Green's functions has hitherto been mainly confined to the theory of the potential, although their use in connection with heat conduction has been mentioned by Minnigerode and Betti. Prof. Carslaw now shows how the functions in question can be obtained by means of contour integrals, and a general method applied to the solution of problems which are usually solved by independent methods.

"RED RAIN" forms the subject of a paper by Messrs. F. Chapman and H. J. Grayson in the *Victorian Naturalist* for June. The occurrence of dust-laden showers is not infrequent in Australia, but one of the most remarkable showers of this kind occurred on February 14 of this year. The writers describe analyses of samples of sediment collected from this shower at Camberwell and St. Kilda, and they compare the substances observed with the minerals contained in the dust commonly present on the roof of the National Museum, Melbourne. A sample collected in a second shower of "red rain" at St. Kilda on March 28 was also examined. The latter sediment was remarkable for the number of diatoms it contained, and the authors enumerate a list of the forms found, including about twenty-five species.

THE coefficient of thermal surface-conductivity across the surface of separation of a solid and a fluid is a quantity the determination of which is of considerable importance, especially in connection with the construction of boilers. In the *Zeitschrift* of the German Engineers' Association, Mr. L. Austin describes experiments made at Charlottenburg on this subject, giving the following results:—From metal to water at the boiling point the resistance is equivalent to a thickness of 1·2 to 2cm. of iron, but is reduced by stirring by an amount equivalent to about 0·75cm. of iron. The resistance increases as the temperature falls, reaching a maximum of 10cm. of iron, which is reduced by 1cm. by stirring. For flow of heat from water to metal, the resistance appears greater than for the reverse flow if the water is undisturbed, and about the same when the water is stirred.

THE *Atti dei Lincei*, xii. 10, contains a brief account of experiments in syntonic wireless telegraphy carried out at Spezia under the direction of the Minister of Marine. At San Vito two Marconi apparatus of frequencies "A" and "B" were connected with the same antenna, and communication was carried on simultaneously with Palmaria and Leghorn at distances of respectively 5 and 70 kilometres.

IN the *Atti dei Lincei*, xii. 11, Prof. G. Agamennone directs attention to an interesting contribution to our knowledge of terrestrial magnetism in the form of a discourse by Father Francesco Eschinardi, published in 1681, in which he makes mention of a sudden change in the magnetic declination at Rome from about 3° to 5° W., which occurred towards the end of October of the previous year. This the writer attributed to the effect of earthquakes in Spain and Malaga.

THE annual list of new garden plants of the year 1902, which is issued as an appendix to the Kew *Bulletin*, has been received.

A RECORD of plants collected in the northern region of Yucatan is commenced in the *Publications* of the Field Columbian Museum. The first fascicle, which treats of the ferns included in the Polypodiaceæ and Schizæaceæ, and the monocotyledonous orders Gramineæ and Cyperaceæ, is the joint work of Mr. C. F. Millspaugh and Miss Chase.

THE question of shade for coffee and cocoa plants is discussed in the Jamaica *Bulletin* of the Department of Agriculture, where it is pointed out that in many cases it is the bacteria working in the soil, and not the plants which require the shade. The choice of leguminous plants for the purpose is a wise one, as the nitrogenous contents of the soil are thereby increased. An article by Mr. Cousins, contrasting the constituents of four definite phosphatic fertilisers, serves to point the absurdity of an indiscriminate application of commercial fertilisers without taking into consideration the nature of the soil.

WHATEVER may be the outcome of the present political question of fiscal reciprocity towards our colonies, there can be no doubt about the advantages of a closer connection between them and the mother country. To further this object a scientific and technical department of the Imperial Institute was established, and a laboratory was provided wherein samples of raw material from the colonies can be analysed and reported upon by experts, as has long been done for vegetable products at Kew. In the second number of the *Bulletin* of the Imperial Institute, there appears an account of recent investigations undertaken by Dr. Dunstan and his assistants. These include the examination of rubbers from Africa, oil shale from Natal, iron ore from a district in the Bombay presidency, and other products. Also there are added special notices on various industries which are receiving attention in our dependencies and those of other European States.

IN vol. ii. of *Marine Investigations in South Africa* Mr. R. Kirkpatrick, of the Natural History Museum, continues his descriptions of the sponges, naming some new genera and species.

THE nature of the so-called terminal buds of fishes—organs scattered over the skin of the head in certain teleosts and ganoids, and at one time regarded as tactile in function—forms the subject of an article by Mr. C. J. Herrick, published in vol. xii. of the *Journal of Comparative Neurology*. It is inferred that these structures have no connection with the lateral line system, but are intimately related to the taste-buds of the mouth.

THE July issue of the *Emu* contains a number of interesting articles devoted wholly, or chiefly, to ornithology. In treating of New Zealand cormorants, Captain F. W. Hutton suggests that one group of these birds reached New Zealand from South America, and that, after considerable modification in the Antipodes, their descendants returned to their ancestral home, whence some found

their way to Kerguelen Island. This, it is argued, indicates that islands were formerly more numerous in the Antarctic than at present. Among the illustrations in the number before us, one plate shows a native high up in a gum-tree taking the nest of the white-tailed cockatoo, and a second the countless swarms of sooty terns which haunt the Great Barrier Reef in the breeding season.

IN an article entitled "The Genesis of the Kangaroo," a correspondent of the *Newcastle Daily Journal* of August 4 seeks to obtain credence for a view, current among Australian settlers, as to the early stages of development in these animals. Briefly stated, this view is to the effect that "after impregnation, the mingled germs find their way from the womb, or receptacle answering to such, through a duct or channel straight to the point of the teats," and that consequently the whole of the development takes place while the embryo is attached to the summit of the nipple. Nothing is said with regard to the position of the mysterious duct or channel alluded to in the quotation, while the commonly accepted view, namely, that the mother transfers the embryo from the vagina to the nipple, is dismissed with the statement that this is not supported by direct observation. Apparently the author is unacquainted with a note published some years ago in the *Zoologist* (and referred to in our columns at that time), in which Mr. D. le Souëf describes this transference in considerable detail, and states that it is effected solely by the maternal lips.

THE report of the British Museum for the year ending on March 31 last has been published as a Blue-book. In the natural history section the director records an increase in the number of visitors, and likewise in the list of donations. Attention is directed to the completion of the Nile Fish Survey, and to Dr. Andrews's geological explorations in Egypt, funds for which have been generously provided by Mr. W. E. de Winton. It is satisfactory to learn that the whole of the collections to be made by the National Antarctic Expedition are to come to the museum, and that the trustees have agreed to publish an account of the natural history results of the voyage. As regards the new section of economic zoology, a summary is given of work accomplished in advising the Board of Agriculture in regard to insect ravages and kindred subjects, and of visits paid in connection with the Board. A long list of correspondence in connection with mosquitoes and malaria indicates the energy with which these investigations are being pushed. Some progress has been made with the exhibition of economic zoology in the north hall, and collections of insects affecting economic products have been received from various parts of the world.

DR. HENRY HOEK, of Davos, has issued separate copies of a detailed paper on the geological structure of the central "Plessurgebirge" in the neighbourhood of Arosa (*Berichte der Naturforschenden Gesellschaft zu Freiburg-im-Breisgau*). Inspired by Prof. G. Steinmann, the author has sought to work out in detail the complex features of the district, which is well known in its general aspect to visitors to the Engadine. In so doing, he gives considerable credit to the observations of the English geologist, the late Mr. A. V. Jennings. The overfolding and repetition of strata by thrust-faults are well shown in numerous sketches and diagrams, and plate xiv. gives us a broad landscape, with the geology marked out on it in the clear and effective manner of Murchison and the early authors. Dr. Hoek concludes by supporting the views of Steinmann and Jennings in opposition to those of Rothpletz and Lugeons, and affirms that the main range, including the Brüggerhorn and the Hörnli, is a mountain-mass of eastern Alpine type, pushed up from the south-east over a "Vorland" of Flysch. This Flysch, it is argued with reason, is entirely of Cainozoic age, and the mass of older rocks has been pushed across it for a distance of some 4 kilometres.

PROF. L. PLATE's memoir "Über die Bedeutung des Darwin'schen Selectionsprincips," which was reviewed in NATURE of May 16, 1901 (vol. lxiv. p. 49), has reached a second edition. The new edition contains nearly one hundred pages more than were included in the original work, and the words "und Probleme der Artbildung" have been added to the title.

THE sixth edition of Prof. R. Hertwig's "Lehrbuch der Zoologie" has been published by Herr Gustav Fischer, Jena. The work originally appeared in 1891, and was favourably noticed in these columns (vol. xlviii. p. 173). The present edition has been enriched with many new illustrations, and the text has been revised in the light of recent theory and investigation in zoological science.

TWO useful volumes have been published by the Treasury Department of the United States Coast and Geodetic Survey. One is a list and catalogue of the publications issued by the survey from 1816–1902, and has been compiled by Mr. E. L. Burchard; the other is a second edition of a bibliography of geodesy, by Prof. J. H. Gore. This bibliography has been carefully revised to 1902, and deals with all books and papers on the subject in every language.

THE "List of Publications of the Smithsonian Institution, 1846–1903," by Mr. William J. Rhees, a copy of which has been received from the institution at Washington, will prove of great assistance to all readers who have access to the volumes indexed. The "list" consists of two parts; the first is a complete list of Smithsonian publications in numerical order, which is also approximately chronological; the second part contains a list of publications, available for distribution, arranged under subjects and authors. In this list are included the papers and addresses by eminent men of science which have appeared in the appendices to the annual reports of the Smithsonian Institution.

THE extension section of the Manchester Microscopical Society has issued a revised list of fifty-four lectures arranged for delivery by its members during the coming winter. The work of lecturing is voluntary and gratuitous on the part of the members, but hire of slides, travelling, and out-of-pocket expenses are charged. The purpose of the lectures is to bring scientific knowledge, in a popular form, before societies unable to pay large fees to professional lecturers, but in all cases where lectures are given before societies which are commercial undertakings, or are subsidised by grants, a fee is charged. The subjects of the lectures are varied and well chosen, and this pioneer work of the Manchester scientific workers deserves wide appreciation.

WE have received a reprint of an article, from vol. ix. of the decennial publications of the University of Chicago, on "New Instruments of Precision from the Ryerson Laboratory," by Mr. R. A. Millikau. The instruments described are a substitute for Atwood's machine, a Young's modulus apparatus, a "moment of inertia" machine, and a vapour-tension device. The pieces of apparatus are ingenious and likely to prove useful in the teaching of practical physics, but two at least can hardly be described as new. The substitute for Atwood's machine is merely a slightly modified form of the familiar smoked glass plate

falling in front of a vibrating tuning fork to which a suitable style is attached. It may interest Mr. Millikau to know that this device has been used by students at the London Royal College of Science for the last twenty years. Similarly the vapour-tension device is an improved form of the bent tube with the shorter limb closed and with mercury in the bend which has long been used in laboratories in this country for the determination of boiling points.

THE additions to the Zoological Society's Gardens during the past week include an Anubis Baboon (*Papio anubis*) from West Africa, presented by Mrs. J. B. Ward; a White-crowned Mangabey (*Cercocebus oethiops*) from West Africa, presented by Mrs. Stevenson; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. F. W. A. Jackson, R.A.; a Black Rat (*Mus rattus*), British, presented by Mr. Oswald M. Courage; six English Vipers (*Vipera berus*) from Dorset, presented by Mr. A. Old; two Slender Loris (*Loris gracilis*) from Ceylon, a Black Hornbill (*Sphagolobus atratus*) from West Africa, three Westerman's Eclectus (*Eclectus westermani*) from Moluccas, ten Common Skinks (*Scincus officinalis*) from North Africa, deposited; a New Zealand Parrakeet (*Cyanorhamphus novae-zealandiae*), a Golden-headed Parrakeet (*Cyanorhamphus auriceps*) from New Zealand, purchased; a Garnett's Galago (*Galago garnetti*) from East Africa, a Stanley Crane (*Anthropoides paradisea*) from South Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE SPECTRUM OF COMET 1903 *c*.—On July 14 and 15 Dr. Curtis, of the Lick Observatory, found that the visual spectrum of this comet consisted of a strong continuous spectrum, and the three characteristic cometary bands, that at λ 4770 being by far the brightest. He tried to photograph the spectrum by giving a six hours' exposure with the 36-inch telescope, but obtained no result, the intrinsic brightness of the comet being too small.

Prof. Perrine, using a small slit spectroscope with the Crossley reflector, obtained a spectrum with four hours' exposure, and found that it contained the five bands obtained by Campbell in Comet *b* 1893 (Rordame) and in Comet *b* 1894 (Gale), viz. 388, 409, 421, 436 and 473. The bands obtained by Perrine also agree in brightness with those previously photographed, with the exception of that at λ 420, which was one of the brightest bands in the former comets, but is very weak in this one (Lick Observatory *Bulletin*, No. 47).

THE SPECTROSCOPIC BINARY β SCORPII.—Working with the new spectrograph of the Lowell Observatory, Mr. V. M. Slipher has determined that the spectroscopic binary β Scorpii has a very wide range of velocity, extending over 250km. from −109km. to +146; these variations are satisfied by a period of 6d. 21h.

The spectrum of each of the components is of the Orion type, and the velocity determinations were made from measurements of the lines Hγ, λ 4388, and λ 4472 (Lowell Observatory *Bulletin*, No. 1).

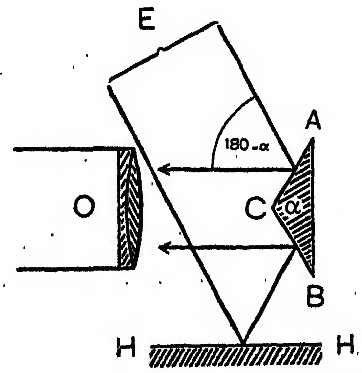
EFFECTS OF ABSORPTION ON THE RESOLVING POWER OF SPECTROSCOPES.—In a mathematical discussion of the manner in which the absorption of a train of prisms affects the resolving power of a spectroscope, Prof. Wadsworth, of the Allegheny Observatory, has found that for small absorption values the actual resolving power is practically identical with its theoretical value, but as the absorption increases a most important diminution of the resolving power takes place. So rapid is this diminution that in several actual instruments now in use, which were designed to give great resolution, this end has been defeated by the high absorptive power of the dense flint prisms used in their prism-trains. Thus in the Young spectroscope, the theoretical resolving power in the neighbourhood of the H and K lines is 300,000, whilst the practical power is only about 57,000, actually less than that which an instrument one-fourth the size would possess.

Prof. Wadsworth summarises the results of his discussion in the following statements. "It is at once evident from these results that if high-power prism spectroscopes are to be used in the investigation of the photographic region of the spectrum, the use of extra dense flint glass, so commonly employed in the past, must be avoided, not only on the score of light-efficiency, but, as now appears, on the score of photographic resolving power and purity as well. The use of lighter flint reduces the theoretical resolving power of any given prism train by decreasing the value of the dispersion coefficient, but this may be easily, and even advantageously, compensated by increasing the refracting angle of the prisms."

Many new spectroscopes have been designed on the principle enunciated above, amongst others those of the Allegheny, Lowell, and Philadelphia Observatories may be mentioned (Miscellaneous *Scientific Papers* of the Allegheny Observatory, No. 11).

A NEW CIRCUMZENITHAL APPARATUS.—A novel apparatus for determining zenith distances has been devised by Fr. Nušl and M. J. J. Frič, of Prague, and is described and illustrated in a *Bulletin International de l'Académie des Sciences de Bohême*.

The accompanying diagram shows the essential features of the apparatus. When the star E approaches the altitude 180-α it forms, at the focus of the telescope O, two images, one of which has been reflected directly from the face AC of the prism ACB, the other from the face CB after reflection from the surface of a bath of mercury HH; these two images coalesce at the moment that the star crosses the zenith circle at altitude 180-α, and that moment is chronographically recorded.



Numerous improvements have been made on the original design, the chief of which consists in substituting two mirrors inclined to each other at the angle α in place of the prism shown here, and, by inserting small prisms, the star images are observed as sharply defined horizontal lines. Using a telescope of 350mm. focal length and 40mm. aperture, with a 50 eye-piece, a determination of time correct to ±0·05s.—0·06s. may be made, and by observations of three stars a determination of latitude correct to ±0″·22 is easily performed.

THE SECCHI COMMEMORATION.—The twenty-fifth anniversary of the death of Padre Angelo Secchi was commemorated at the Collegio Romano last spring, when an address was read by Prof. Elia Millosevich. This has since been published, with a portrait of Secchi, by the Press of the Lincei Academy.

THE NEW YORK ZOOLOGICAL SOCIETY.[1]

ALTHOUGH the preservation of the native animals of the United States is one of the avowed objects of the New York Zoological Society, the establishment of small parks, where the larger species can live and multiply under conditions approximating as nearly as may be to their natural surroundings, has been specially undertaken by the sister society at Washington. And, so far as we gather from the report before us, the authorities at New York are directing their attention to the exhibition of animals from all parts of the world on an equal footing. Considering that the year (1902) to which the report relates is only the fourth

1 "Seventh Annual Report of the New York Zoological Society." Pp. 205; illustrated. (New York, 1903.)

in the development of the Zoological Park and of the serious work of the society, all concerned are to be heartily congratulated on the progress that has been made up to date, and the promise of rapid advance in the near future. A gratifying feature in the year's record was the transference of the New York Aquarium to the management of the society, since, as we are told in the report, this was made spontaneously by the municipality without any suggestion on the part of the governing body. The society has organised the administration of the aquarium on practically the same basis which has been found so effective in the case of the Zoological Park, with a director and council who secure the best expert advice obtainable. As regards the general progress of the park, the report records the completion of a lion house, and the issue of a contract for a building devoted to the exhibition of antelopes. The executive committee states, however, that if the menagerie is to equal the best European institutions of a like nature, even, greater efforts in the way of new buildings must be made in the future.

Judging from the excellent reproductions of photographs with which the report is illustrated, the larger mammals are allotted ample space, and enjoy, whenever practicable, surroundings suitable to their particular requirements. This is well exemplified in the annexed illustration of a group of Barbary wild sheep in the collection.

FIG. 1.—A group of Aoudad, or Barbary wild sheep. (From Report of the New York Zoological Society.)

Perhaps the most important part of the society's work, so far, at any rate, as menagerie administration is concerned, is the establishment of a medical department on what it is hoped may be a permanent basis. In the words of the report, "the object of this service is, by systematic observation and record, and by experimental treatment, to extend our knowledge of the care and health of wild animals in captivity, the causes of various diseases, and the means which should be taken for their prevention. This is both humane and part of an economic administration." The establishment includes a well-known medical pathologist, a trained veterinarian, and an expert in microscopic investigation and the preparation of pathological cultures. To the report before us the last-named official contributes two communications of prime importance in regard to menageries, namely, one on the modes of tubercular infection in wild animals in captivity, and a second on cysticerci in wild ruminants. The work of the department in question is therefore already in full swing, and its investigations will doubtless be found of the highest value to menagerie authorities throughout the world. None of us can fail to be pained at the large percentage of ailing animals to be seen in every menagerie, and all will therefore welcome anything that can be done to render such cases less common in the future.

In addition to the aforesaid special papers and the reports of various officials, the volume before us contains other articles of interest. In one of these, for instance, Mr. R. H. Beck gives a graphic account of hunting for giant tortoises in the Galapagos Islands, illustrated by a photograph of these reptiles coming to a pool to drink, and by a second of the mode in which their empty shells are carried on mule-back to the coast. The psychology of birds forms the subject of a communication by Mr. C. W. Beebe, while Mr. R. L. Ditmars discourses on the method of feeding reptiles in captivity, with especial reference to the somewhat forcible measures adopted in the case of a recalcitrant python.

To those who make the study of mammals a speciality, as well as to big game hunters and sportsmen generally, a paper by the secretary, Mr. M. Grant, on caribou, or reindeer, will be of special interest, not only from the excellent account of the various local forms, but from the numerous illustrations by which their distinctive features are displayed. One of these we herewith reproduce, on account of its being taken from an animal in the wild state. Mr.

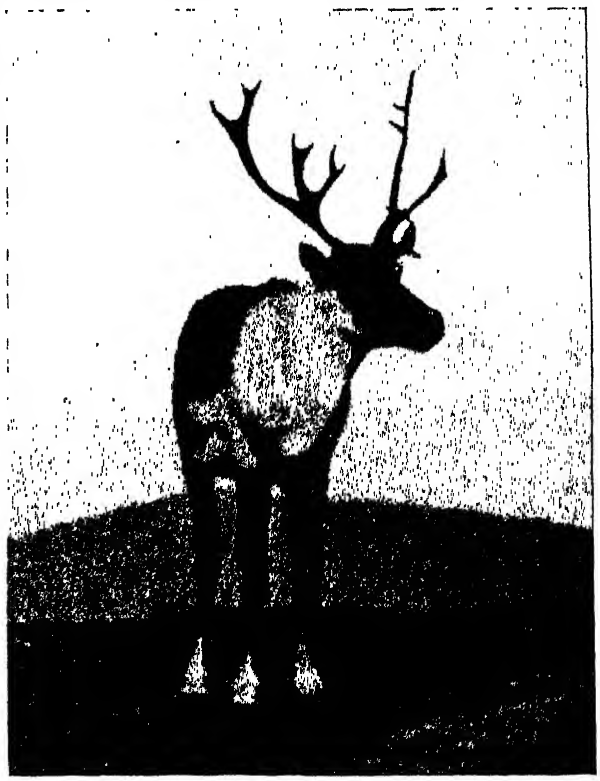


FIG. 2.—Wild Newfoundland Caribou. (From Report of the New York Zoological Society.)

Grant considers that all the American caribou may be divided into two groups, the large and light antlered barren ground group, and the woodland group, distinguished by the short, heavy, and much-branched antlers. The distribution of the various members of these two groups is illustrated in a coloured map. R. L.

THE ORIGIN OF SEED-BEARING PLANTS.[1]

WHEN Linnæus, in 1735, brought out his famous sexual system of classification, which for so long dominated systematic botany, twenty-three out of his twenty-four classes were occupied by flowering plants, and one only was left for the flowerless plants or Cryptogamia.

As the name "Cryptogamia" indicated, a thick veil of mystery still hung over the reproductive processes of these flowerless plants. When this obscurity became gradually dissipated, with the aid of improved microscopes, by the brilliant researches of Hedwig, Mirbel, Nägeli, Pringsheim, Cohn, Thuret, and above all Hofmeister, and the "Crypto-

[1] Discourse delivered at the Royal Institution on Friday, May 15, by Dr. D. H. Scott, F.R.S.

gamia," to quote a phrase of Prof. Sachs's, became the true "Phanerogamia," their relative importance received better recognition. In a recent classification—that of Prof. Warming—out of twenty-three classes no less than eighteen are assigned to Cryptogams.

In spite of our vastly increased knowledge of the Cryptogamia, the flowering plants are still in the majority as regards species. According to a recent census, out of about 175,000 known species of plants, about 100,000 or 4/7 are phanerogamic. For our present purpose we may speak of the flowering plants as the seed-bearing plants or Spermophyta, for at least in recent vegetation the two characters, the grouping of the reproductive leaves in a flower and the formation of a seed, go together, and the latter is the more definite and constant feature. The Cryptogams, such as ferns, mosses, seaweeds, and fungi, may, in contradistinction, be spoken of as the spore-bearing plants or Sporophyta. In the vegetation, then, of the present day, the seed-bearers are enormously predominant, not so much in mere number of species as in importance, including, with few exceptions, all plants of utility to man, and almost all of conspicuous stature, and occupying vastly the greater part of the earth's land surface.

To what do the now dominant seed-plants owe their success?

This is a difficult question, for all organisms are well adapted or they could not exist, and nothing requires more careful discrimination than the attempt to determine the exact factors which constitute the relative superiority of one group over another in the struggle for life. Everything depends on the conditions of the contest.

In the simpler of the higher Cryptogams, such as ordinary ferns, the spores are all of one kind, and on germination give rise to an independent plantlet, the prothallus, on which the sexual organs are borne. Fertilisation requires the presence of water for the actively moving male cells, the spermatozoids, to swim in. This condition may be something of a handicap to the plant, but if water is present, reproduction is fairly well ensured. In the more advanced spore-plants, such as the Selaginellas, so commonly grown in our greenhouses, the differentiation of the sexes begins earlier, for the spores themselves are of two kinds. There are numerous male spores of very small size (microspores) and comparatively few female spores of relatively large size (megaspores). In the group of the water-ferns (Hydropterideæ) only one of these large spores is produced in each spore-sac, which then, if provided with a special envelope, as in Azolla, may closely simulate a seed.

In the microspores, the prothallus is scarcely developed; the spore has practically nothing else to do but to produce the spermatozoids. On the female side, provision has to be made for the nutrition of the embryo, and here there is a comparatively bulky prothallus, though, as compared with that of the ferns, it tends to lose the character of an independent plant, and to become a mere storehouse of food-materials. There are certain obvious advantages in this heterosporous condition. The male spores are kept small for easy dispersal, and can be produced in correspondingly large numbers. The prothallial tissue is economised and only formed where it is wanted, *i.e.* in connection with the egg-cells from which the embryos arise.

The differentiation of microspores and megaspores is, in fact, comparable to that earlier differentiation of minute active spermatozoids, and large stationary ovum, which took place far back in the history of both animals and plants, and laid the foundation of sex.

At the same time the heterosporous arrangement, as we find it in Cryptogams, puts a new obstacle in the way of the successful accomplishment of the act of fertilisation. In order that this may happen it is necessary that the two kinds of spores should germinate together, as well as in the presence of an adequate water supply. The necessary association of the large and small spores is, as a rule, left to chance, the small spores being produced in enormous numbers, so that the chance may be a good one.

In the case of the great cryptogamic trees of the Palæozoic period the difficulty must have been a serious one. We know that their spores often differed in mass in the proportion of at least 100,000 to 1, and when bodies of such diverse weights were scattered by the wind from the tops of lofty trees, the chances must have been enormously against their coming to rest at the same spot. It was perhaps to this difficulty that the series of adaptations leading up to seed-formation owed their first inception.

If the microspores could be brought to the megaspores while the latter were still attached to the parent plant, much greater certainty of their union would be gained, for adaptations would now become possible for catching the small spores and retaining them in position. Some of the Cryptogams now living have got as far as this; the work of an American lady, Miss Lyon, has shown that in some species of Selaginella the microspores and megaspores meet and the spermatozoids are discharged within the sporangium; fertilisation is effected, and even an embryo may develop before the megaspore is shed. In this last respect these Selaginellas go beyond the seed-plants of the Palæozoic period, as we shall presently see. The first advantage, then, to be secured was the occurrence of fertilisation, or rather the bringing together of the two kinds of spore, on the parent plant. This is one of the constant characteristics of the seed-bearing plants; the process is spoken of as *pollination*, for what we call the pollen-grains are nothing but the microspores of the Spermophyta.

We will now see how the process actually goes on in some of the simpler seed-plants of the present day.

The seed-plants, as is well known, are divided into two great classes, the Angiosperms, in which the seeds are enclosed in a seed-vessel, and the Gymnosperms, in which they are exposed. In the former, fertilisation is effected by the growth of the pollen-tube through the tissues of the young seed-vessel; in the Gymnosperms the pollen falls directly upon the young seed or ovule, and the pollen-tube has only a short way to grow before reaching the egg-cell.

The Angiosperms (Monocotyledons and Dicotyledons) include practically all our familiar flowering plants, but with them we are not concerned at present. The question of the origin of Angiosperms is one of the great unsolved problems of botany, but it does not immediately touch our present subject. It is to the simpler seed-plants—the Gymnosperms—that we must turn for light on the origin of the seed-plants as a whole. The Gymnosperms are enormously the more ancient of the two classes, extending back through the whole of the Carboniferous period into the Devonian, while the Angiosperms, so far as we know, only appeared quite late in the Mesozoic period.

The most familiar of the Gymnosperms—the Coniferæ or cone-bearing trees—are themselves too far advanced on the seed-bearing line for our purpose. We will concentrate our attention on a family which, of all living flowering plants, stands nearest to the Cryptogams, namely, the Cycads. This group, not very well known to the non-botanist, but of which a splendid collection will be found in the palm-house at Kew, is now a small one, including nine genera and about seventy species, distributed through the tropical and sub-tropical regions of both the old and new worlds. In habit these plants, which may rise to the stature of small trees, bear some superficial resemblance to palms; the agreement with ferns is, however, much more striking.

In the genus Stangeria from tropical Africa, the leaves bear so close a resemblance to those of some ferns in form and veining that the plant, before its fructification was known, was described by competent botanists as a species of the fern-genus Lomaria.

In all Cycads the male fructifications are in the form of cones; the pollen-sacs are borne in great numbers on the under surface of the scales of the cone. In all the genera but one, the female fructifications are also cones, each scale bearing two large ovules. In the type genus Cycas, however, there is no specialised female cone at all. The fertile leaves are borne in rosettes on the main stem, alternating with zones of the ordinary vegetative leaves.

The fertile leaves are of large size and compound form, and usually each of them bears several ovules, which, whether fertilised or not, grow to a great size, sometimes as big as an egg-plum. They are in some species of a bright red colour, and contrasting with the yellow woolly leaves on which they are borne, are conspicuous and beautiful objects.

In thus bearing its seeds on leaves so little modified, and springing like the ordinary leaves from the main stem, Cycas is the most fern-like genus of flowering plants.

The ovule, at the time when pollination takes place, is

about the size of a small hazel nut. It consists of an outer envelope and a central body, the two being closely joined together, except towards the top, where the envelope leaves a narrow passage open, leading down to the central body. The apex of the latter becomes excavated into a hollow pit—the pollen chamber—a feature almost peculiar to Cycads amongst *living* plants, discovered by our countryman Griffith so long ago as 1854, though the credit is often wrongly given to later French or German investigators.

The pollen, blown by the wind or possibly conveyed by insects, is received in the opening of the envelope by a drop of gummy substance, and as this evaporates the pollen-grains are drawn down through the narrow passage into the pollen chamber below. There each grain anchors itself by sending out a tube into the neighbouring tissue of the ovule. Thus pollination is accomplished. Fertilisation, *i.e.* the actual union of the male and female cells, takes place some months later, when the ovule, now to all external appearance a seed, has reached its full size. In the meantime, the single megaspore or embryo-sac, embedded in the tissue of the central body of the seed, has grown to enormous dimensions—filled itself with prothallus and developed the egg-cells at its upper end, which are so large as to be easily seen with the naked eye.

The pollen-grain behaves like a cryptogamic microspore and produces two large spermatozoids, each with a spiral band bearing numerous cilia—the organs of motion. The pollen-tube becomes distended with water, bursts, and sets free the sluggishly moving spermatozoids, which by aid of the water discharged from the pollen-tubes are able to swim to the egg-cells and effect fertilisation.

This remarkable process, first discovered in 1896 by two Japanese botanists, Ikeno and Hirase, and independently in 1897 by the American Webber, occurs not only in the Cycads, but also in that strange plant the maiden-hair tree, Ginkgo, a form now completely isolated, certainly rare in a wild state, and said to have been only saved from extinction by cultivation around Buddhist temples in China and Japan, but which has a long geological history.

The cycadean method of fertilisation holds exactly the middle place between the purely cryptogamic process, where the active male cells accomplish the whole journey to the egg by their own exertions, and the method typical of seed-plants, where these cells are little more than mere passengers carried along by the growth of the pollen-tube.

The adaptations, which in the Cycads allow of pollination and fertilisation on the plant, are chiefly three:—

(1) The envelope of the seed with its narrow opening down which the pollen-grains are guided.

(2) The pollen-chamber below in which they are received.

(3) The pollen-tube which, however, plays a somewhat less important part here than in the higher flowering plants, and in the Palæozoic allies of the Cycads may perhaps have been dispensed with altogether.

There are, however, other points in which the ovule of a Cycad differs from the spore-sac of a Cryptogam. Not only is the megaspore solitary—that is a condition already reached among the water-ferns—but it is firmly embedded in the surrounding tissue. It is no longer a mere spore destined to be shed, but remains throughout an integral part of the ovule, while the ovule ripens into a seed and ultimately germinates. Thus the whole development of the prothallus takes place within the seed, and this requires special methods of food-supply, involving a complexity of structure far beyond that of any cryptogamic spore-sac. When the time for dispersal comes, the seed is shed as a whole.

There is, however, another character commonly regarded as essential to the definition of a seed; a seed should contain an embryo. This implies that, after the egg-cell has been fertilised, the young plant develops to a certain extent while still within the seed, and before it is shed. In the ripe seed the embryo passes into a resting stage, and only resumes its development when the seed begins to germinate and the embryo becomes a seedling. Usually, too, the ripening of the seed itself is dependent on the development of the embryo; if there is no fertilisation there is no true seed, only an abortive ovule.

In the Cycads this is not the case; the ovule ripens into a full-sized and apparently normal seed, even if fertilisation has failed. In our hot-houses Cycads are seldom fertilised; yet the conspicuous scarlet seeds of *Cycas revoluta*, or the crimson seeds of Encephalartos, are familiar objects to many Kew visitors. Further, the degree of development of the embryo at the time the seed is shed is very inconstant; sometimes, although fertilisation has taken place, the embryo is scarcely to be detected.

The definite resting stage of the young plant in the dry seed, so characteristic of the higher Phanerogams, is unknown to these primitive seed-bearers, the Cycads and the maidenhair-tree. The same appears to hold good for the seeds found in the Palæozoic rocks. Such seeds are common in certain localities, as in the Coal-measures of central France, and to a less degree in our own coal-beds. In petrified specimens the structure is often beautifully preserved, yet in no single case has a Palæozoic seed been found to contain an embryo. It is not merely a matter of preservation, for that is not unfrequently so good that the delicate egg-cells can still be recognised. Thus there is no known "seed" of Palæozoic age which, according to current definitions, strictly deserves the name. Technically, the term "ovule" would be more appropriate, but the obvious maturity of the integument makes the word "seed" seem more natural. So far the case is parallel to that of our recent Cycads or the maidenhair-tree.

It is, of course, possible that any day we may light on some Palæozoic seed with an embryo; it may be that the specimens hitherto found were all unfertilised, though the frequent presence of pollen-grains in the pollen-chamber makes this explanation unlikely. It seems not improbable that the development of an embryo in the ripening seed was a later device—that in the older seed-plants the period of rest came immediately after fertilisation, and that the growth of the embryo, when once started, went on rapidly and continuously to germination. In that case a seed with a recognisable embryo would rarely be preserved.

We are now in a position to see what are the chief advantages gained by a plant in adopting the seed-habit; they are:—

(1) Pollination on the parent plant, and consequently greater certainty in bringing together the two kinds of spore.

(2) Fertilisation either on the plant or at least within the sporangium, giving greater certainty of success, and protection at a critical moment.

(3) Protection of the young prothallus from external dangers.

(4) A secure water-supply during its growth.

(5) Similar protective and nutritive advantages for the young plant developed from the egg-cell.

This last end, however, was very probably not yet fully attained in the earlier seed-bearing plants.

We may now go on to consider our main subject—the historical question, from what group of spore-bearing plants were the seed-plants derived?

One thing is plain; the stage of heterospory was the immediate precursor of seed-formation, and it was from some group of Cryptogams producing spores of two kinds that the seed-plants sprang. Such heterosporous groups are, however, known in three of the main phyla of the higher Cryptogams.

In the Lycopod series we have, among their living representatives, pronounced heterospory in Selaginella and Isoetes; among the Palæozoic Lycopods it was commoner still. Within the class of the ferns we have the heterosporous water-ferns. In the third series, that of the horsetails, we have, it is true, only homosporous forms now living, but in Palæozoic times a well-marked differentiation of micro- and megaspores was attained, though less extreme than in the other two lines.

So far, therefore, there is no reason why the early seed-plants might not have had family relations with any of these great cryptogamic classes, and, as a matter of fact, all three lines have been championed by one botanist or another as the probable ancestors of the seed-plants.

The horsetail stock, though it attained an extraordinary development, shows no further sign of transition towards the higher plants.

The case for the Lycopods is stronger, and, indeed, they were long the "favourites," and were commonly regarded as lying nearest the true line of spermophytic descent. This idea was specially based on the mode of development

of the spore-sacs, which has much in common with that of the pollen-sacs and ovules of Phanerogams, and this, combined with the occurrence of well-marked heterospory in some genera, appeared to point to a relationship. But the former character (the development of the spore-sac from a group of cells instead of from a single one) is now known to be common to certain ferns, and to just those ferns (the Marattiaceæ, &c.) which prove to be the most ancient, so that this argument has lost its weight. It has lately been found, indeed, that some of the Carboniferous Lycopods produced seed-like organs, presenting the most striking analogies with true seeds, but the plants which bore them were in all other respects Lycopods pure and simple, and the case appears to have been one of homoplastic modification. There is no indication, as yet, of any forms really transitional between the Lycopods and the Spermophyta.

The one line which, so far, has yielded truly intermediate types is that of the ferns.

Among recent plants, the Cycads, as we have seen, offer some points of agreement with ferns, sufficient to have led certain distinguished botanists, for example Sachs and Warming, strongly to maintain their fern-ancestry. The chief points of agreement are:—

(1) The fern-like foliage in some Cycads, and in many the mode of folding of the leaflets in the bud.

(2) The arrangement of the pollen-sacs in groups on the underside of the cone-scales, like that of the spore-sacs of ferns on the underside of the leaves.

(3) The carpels or fertile leaves of Cycas, which, though bearing true seeds, are more like fertile fern-fronds than any other reproductive leaves.

By themselves, these characters, though suggestive, would be inconclusive; the anatomy is not directly comparable with that of any living ferns.

What, then, do we know of the history of this family in past times? The Cycads are now a small and isolated group; in the Mesozoic period, from the Trias to the Lower Cretaceous, they were one of the dominant types of vegetation, and spread all over the world. Of the fossil species recorded from the Oolite of the Yorkshire coast and from the Wealden of the south of England, one-third are referred to Cycads, and they were equally abundant in the Mesozoic floras of North America, India, and other countries. If they existed in the same proportion now as then, they would have about 35,000 species instead of 70! The Cycads of the Mesozoic, however, were not, as they are now, a single family, but a great class (the Cycadophyta of Nathorst) embracing very diverse types, often with organs of reproduction widely different from those of their surviving relatives, and showing a certain parallelism with angiospermous fructifications. But with all this there was on the whole a remarkable uniformity in habit, just as we find a general similarity in outward characters among so many dicotyledonous trees of the present day, though belonging to the most diverse families.

In the Mesozoic rocks we also find a certain number of plants (known only from their foliage) as to which it remains doubtful whether they belonged to Cycads or ferns, or to some intermediate group.

Besides the Cycadophyta, seed-plants were represented in Mesozoic days by a great number of Coniferæ, more or less allied to those still living, and by various forms akin to the maidenhair-tree, perhaps the more ancient type surviving in the recent flora.

When we go further back, to the Palæozoic rocks, it is only in their uppermost strata that we find forms clearly referable to Cycads or Conifers.

The best known seed-bearing plants of the older rocks are those of the family Cordaiteæ, which stretches back to the Devonian. They were tall, branched trees, bearing great simple leaves, sometimes a yard long. The anatomy of stem and root resembled that of an Araucarian Conifer, but the leaves had just the structure of the leaflets of a Cycad. Male and female flowers were borne in little spikes or catkins, and may best be compared with those of the maidenhair-tree. The seeds, of which the structure is known, closely resemble those of that plant, or of recent Cycads.

The Cordaiteæ, however, ancient as they are, were already pronounced gymnospermous seed-plants—by themselves they give no direct clue to the origin of Spermophyta. We must look elsewhere for the key to our main problem.

The vast number and variety of fern-like remains throughout the Palæozoic strata, wherever land-plants are known, is familiar to all. Almost every form of recent fern-frond can be matched from the impressions in the Carboniferous and Devonian rocks. A considerable number of these fossil fern-fronds are known to have really belonged to ferns, for typical fern-fructifications are found upon them. An experienced collector of Coal-measure plants, Mr. Hemingway, once told me that he reckoned on finding about 20 per cent. of the specimens of any true fossil fern in the fertile state. When, therefore, a common fossil fern-frond (so-called) is *never* found fertile, a strong suspicion is awakened that the plant must have had some kind of fructification other than that of an ordinary fern. This is the case with a surprisingly large proportion of the Palæozoic plants commonly described as ferns, and holds good of certain entire "genera"; the important genera Alethopteris, Neuropteris, Mariopteris, Callipteris, Tæniopteris, and others, have never yet been found, in any of their species, with fertile fronds, if we except one or two specimens so questionable and obscure that no conclusion can be drawn from them. It is probably under the mark to say that one-third of the so-called ferns of Palæozoic age afford no evidence from fructification that they were really ferns, as we now define them.

The absence of recognisable fertile fronds may, it is true, be partly accounted for by dimorphism. Many ferns, both recent and fossil, bear their reproductive organs on modified portions of the frond, or even on special fronds, very different from the vegetative foliage. Fossil remains are usually fragmentary, and when the sterile and fertile fronds are found isolated, there may be nothing to show that the one belonged to the other. But, allowing for this, there are very many "fern-fronds" which offer no evidence, even from association, of any fern-like fructification, while the fructifications actually associated with them are often anything but fern-like. There are, in fact, a number of unassigned seeds from the Coal-measures, some of which are commonly associated with certain of the quasi-ferns of which we are speaking.

On the whole, however, we have, up to this point, had before us merely negative evidence, indicating that many of the leaves, so familiar to palæobotanists, classed on account of their form and veining as fern-fronds may really have belonged to some group different from the true ferns. Negative evidence is notoriously weak; at most it only justifies us in taking up a position of philosophic doubt, though in this case it was enough to induce the distinguished Austrian palæobotanist Stur to suspect that the genera Alethopteris, Neuropteris, and others were not ferns, but Cycads.

During the last thirty years, however, positive evidence has been accumulating proving that certain of the fern-like Palæozoic plants were at any rate something distinct from true ferns, as we now know them. This evidence is derived from a study of the anatomical structure, which in Cycads and ferns, as they now exist, is sufficiently different to prevent any possible confusion between the two groups. A single section from the leaf-stalk of the fern-like Cycad Stangeria would be enough to show that it is a true Cycad and no fern, and conversely, a single section from the frond of Lomaria, with which Stangeria was once confused, would show it to be a true fern and not a Cycad.

A common Coal-measure plant, named *Lyginodendron Oldhamium*, was one of the first of the Palæozoic quasi-ferns to be examined anatomically. We owe this work, like so many other great advances in fossil botany, to the late Prof. Williamson, who thus led the way to the solution of the problem before us.

Externally, the plant is wholly fern-like; its characteristic highly compound foliage is that of a Sphenopteris (*S. Höninghausi*) with a Davallia-like habit. The large fronds were borne, at intervals, on a somewhat slender stem, which rooted freely. The slender proportions and the presence of spines everywhere, on leaf and stem, suggest that the plant may have been a scrambling climber like *Davallia aculeata*, for example, among recent ferns.

The structure of all the vegetative parts of the plant, stem, leaf, and root, is known as perfectly, perhaps, as in any plant now living. The leaves turn out to be

true "fern-fronds" in structure as well as in external aspect. The vascular bundle traversing the petiole, for example, is of the "concentric" type characteristic of ferns, and any differences there may be are in details only.

A section of the stem, however, bears at first sight no resemblance to that of a fern; outside the pith we find, in all mature specimens, a broad zone of wood and bast with its cells arranged regularly in radial series, like that of an ordinary "exogenous" tree, and in detail approaching especially the cycadean structure. At the border of the pith there are distinct strands of wood, and this region, which was laid down before the radially arranged zone, recalls the structure of an Osmunda. The bundles in the cortex of the stem, on their way out to the leaves, have, in this part of their course, exactly the structure of the strands in the leaf-stalk of a Cycad—a structure found, in this form, in no other living plants.

The roots, when young, resembled those of certain ferns (Marattiaceæ), but as they grew older they also formed radially arranged wood and bast like the roots of Gymnosperms.

On the ground of this remarkable combination of structural characters, it was inferred that Lyginodendron could not have been a true fern, but must have occupied a position intermediate between the ferns and the cycadean type of Gymnosperms.

A similar association of diverse anatomical characters has now been proved to exist in various other quasi-ferns of Palæozoic age. In Heterangium, for example, also investigated by Williamson, leaves and roots resemble those of the previous genus, but the stem is more obviously fern-like, agreeing in its earlier stages with that of a Gleichenia, but acquiring, with advancing age, a zone of secondary wood and bast of the cycadean type. This plant likewise bore foliage of the Sphenopteris form (*S. elegans*).

In Medullosa, on the other hand, to which the Alethopteris and Neuropteris foliage belonged, the original ground-plan of the tissues in the stem is like that of a complex fern, but the structure of leaves and roots, and the secondary structure of the stem itself, is almost purely cycadean. We might continue the list much further. Wherever one of these quasi-ferns has been examined anatomically, a similar combination of characters has been found. It may be pointed out in passing that, while many of these intermediate forms lead on towards the Cycadophyta themselves, others approach more nearly to the extinct family Cordaiteæ, and indicate that they also, though so different from ferns in habit, may yet have sprung from the same stock.

But so far the positive evidence has been wholly anatomical, and botanists are not yet altogether in agreement as to the value of anatomical characters. The anatomist very naturally thinks that there is nothing like anatomy, but the pure systematist will not be satisfied without the characters on which he has been accustomed to rely, and his faith in which has been so amply justified, those, namely, drawn from the reproductive organs. Darwin, however, who neglected nothing, was fully alive to the importance of anatomical evidence; he expresses his interest in an anatomical character in an amusing way in one of his lately published letters (1861), saying, "The destiny of the whole human race is as nothing compared to the course of vessels in Orchids!"

Until the present year, we had no satisfactory knowledge of the fructification in any one of the Cycadofilices, as we now call them, of the Palæozoic period. There is, it is true, some reason to believe that a form of fructification with long tufted spore-sacs belonged to Lyginodendron, but we know nothing as yet as to the details—it may prove to represent the male reproductive organs of the plant. Among the unidentified seeds of the Coal-measures, there are some—the great seeds known as Trigonocarpon—which are not only associated with Medullosa, but which show a certain structural resemblance to some of its tissues. But still the indications were slight—so slight that Prof. Zeiller, of Paris, than whom there is no higher authority, has recently expressed a doubt whether these Cycadofilices were, after all, anything more than a peculiar group of ferns.

Within the last few months, however, an altogether new light has fallen on our subject. Among the seeds discovered by Williamson in the English Coal-measures were three species which he placed in his genus Lagenostoma. These, as we shall see, are characteristic seeds of complex structure. One of them, named *L. Lomaxi* by Williamson, though not described by him, has lately been reinvestigated, in the first instance by my friend Prof. F. W. Oliver (see NATURE, June 4). The great peculiarity about it is that the seed itself was borne in a little calyx-like cup, fitting loosely round it, just as a hazel nut is borne in its husk. The cup, or cupule, which is deeply lobed, bears very peculiar glandular bodies, usually with a short thick stalk and a round head which is empty, as if the secretory tissue had broken down. These glands, on the cupule of the seed, have been found to agree exactly in dimensions, form, and structure with the glands borne on the leaves and stems of the particular form of *Lyginodendron Oldhamium* with which the seeds are associated.

Suppose that in some tropical forest where the trees were too lofty for their leaves and fruits to be reached, seeds and leaves and twigs were found scattered together on the ground, and that they all proved to bear exactly similar glandular outgrowths of a kind unknown elsewhere. Suppose, further, that the structure of the envelope of the seed turned out to agree in other respects with that of the vegetative fragments, should we hesitate to conclude that the seeds belonged to the same plants as the leaves and twigs, though we had never seen them actually in connection? Such is the argument with regard to the relation of the seed Lagenostoma to the plant Lyginodendron. Short of finding the vegetative and reproductive organs in continuity, the proof is as strong as it can be, and I think we need not hesitate to conclude that the one belonged to the other.

But, if this be so, the question as to the nature of the Palæozoic Cycadofilices is settled, at least as regards one member of the group. Lyginodendron was already a seed-bearing plant. The seeds are highly organised, and, broadly speaking, of the cycadean type. The integument and central body of the seed are closely joined to near the tip and along the line of junction run the strands which conveyed the water-supply. The upper part of the integument has a curious chambered structure—the central body terminates in a large pollen-chamber of peculiar bell-shaped form, in which the pollen-grains are sometimes found. The neck of the pollen-chamber fits into the opening of the integument and reaches the surface. The centre of the seed is occupied by the large megaspore or embryo-sac, in which remains of prothallial tissue can sometimes be detected. The seed, in fact, is as highly differentiated as any seed of its period, lacking only an embryo, as do all its contemporaries.

But if Lyginodendron, with all its fern-like characters, was thus a true seed-plant, we cannot doubt that other quasi-ferns of that period, exhibiting a similar combination of characters, had also entered the ranks of the Spermophyta, and we may confidently expect that, one by one, many of the as yet unowned Palæozoic seeds will be traced to their fern-like possessors.

Further positive indications of this are already presenting themselves. For example, there is a specimen in the British Museum collection showing a cast of a branched rachis accompanied by a multitude of ribbed seeds, many of which are in clear connection with the rachis itself. At one place we see a leaflet of *Sphenopteris obtusiloba,* a well-known Coal-measure "fern," and everything indicates that we have here the fertile, seed-bearing rachis of that species. There are other specimens which point in the same direction, and now that the eyes of collectors are opened to the possibility of their so-called "fern-fronds" bearing seeds—an idea which before seemed too improbable to be entertained—more of such specimens will doubtless find their way into our museums.

The present position, then, of our question is this. Some, probably many, of the fern-like plants of Palæozoic age bore seeds of the same general structure as those of the Cycads among living Gymnosperms. The plants in question were not merely fern-like; their anatomical structure proves them to have had so much in common with true ferns that there can be no doubt of their affinity with them. In fact, apart from the newly discovered seeds, these plants, for the most part, show a balance of characters on the fern side.

The evidence thus points unmistakably to the conclusion

that the Cycadophyta—the most primitive of the seed-plants—sprang from the fern stock. Thus the origin of the great mass of cycadean forms which overspread the world during the Mesozoic epoch is accounted for—they were doubtless derived from the more primitive Cycad-ferns of the preceding Palæozoic age, and through them from some early filicinean ancestry. The first divergence from this original cryptogamic stock must have occurred very far back; the seeds of Lyginodendron and other Carboniferous seeds referable to the Cycadofilices are, as we have seen, already highly organised, and the stages of their evolution from the cryptogamic sporangium are still to be discovered.

The origin of the seed-plants from the fern phylum will probably prove to hold good for other groups besides the Cycadophyta. The great Palæozoic family Cordaiteæ combines the characters of Cycads and Coniferæ, and at the same time shares certain of those anatomical features which first betrayed the true nature of the Cycadofilices. There is thus a strong presumption that the Cycadophyta, the Cordaiteæ, and the Coniferæ themselves had a common origin, or at least that they all sprang, directly or indirectly, from the great plexus of modified ferns which played so large a part in Palæozoic vegetation.

Hence, so far as the gymnospermous seed-plants are concerned, we are led to the conclusion that they were derived, at a very early period, from the fern stock. The following up of the clue, which, as I believe, we have now grasped, will afford a pursuit of the utmost interest and promise.

But the other great problem—the origin of the angiospermous seed-plants, which are now supreme in the vegetable world—is as yet untouched. And so, though real progress has been made, it will be long before we can hope for a complete answer to the question which we have had before us.

THE GOVERNMENT LABORATORY.

THE report of Dr. T. E. Thorpe, F.R.S., upon the work of the Government Laboratory for the year ended March 31, 1903, with appendices, has now been published, and the following extracts from it are of interest.

It appears from the report that the descriptions of imports as given in merchants' entries are often erratic, and give no clue whatever to the real nature of the goods. For example, crushed bones were entered as "semolina," gingerbread as "paints," sodium peroxide as "fancy goods," varnish as "iron goods," whilst "machinery" and "razor strops" turned out to be tobacco fumigating powder and sugar-coated pills respectively.

Many preparations containing spirit are liable to duty also in respect of other ingredients. Soaps, for example, may contain cocoa-butter, spirit and sugar, the latter being frequently used as a cheap substitute for glycerine. Blacking and polishes are examined for sugar or molasses; confectionery for sugar and chocolate; and essences for dutiable tariff articles, in addition to spirit, such as acetic and butyric ether, used for flavouring purposes.

During the year 1173 samples of beer, wort, and brewing materials were tested for the presence of arsenic, the great majority of which were either quite free from that impurity or contained only traces; but in 44 instances the amount was so notable that the brewers were informed in the case of materials that they should not be used, and in the case of wort or beer that it should not be sent into consumption. The largest quantity of arsenious oxide found was, in malt, 1/50th of a grain per pound, in glucose, 1/40th of a grain per pound, in wort, 1/36th of a grain per gallon, and in water-softening material, 7/10ths of a grain per gallon.

No imported sample of butter has been reported as adulterated during the year. Boric acid preservative was present in 98 per cent. of the samples of butter from Australia and Belgium, 86 per cent. of the French samples, 78 per cent. of those from New Zealand, 77 per cent. of the South American samples, 45 per cent. of those from Holland, and 43 per cent. of the samples from the United States. Sixteen per cent. of the Canadian samples contained this preservative. There has been a decrease in the proportion of samples containing boric preservative from 36·3 per cent. in 1902 to 33·5 per cent. in 1903, for which the samples from Holland are chiefly responsible.

Among articles submitted by manufacturers to the Government Laboratory was a filter which was required to deliver a sterile filtrate, but on examination was found to permit the passage of unfiltered water into the reservoir to which only filtered water was supposed to gain access. This is a danger to which insufficient attention appears to be paid by both manufacturers and users of filters. The inefficiency of many of the old filters was long since established, and as a result improvement was effected in the filtering substance, so as to secure that the water passing through should be free from all micro-organisms. In consequence of the precautions necessary where biological investigations are made, it is to be feared that in some instances, when testing the sterility of the filtrate, the filtering cylinders, cones, or candles, have been examined apart from the filter cases in which they are ordinarily fixed, and no subsequent test has been made of the filter as a whole, with its parts fitted together as in common use. Where this is so it is, of course, possible that though the filtering cylinder itself may be entirely satisfactory, its whole value may be destroyed by a faulty connection.

Among work undertaken for the Home Office was an investigation of the character of the products of combustion in gas and oil stoves. It was desired to ascertain whether along with the main products of complete combustion there was an appreciable production of carbon monoxide and acetylene. Five of the best known stoves—three gas and two oil—were experimented with, and, as a result, it was found after the stoves had been alight for some time (1) that no acetylene was produced by any of the stoves, and (2) that a small amount of carbon monoxide was a regular constituent of the products of combustion of all the stoves, the actual quantity per hour's combustion being, for the gas stoves 0·0024, 0·0048 and 0·0480 cubic foot, and for the oil stoves 0·023 and 0·032 cubic foot.

Of the gas stoves, the first two results quoted were from stoves of different type, the first being of the argand class and burning with a luminous flame, whilst in the second the burners were of the Bunsen type, and the flame impinged on skeleton non-combustible fuel. The production of carbon monoxide is greater in the oil stoves than in two out of the three gas stoves, and it emphasises the necessity of carrying off the products of combustion from every class of stove by means of a flue, if possible, or, where this actually cannot be attained, at least securing that, by good ventilation, there shall be no chance of an accumulation of these gaseous products.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE report has been issued of the commission appointed to inquire into the steps to be taken to bring into existence an institution which should form part of a teaching university for the Transvaal, and which should provide the highest training in the arts and sciences connected with mining and other industries. The commission recommends that, in establishing the proposed technical institute to form an integral part of a teaching university, simultaneous steps should be taken to lay the foundations of the university itself. Recommendations are made for the establishment of a permanent teaching institution and the acquisition of a site within a convenient distance of Johannesburg and Pretoria for a teaching university for the Transvaal, and for any other parts of South Africa which may wish to take part in the scheme. On this site should also be, besides the school of mines, the proposed agricultural school, the State laboratories for chemistry and animal and vegetable pathology. At the outset the appointment is recommended of a principal of the highest scientific attainments and proved organising capacity, with a salary of not less than 3000*l*. a year.

THE Columbia University of New York has, by an agreement with Mr. Joseph Pulitzer, undertaken to establish and conduct a school of journalism. President Eliot, of Harvard University, has proposed an outline for a practical scheme which details the subjects appropriate to a course

of study leading to the profession of journalism. But though Dr. Eliot says "that a journalist needs, more than most men, to be trained in the best methods of ascertaining truth," his scheme does not appear to include a provision for the due instruction of the future journalist in the broad principles of science, which, in view of the large part taken by scientific questions in modern life, seems an omission.

THE Commission of Inquiry into the educational systems of the United States in their bearing upon national commerce and industry, projected last year by Mr. Alfred Mosely, C.M.G., will start on October 3. The itinerary of the commission, drawn up with the assistance of President Butler, of Columbia University, embraces most of the leading educational centres in the United States. Among universities which will be visited may be mentioned Columbia, Yale, Harvard, Cornell, and Pennsylvania, and in addition to the work of these seats of learning, the commission will study the methods, equipment, and curricula of technical colleges and secondary schools for boys and girls, and be given opportunities to examine the procedure of educational institutions of special types. Each member of the commission will, we understand, be invited to record his own impressions, or to combine, if he prefers it, with others interested in the same subjects of education. In this way more varied light will be brought to bear upon all the points in American education. The reports will be printed in a volume or volumes, and distributed to educational bodies throughout the United Kingdom. In an article on the commission in the *Times*, it is stated that "the startling growth of American and German industrial competition is a fact, and a daily more alarming fact. Closely related with it, and in the opinion of many keen observers, largely responsible for it, is the fact that these are precisely the two countries in which national education of all grades has made the greatest strides, and in which its importance is most widely recognised by the people at large." These truths have long been insisted upon in these columns, and we are glad to find they are coming to be more generally appreciated, for it brings us nearer to the day when this country will be properly equipped educationally. The list of commissioners includes with others the following names:—Prof. W. E. Ayrton, F.R.S., Mr. R. Blair, Dr. J. Rose Bradford, F.R.S., Dr. Magnus Maclean, Principal Reichel, Prof. John Rhys, and Prof. W. Ripper.

THE Royal Geographical Society, in response to requests from various school authorities, recently appointed a committee to draw up syllabuses in geography to guide teachers in elementary and secondary schools in their work of imparting geographical knowledge. This committee secured the assistance of Mr. H. J. Mackinder to draw up the syllabus for secondary schools, and of the late Mr. T. G. Rooper to prepare that for elementary schools. Owing to Mr. Rooper's death, Mr. G. G. Chisholm consented to complete the revision of the latter syllabus. The course laid down for elementary schools includes first a preliminary stage for children between five and eight years, who are, it is said, best taught by reading to them suitable extracts from books of famous travellers, and accompanying the readings by the explanation, with the aid of sand-trays, &c., of geographical terms. The second stage is that for children between eight and eleven years old, and includes observational preparation with a view to the necessity of reading maps. Some observations within the reach of town children suggested are the use of the globe, the acquirement of the idea of direction and differences in elevation, and their representation on maps. Country children are, in addition, to learn the use of the compass and to compare Ordnance maps of the same district on different scales. In all study of maps the same ideas must be emphasised as in the observational work. In the third stage children of eleven to fourteen years old begin the systematic study of various parts of the world, and such subjects as climate, rainfall, temperature; the connection between geography and history are also insisted upon. The syllabus for secondary schools is divided into four years' work, and the years between thirteen and seventeen are particularly concerned—in fact, the student is supposed to have mastered the contents of the elementary schedule. In the first year it is proposed that a portion of Britain, extending some distance from the school, should be carefully studied. The portion should be large enough to contain complete examples of river-basins, and such lengths of road and rail to show the influence of physical features on their course. The work should be correlated with instruction in elementary geology. In the second year, Britain as a whole is prescribed as the subject of study, and its several parts are to be traversed by the comparative method, the work of the first year being the standard. For the third year the subject suggested is Europe and the Mediterranean, and it is proposed that the complexion of the teaching shall depend on the other work of the school. The non-European portions of the globe are reserved for the fourth year's work. "What is essential throughout is that nothing should be taught as an isolated fact, and yet that the line of argument should be so chosen that, in the end, every essential fact . . . would have been learnt in its due setting of related facts, and in its proper perspective."

THE report of the Technical Education Committee of the Derbyshire County Council for the session 1901–2 has reached us, and contains detailed statistical information as to recent progress in secondary and technical education in Derbyshire. The statistics relating to the subject of mining are of especial interest. Prior to 1891 not more than twenty students appear to have been attending public classes in this subject, whilst the average enrolment in local classes in coal mining for the past eight years has been about 500. It is also mentioned that, whereas at the time of the initiation of the scholarship scheme in Derbyshire in 1892 only six out of sixty successful candidates were sent to schools in the county, at the present time, out of about 250 minor scholarships, 230 are being held at schools within the administrative county, and only twenty at schools outside the administrative area.

THE catalogue of books on the useful arts contained in the central library at Newcastle-upon-Tyne, which was recently published by the Public Libraries Committee of the city, is the third of a useful series of catalogues prepared by Mr. Basil Anderton, chief librarian. The catalogues provide satisfactory evidence that students residing in Newcastle have at their disposal an excellent library conducted with tact and intelligence. The useful arts dealt with in the present catalogue include all branches of agricultural, chemical, engineering, and mechanical technology, as well as many aspects of medical and domestic science. Some idea of the number of books in the Newcastle central library may be obtained from the statement that the author-list of books on the useful arts runs to 115 closely printed pages of large size.

SOCIETIES AND ACADEMIES.

EDINBURGH.

Royal Society, July 6.—Principal Sir Wm. Turner, K.C.B., in the chair.—Mr. William **Murray** communicated a paper on statistical evidence regarding the influence of artificial propagation upon the salmon fisheries of the American rivers.—In a paper on the origin of the pineal body as an amesial structure deduced from the study of its development in Amphibia, Dr. John **Cameron** showed that the epiphysis in certain types of Amphibia arose in the form of two recesses or outgrowths from the roof of the fore-brain. The right outgrowth disappeared very early by blending with the left. The latter showed most active growth, and the result of this was to cause the epiphysial opening to become situated to the left of the mesial plane in most cases. The epiphysis in Amphibia was therefore to be regarded as a bilateral, and not as a mesial, structure. These results corresponded in the main with those of Béraneck, Dendy, Gaskell, Hill, and Locy in other vertebrate types.—Dr. O. Charnock **Bradley** communicated an elaborate paper on the abdominal viscera of *Cercocebus fuliginosus* and *Lagothrix humboldti*.—Mr. A. Cameron **Smith** described his final form of apparatus for determining by a direct method latent heats of evaporation at the boiling point in electrical units. The essence of the method is to determine the electrical energy required to effect the evaporation of a measured mass of the liquid. The energy

was supplied by a large current through a small resistance immersed in the liquid. The vessel containing the liquid was surrounded by a double-walled shield filled with the saturated vapour of the liquid itself, and the mass evaporated was measured by weighing on a delicate balance. To have the vessel hanging freely from the one arm of the balance and yet to keep it practically surrounded with the saturated vapour were among the principal difficulties to be surmounted. Promising results had already been obtained.—Dr. Thomas **Muir** communicated a note on a special circulant considered by Catalan.

PARIS.

Academy of Sciences, August 10.—M. Albert Gaudry in the chair.—The president announced to the Academy the death of M. Munier-Chalmas, member of the section of mineralogy.—On aërodynamics and the theory of the acoustical field, by M. le Général **Sebert**. Remarks on the theory of M. Charbonnier on the waves set up in air by projectiles moving with a greater velocity than that of sound.—Description of a new apparatus for the preparation of pure gases, by M. Henri **Moissan**. The gases are dried by cooling to about $-70°$, and then liquefied by boiling oxygen or air; substances gaseous at this latter temperature are removed by the mercury pump, and the pure gas allowed to boil off into a suitable gasholder. Details are given for carbon dioxide, hydrogen iodide, hydrogen phosphide, and sulphide. By the use of suitable temperatures the gas obtained from copper and dilute nitric acid was separated into water, nitrous oxide, nitric oxide, and nitrogen.—On the mechanical analysis of soils, by M. Th. **Schlœsing**, sen. An apparatus is described permitting of the mechanical separation of earth into fractions depending on the time taken to deposit from water. A microscopical examination of the deposits showed that the size of the deposited grains varied with the time required to fall out. Grains less than 0·005mm. remain in suspension in pure water for an indefinite time.—Corrections relating to a note of M. Armand **Gautier** on the estimation of arsenic in sea water, common salt, mineral water, and reagents. In the original note, by an error, there is a confusion between milligrammes and thousandths of a milligramme which is here rectified.—On the death of M. Prosper Henry, by M. **Janssen**.—On the relations between the complete integrals of S. Lie and Lagrange, by M. N. **Saltykow**.—The theory of the acoustical field and the internal friction of gases, by M. P. **Charbonnier**.—The appearance of Bishop's Circle in 1903, by M. F. A. **Forel**. This phenomenon, which appeared last in 1884, after the Krakatoa eruption, has been noticed again this year, and is considered by the author to be connected with the eruptions at Martinique.—On some binary compounds of uranium, by M. A. **Colani**. Compounds of uranium with sulphur, selenium, tellurium, nitrogen, phosphorus, arsenic, and antimony are described.—The nature of the alkaline reaction of the blood and its estimation, by M. H. **Labbé**. The alkalinity is not completely removed by the precipitation of the phosphates by barium chloride, and it is this residual alkalinity which is most strongly affected by pathological variations.—Phenols and phenolsulphonic acid in the animal economy, by M. L. **Monfet**.—On the passage of the Rhine by the Doubs valley and Bresse valley during the Pliocene age, by M. le Général **de Lamothe**.

NEW SOUTH WALES.

Linnean Society, June 24.—Dr. T. Storie Dixson, president, in the chair.—On the botany of the Darling, N.S.W., by Mr. Fred. **Turner**. The characteristics of the flora of the country lying between 29° and 33° S. lat., and 141° and 147° E. long., are discussed. The census of the Phanerogams and vascular Cryptogams now brought forward gives a total of 314 genera and 760 species.—The corpus luteum of *Dasyurus viverrinus*, with observations on the growth and atrophy of the Graafian follicle, by Dr. F. P. **Sandes**. The chief conclusions arrived at in this investigation may be thus summarised:—(1) The characteristic cells of the corpus luteum are formed by hypertrophy of the cells of the membrana granulosa. (2) The theca interna folliculi is rudimentary, and forms only the vascular connective tissue of the corpus luteum. (3) The corpus luteum atreticum is formed in the same way as the corpus luteum verum. (4) Other atresic follicles are reduced to fibrous tissue or remain cystic. (5) The corpus luteum is probably a gland with an internal secretion of use in the organism. It has the function of stopping ovulation during pregnancy and at the cestral periods.—Notes on the genus Psychopsis, Newm., with descriptions of new species, by Mr. W. W. **Froggatt**. Three species of the genus were noticed in a previous paper in the *Proceedings* for 1902. From the study of a fine series of specimens acquired in the interval, the author is now able to show that it has been customary to apply Newman's name, *P. mimica*, to what are in reality the representatives of two different species. These are differentiated; a second species from Queensland is also described as new, raising the total to five.—Notes on Prosobranchiata. No. 3. The neanic shell of *Melo diadema*, Lamk., and the definition of the nepionic stage in the gasteropod mollusc, by Mr. H. Leighton **Kesteven**. A description of the mass of egg-capsules of *M. diadema* is given, and attention is directed to the sequence of the acquisition of the columellar plaits which, in this species, is in perfect conformity with a phylogenetic scheme of their origin advanced by Dr. Dall in 1890. Then follows a comparison of the molluscan stages of development with those of the Lepidoptera.—The continental origin of Fiji, by Mr. W. G. **Woolnough**. Part i., general geology. The author's provisional conclusions are:—(1) That Viti Levu, the chief island of the Fiji group, was part of a continental area probably united to New Hebrides and New Caledonia during early Palæozoic time, and that it remained a land area undergoing denudation probably to at least the close of Palæozoic time. (2) That in Mesozoic time and Older Tertiary time subsidence predominated in the Fiji area, the subsidence at Drau, in Viti Levu, carrying the island at least about 1300 feet further below the sea than it is at present. During this period the Fiji Soapstone was deposited. (3) In late Cainozoic time elevation set in, and synchronously with it occurred violent and extensive eruptions of andesitic dolerite and basalt. Elevation has continued into late Cainozoic time, and may be still in progress. On the whole, therefore, negative movement of the land has probably greatly predominated over positive movement since Palæozoic times.

ALCOHOLIC FERMENTATION.

Die Zymasegärung Untersuchungen über den Inhalt der Hefezellen und die biologische Seite des Gärungsproblems. By Eduard Buchner, Hans Buchner, and Martin Hahn. Pp. viii + 416. (München: Oldenbourg.) Price 12 marks.

IN the preface to this book, written by Profs. Eduard Buchner and Martin Hahn, credit is given to the late Prof. Hans Buchner for the general scheme of arrangement which has been carried out after his death by the other authors.

There are four parts to the treatise; the first, by Prof. Eduard Buchner, entitled "Über die Zymasegärung," occupies nearly three-quarters of the entire book, and deals with the important researches of this author and others on the soluble ferment first separated by him from yeast-cells and called *zymase*, the ferment which induces alcoholic fermentation of sugar.

His original papers on the subject have appeared in contributions to scientific journals since the end of 1896, and are now presented in book form.

After a brief historical review of the development of ideas on the subject of alcoholic fermentation, and a comparison of Liebig's and Pasteur's theories with regard to this process, he discusses the nature of "zymase," which he brings into the category of the enzymes, or soluble ferments. A very full and complete account is given of the method of preparing "active" yeast-juice, the main steps of which are now familiar to all students of the subject. Especial stress is laid on the powdering of the yeast-cells with quartz sand in order to break up the cell-membranes. Without this, no amount of pressure avails for getting active juice from the cells, while, after breaking the cells, comparatively little pressure will give some active juice, increase of pressure increasing both the activity and the yield. The activity of yeast-juice, *i.e.* its capacity for inducing the alcoholic fermentation of sugar, varies with different species of yeasts; no conclusion as to richness in zymase can be drawn directly from observed variations in activity, as yeast-juice contains, besides several previously discovered ferments, one, endotryptase, which digests and destroys zymase, and this is present in very variable amounts in the different yeasts. Juices also of very different activity are obtained from different batches of the same variety of yeast. These differences are partly explained by the action of endotryptase on zymase.

The method of determining the "activity," dependent as it is on these conflicting factors, is fully described, and consists in the estimation of the quantity of carbon dioxide formed in a given time under standard conditions.

When the juice is collected in fractions, the first fraction that is pressed out shows least activity, and the activity increases with successive fractions to the last, so that methods which give a small yield may also give juice of relatively small activity. The most active juice is much less active than fresh yeast, and the explanation is that in fermentation with the latter there is always a fresh production of zymase. The so-called self-fermentation of yeast-juice is fully discussed, and shown to be a function of the glycogen content. Some interesting results are recorded in the fermenting of sugars other than glucose. For instance, glucose and fructose are fermented equally fast by the yeast-juice, whereas fresh yeast ferments glucose the more quickly. The author explains this as due to the fructose having a lower rate of diffusion into the yeast-cell. Similarly, glycogen was fermented by yeast-juice obtained from yeast which, in the fresh state, did not ferment this carbohydrate, the explanation being that the glycogen cannot diffuse through the cell-membrane. The experimental proof that the juice can ferment glycogen is an interesting confirmation of what has been induced theoretically, viz. that any cell which can synthesise glycogen must be capable also of hydrolysing it, at least intracellularly. It explains the phenomenon of "self-fermentation," and accords with the new theory of the reversible action of ferments.

The discussion on the mode of action of antiseptics is interesting, but not always convincing. As regards chloroform, the hypothesis is adopted that living cells are subdivided into separate workshops by partitions of cholesterin (Overton), which the author thinks may be injured by the drug and thus allow of a mingling of substances which ought to be kept apart. He gives the impression that chloroform is a substance almost inert towards ferments, for which, therefore, some mechanical action on living cells is to be sought. Chloroform is, however, certainly not without action on ferments, and affects some much more than others; the maltase of yeast, for instance, is distinctly affected by it, and it may be that some ferment essential to cell-growth and multiplication is extremely sensitive to it. It is difficult to estimate at all quantitatively from his experiments the sensitiveness of zymase to such antiseptics, on account of the unknown factor of their action on endotryptase. This also applies to the experiments on the action of added alcohol; expt. 425*b* especially suggests that the alcohol has no negligible effect on endotryptase. The experiments with arsenites are interesting, and give food for reflection to physiologists and physicians alike.

The quantitative fermentation of cane sugar in concentrated solution by zymase was attempted, but the yield of CO_2 and alcohol was always less than the calculated amount, and the author considers and discusses several possible explanations of the phenomenon. In this connection he touches on cases of zymo-hydrolysis where incompleteness has been traced to the action of the hydrolytic products, but does not clearly distinguish between a direct paralysing action of one of the products on the enzyme, such as was found by Taumann in the hydrolysis of amygdalin by emulsin, and a slowing down due to mass-action of the products, a consequence of the reversible nature of enzyme-action, and occurring only on the approach of chemical equilibrium in the system on which the enzyme acts. The fermentation residue was examined for cane sugar with a negative result, but not for a reversion sugar. The author, however, hopes to

investigate this question further. In an experiment given later, done with a lower sugar concentration than in the above, the yield of alcohol approaches the calculated amount.

Glycerol is probably not found in the cell-free fermentation, and is considered a product of cell-metabolism, a similar view to that held by Pasteur about ethyl alcohol. May not the production of glycerol and other higher alcohols be equally due to the action of soluble ferments not yet discovered?

The experiments on regeneration of yeast, which conclude part i., serve to show how much work remains to be done in this direction. The whole account of the general research is given in a lucid and interesting manner, and deals with many lesser matters arising out of the main thesis, each point being illustrated by tables of the actual experiments performed, and the results of the experiments are fully discussed. The author establishes himself especially firmly where other investigators have questioned some of his work.

Part ii., by Profs. Hahn and Geret, gives an account of the discovery of endotryptase by the former author, the description of the experimental work being followed by a good summary.

Part iii. is by Prof. Hahn alone, and describes the reducing properties of yeast-juice as shown by experiments performed by himself and Dr. Cathcart. Some reasons are given for the author's thinking that the reducing power is due to the same ferment, zymase, which induces alcoholic fermentation.

Part iv., by Profs. Hans Buchner and Rudolph Rapp, is on the relation of oxygen-supply to the fermenting power of living yeast-cells.

The contradictory results of previous workers are first reviewed, Pasteur's theories being considered and Chudiakow's work repeated and examined critically in detail. The latter had found that air had no effect on the fermenting power, but that it killed yeast-cells more rapidly than hydrogen, when each was drawn through a sugar solution containing a small quantity of the yeast. The authors find that his results were partly due to defects in his aspiration methods, more air than hydrogen being drawn through in a given time, with consequent injury from shaking. They state also that he used a yeast of too little vitality for general conclusions. They find that neither air nor hydrogen, as such, affects the fermenting power, and that the mechanical shaking of the fluid is detrimental if it exceed a certain limit. The effects of air and hydrogen differ only in that the former induces a slight multiplication of the yeast cells, and thus leads to a rather larger production of CO_2.

The authors then pass on to investigate the effect of air on cultures of yeast grown on beer-wort-gelatin with 10 per cent. of glucose. Here, with a free supply of air, they find one part of sugar oxidised to every five parts fermented. The yeast multiplies more rapidly under such conditions than when very little air is supplied, but in the latter case a given weight of yeast ferments more sugar.

The whole volume is full of interest and instruction, and cannot fail to give the greatest pleasure to a student of alcoholic fermentation.

ARTHUR CROFT HILL.

AN INDIAN FLORA.

The Flora of the Presidency of Bombay. Vol. i. Ranunculaceæ to Rubiaceæ. By Theodore Cooke, C.I.E., M.A., M.A.I., LL.D., F.G.S., M.Inst.C.E.I. Pp. 645. (London: Taylor and Francis, 1901–3.) Price 27*s*.

THE labours of botanists and of a small band of foresters, in India and at Kew, have supplied us with rich stores of information as to the Indo-Malayan flora. These rendered possible the issue of Sir Joseph Hooker's monumental "Flora of British India."

But British India and Malaya, including as they do countries far apart, with climates ranging in temperature from low alpine to high torrid extremes, in humidity from the perpetual aridity of the desert to the permanent moistness of the equatorial tropics, exhibit subfloras and kinds of vegetation of corresponding variety. In order to map out these separate floras of British India, including Burma, the Government of India has decided to issue a series of "regional floras." Such a series will be of great service, because the information at present available as to the floras of certain large tracts of India is lamentably deficient. This deficiency Sir George King's inauguration of a botanical survey of India is calculated to remove.

For the preparation of the first of the "regional floras"—that of Bombay Presidency—the Government of India was fortunate enough to secure the services of Dr. T. Cooke.

To write an ideal "flora" of Bombay is at present impossible. For such a work should not only enable persons to identify plants found in the Presidency, but should also give information as to the geographical distribution of the indigenous species, including their general and local distribution, their habitats, and their frequency of occurrence; it should also impart information, often unavailable to the worker in Europe, as to the habits, colours, dates of flowering, of sprouting, and of defoliation. Finally, it should give a general account of the whole flora and vegetation of the region, and map out their subdivisions within that region. The present "flora" does not contain all these desiderata, for it is not yet concluded, and much remains to be discovered in regard to the local distribution and periodicity of the Bombay plants. This, the first volume, includes the whole of the Polypetalæ, following Hooker's sequence of orders, and the natural order Rubiaceæ.

The characters exhibited by the natural orders are given very fully, so much so that an inexperienced person would find it difficult to decide upon the really salient features. This difficulty might be reduced by printing important diagnostic characters in different type. But when the work is finally complete, the author may aid the tyro by giving abbreviated diagnoses, or possibly an analytical key of the natural orders.

In describing genera and species of exotic plants the botanist working in a herbarium is often at a disadvantage. The specimens reaching him are frequently comparatively small, their colours are changed,

and the information supplied by the collector regarding them may be meagre. But Dr. Cooke, with his ripe experience in India, is in a position of vantage. His descriptions of genera and species are clear and vivid, and at times include information on vegetative characters that can be observed only on the spot. It may be suggested, however, that an even more free record of vegetative characters would greatly facilitate the identification of a plant by a person happening to meet with it in blossom but not in fruit, and would supply botanists at a distance with valuable information otherwise inaccessible. To take specific examples. The two indigenous lythraceous genera with indefinite stamens, Lagerstrœmia and Sonneratia, are distinguished from one another in the analytical key by their fruits; yet their habits and habitats are sufficiently dissimilar to be of immediate use in an analytical key, but we are not told in the present work whether or no *Sonneratia apetala* possesses the erect respiratory roots so characteristic of *S. acida*. Again, in the Rhizophoraceæ, the four genera of the saline swamps and littoral situations are at once separable from the inland Carallia by their habitats, apart from the seeds, which are used as the basis of distinction in the analytical key. Furthermore, species of Rhizophora emit aërial roots from their epigeous branches, and thus stand apart from other rhizophoraceous plants, and, indeed, so far as I know, from all mangrove plants except *Acanthus ilicifolius*. Surely the mention of these roots would greatly facilitate recognition of species of Rhizophora, yet no mention is made of them; and if, as is quite conceivable, these species are apt not to possess them in Bombay Presidency, information to this effect would be of extreme interest to botanists. Whilst discussing vegetative characters, it may be remarked that the "white spongy bodies" in the shoots of *Jussiaea repens* are adventitious roots, not stipules. And the generally accepted view in regard to the leaves of Rubia is that they are stipulate, but that the stipules are often leaf-like in form.

Dr. Cooke's analytical keys of genera and species are, it need hardly be stated, admirable examples of the approved form, and he may be wise in adhering to the system that experience has shown to be most useful, even though it frequently assumes that a person using the "flora" possesses shoots, flowers and fruits of the specimen he desires to identify.

The attractive and clear detailed descriptions of the species are succeeded in most cases by mention of the times of flowering. In many instances there is no record as to whether a plant described is deciduous or evergreen. Records on this point, coupled with additional information as to the times of opening of floral and vegetative buds, and of the shedding of the leaves, would throw much light upon the scarcely touched subject of the periodicity of plant-life in the tropics. As this subject has, in addition, considerable practical economic significance, it is to be hoped that authors of the Indian "regional floras" will record such of these data as are known, and will thereby stimulate further observation.

On the question of geographical distribution, facts are given as to the occurrence of the indigenous species in places outside the Presidency, and many details are added concerning their frequency of occurrence, localities and habitats, within the Presidency. But the author specially directs attention to the need for information on the local distribution of species. Despite of this lack of complete information, the hope may be expressed that Dr. Cooke will include in his work some account of the floristic subdivisions of the Presidency dealt with, and that the authors of other Indian "regional floras" will do likewise. Of equal scientific interest, and probably of greater practical importance, would be an account of the distribution of types of vegetation, or plant-formations, within the area. Such an account of the distribution of types of vegetation within Bombay Presidency would be of especial botanical interest, for

"the rainfall varies . . . from 3 or 4 inches, or even less in the almost rainless districts of Sind, to upwards of 300 inches on the Western Ghâts."

The vegetation shows corresponding diversity, varying from arid or rocky desert-tracts to moisture-laden evergreen forests. As to the practical aspect, we now recognise that vegetation reflects in its form the environment, and that plants, when their actions are interpreted aright, are more cunning analysts of external conditions, including soil and climate, than are the most accomplished chemists and meteorologists.

Brief references to the economic uses of many of the species described, and vernacular names, add value to the book before us.

In conclusion, Dr. Cooke is to be congratulated on producing a most excellent work.

PERCY GROOM.

THE STUDY OF FERMENTATION.

Fermentation Organisms, a Laboratory Handbook. By Alb. Klocker. Translated from the German by G. E. Allan, B.Sc., and J. H. Millar, F.I.C. Pp. xx+392. (London: Longmans and Co., 1903.) Price 12s. net.

THE importance of a systematic study of the micro-organisms which play a part in the various processes of fermentation is making itself felt more and more as time goes on and new facts and phenomena are brought to light. The old empirical methods of twenty years ago have passed away before the marvellous changes first introduced by Hansen, and the culture of yeast is recognised as one of the secrets of success in the manufacture of the various kinds of beer. The study has long been carried on under the personal supervision of Hansen and his assistants, but until recently has been almost entirely conducted under some form of personal supervision. As in other cases, however, the study has outgrown so limited a method of teaching, and we have in this volume a laboratory handbook which will enable practical work in the culture of fermentation organisms to be more widely spread, and probably more successfully conducted, than has hitherto been the case. The volume is welcome on this account especially, but it has other claims also on the student, coming as it does from the

Carlsberg laboratory, and embodying the ideas and teaching of Hansen himself. It is welcome also to English readers from the fact that it has been translated in great part by one of the disciples of the Burton-on-Trent school, from which have come so many valuable contributions to our knowledge of the chemistry of the carbohydrates concerned in brewing.

The author has described at great length what we may consider to be an ideal laboratory for the practical study of the lower fungi, including, indeed, the pathological bacteria, though these are not necessarily included in the range of study he sets forth. His description is greatly to be commended, for he is not satisfied with saying what apparatus should be provided and what precautions observed in arranging the laboratory, but he gives a careful explanation of the reasons underlying his plans, so that mere empirical work has no place in this course. The descriptions of apparatus are good, showing what are the best forms of the modern appliances now at the disposal of workers at the subject. Perhaps a little less detail would have sufficed in the section upon the microscope, as the instrument has now so widespread an application in so many branches of science. Workers will welcome especially the instructions given in the methods of culture of micro-organisms, from the original methods of water culture of Hansen to the modern plate cultures, in which gelatin and similar media take so large a part.

A very important section of the work is devoted to the biological analysis of yeasts, and the methods of ensuring pure cultures. Also to the biological analysis of water, air, and soil.

In the later portion of the volume the author treats in some detail of the fermentation organisms themselves. In this section the Saccharomycetes occupy the largest place, as is natural when we consider the fermentations in which they play a part. Mucor and its allies, however, are not neglected, and fair attention is given to the ascomycetous moulds. Their diagnostic features are described, and the part they play in various fermentations is discussed, the idea being kept prominently in view that the author is writing as a teacher for students, and that the work is a laboratory handbook. Finally, the bacteria come in for recognition.

The book will be welcomed further for the very admirable historical sketch of the gradual development of our knowledge of fermentation from the earliest times. It is very satisfactory to find that this section contains an admirable summary of the work of Hansen himself.

The volume concludes with a very complete bibliography.

OUR BOOK SHELF.

Five Figure Logarithmic and other Tables. By Alex. M'Aulay, M.A. Pp. xl + 161. (London: Macmillan and Co., Ltd., 1903.) Price 2s. 6d.

Siebenstellige Logarithmen und Antilogarithmen. By O. Dietrichkeit. Pp. 64. (Berlin: Julius Springer, 1903.) Price 3 marks.

THE book by Mr. M'Aulay is of a very handy size, specially adapted for the pocket. The author, in the preliminary pages, explains the general properties of logarithms and the use of the tables which follow. The tables themselves comprise, first, an ordinary four-figure table of logarithms of numbers, occupying two pages, and without the usual antilogarithms. Next, a five-figure table of logarithms of numbers from 0 to 100,000, with a complete set of proportional parts or differences; these take up thirty-six pages. Then comes the second principal table of the book, giving the logarithmic sines, cosines, tangents, and cotangents of angles for each minute, with differences for intervals of ten seconds. Some subsidiary tables and useful numbers follow, very much condensed, so as not materially to add to the size of the book.

The tables would be improved if they could be provided with a marginal or thumb index to facilitate reference. The two main tables are printed in clear bold type, and the little volume will prove extremely useful to all who require greater accuracy than is given by four-figure mathematical tables.

The tables of Herr O. Dietrichkeit are most ingeniously arranged. The numbers in the columns are given to seven figures, the last two of which are written as suffixes in smaller type. The logarithm or anti-logarithm of any four-figure number can be read directly from the tables to any desired accuracy up to seven figures without requiring differences to be used. The two tables of logs and anti-logs are printed on paper of different tints, a very good feature, and they occupy only eighteen and twenty pages respectively. They are provided with a complete thumb index, reading both backwards and forwards, and it will be found that readings may be taken from the tables almost, if not quite, as quickly as from the well-known four-figure tables.

If five-figure accuracy were required for five-figure numbers, the difference for the fifth figure would have to be calculated. And it is possible from these tables, although occupying only a few pages, to obtain seven-figure accuracy for seven-figure numbers, by means of an interpolation constant and a most ingenious method of calculation, which, however, would be too long except for occasional use. The tables will prove most valuable in cases where, though four-figure accuracy is usually sufficient, it is desired to have at command a means of greater accuracy for special purposes. The volume is beautifully got up and printed, and it is quite a pleasure to use the tables.

Économie rurale. By E. Jouzier (Encyclopedie agricole). Pp. xv+476. (Paris: Baillière et Fils, 1903.) Price 5 francs.

THIS book belongs to a type of which we have few representatives in this country; it consists of a discussion of such general principles of political economy as may be illustrated in the conduct of a farm.

Beginning with an account of the relations of agriculture to the State, questions of taxation, transport and markets, it proceeds to discuss the capital required in the business of agriculture, the live and dead stock, insurance, depreciation, and the valuation of such contingencies as cultivations and manurial residues. Such general principles as the minimum of production necessary to profit and the law of diminishing returns are explained and illustrated. Questions of labour, methods of finding the cost and profit or loss of the different operations are considered; finally, tenure, compensation for improvements, systems of land holding, cooperation, and similar matters touching on the economics of agricultural production are dealt with. The whole is treated in a somewhat abstract and generalised fashion, and would find little favour with the practical farmer or landowner here; we can, however, commend the book to teachers of agriculture as suggestive and likely to lead to a wider outlook than generally prevails in the treatment of similar questions in this country.

A Naturalist's Calendar, kept at Swaffham Bulbeck, Cambridgeshire, by Leonard Blomefield (formerly Jenyns). Edited by F. Darwin. Pp. xix + 85. (Cambridge: University Press, 1903.)

IN his introduction the editor has given several reasons (all of them excellent in their way) for the reissue of this excellent memorial of an exceedingly accurate and gifted naturalist. He has apparently omitted, however, that which, in our opinion, is the most important argument of all, namely, the relatively early date (previous to 1846) at which the record was kept. This renders it extremely valuable for comparison with observations of a similar nature made at the present day, for the purpose of ascertaining whether any secular changes in the date of the arrival of migratory birds or in the flowering of plants has taken place in this country since the compilation of this calendar. Whether any such differences do occur would require very careful comparison, but we should not be surprised to learn that the average date of the cuckoo's arrival has altered somewhat since Blomefield's time. Be this as it may, the well-known scrupulous accuracy of its compiler renders his calendar of nature a record of exceptional value and interest, belonging to a period when such compilations were rare. There is, therefore, every justification for its republication in the present convenient form, and its appearance at a morphological centre like Cambridge may certainly be regarded as a good augury for the future of natural history studies.

Mr. Darwin gives several anecdotes of the author, to which the present writer can add another. Mr. Jenyns (as he was then called), who was by no means a handsome man, was in early life accustomed to preach occasionally in a church attended by the Henslow family. After one of these periodical visits, the younger members of the family were asked why they were always so unusually quiet in church when Uncle Leonard preached. To which query came the reply that "he kept on making such ugly faces."

R. L.

Elements of Physics, Experimental and Descriptive. By Amos T. Fisher, B.Sc., assisted by Melvin J. Patterson, B.Sc. Pp. 184. (London: D. C. Heath and Co., 1903.) Price 2*s.* 6*d.*

THOSE of us who are engaged in university teaching are personally interested also in the kind of science teaching which is given in schools. Lads come to college fresh from school crammed with what is called physics; but, owing to its unsatisfactory character, our first effort is usually to knock out of them the loose and erroneous knowledge with which they have been crammed. We are afraid that the book under review is not likely to improve matters. A long list of errors which we have noted down lies before us—far too long to reproduce here—and we must be content with a few as a sample.

The diagrams of lines of magnetic force of currents (p. 131), of the dispersion in a prism (p. 96), of the formation of a rainbow (p. 98), are all wrong. It is incorrect to state that the image of (*sic*) a concave lens is always smaller than the object, and that a concave meniscus is a converging lens. The field of a magnet does not vary as the inverse square of the distance. An induced charge is not usually equal to the inducing charge. . . .

A paint-brush illustration of the production of induced currents (p. 137) gives the wrong direction to the current. The conservation of energy is stated to be a consequence of the conservation of mass!

In spite of numerous errors and fallacies, and weaknesses of description, the book is not wholly bad; but what a burden is thrown upon the teacher who has to put all these wrong things right! For the private student the book cannot be recommended.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

An Earthquake Shock at Kimberley.

LOCAL earthquakes are rare phenomena here. There was, however, a small shock at 8h. 43m. p.m. (G.M.T.) on Friday last, July 31. It was accompanied by the loud rumbling noise resembling the passing of a heavy waggon, and caused some shaking of furniture. It appears to have been felt and heard over a considerable area. The record by my large horizontal pendulum showed a single nearly sudden dip to the west of 3·6mm. (*i.e.* from 30·4mm. to 34·0mm., measured from the reference base-line), roughly corresponding to a tilt of about 3″, and a rather more gradual recovery, with very little (if any) return swing to the east. No certain signs of preliminary tremors could be detected upon the record. It seems important (*cf.* Milne, "Earthquakes," p. 309, 4th ed., 1898) that for some days previously there had been a gradual, general dip of the level to the east, the mean distances of the hourly readings from the reference base-line, measured from east to west, being:—

July 27	34·3 mm.
„ 28	34·0 „
„ 29	31·1 „
„ 30	27·0 „
„ 31	28·1 „
Aug. 1	29·0 „

The weather during the week had been moderately warm and cloudy, but, so far as I know, there was not any rain anywhere on the table-land. There was no disturbance of the barometer accompanying the shock.

I enclose a cutting from the *Diamond Fields Advertiser* of August 3. It gives the duration at Koffyfontein as three minutes, which probably really means that some loose articles of furniture might have remained swinging for some time after the shock had passed. Koffyfontein, however, like Kimberley, is a diamond mining centre, and from various reports it seems to be demonstrated that the earth-movement was much more pronounced in the vicinity of the open workings than elsewhere.

J. R. SUTTON.

Kenilworth, Kimberley, S. Africa, August 3.

Sun-spots and Phenology.

IT can be shown in several ways, I think, that we have, on the whole, in these parts (London), more warmth when the sun-spots are numerous than when they are few, a state of things rather opposite to that in the tropics, where (according to M. Nordmann, who has lately confirmed the work of Dr. Köppen some thirty years ago) sun-spots mean coolness, and there is most warmth about minima.

The recurring contrast, in the case of Greenwich, appears to be most distinct in the early part of the year. Thus we may show it by taking the mean temperature of February and March, and smoothing the curve with averages of five (curve A in diagram). B is the sun-spot curve. Thus about sun-spot maxima, the milder weather of spring seems to set in, on an average, *earlier* than at other times. It might be expected that this would have an influence on the data of phenology (time of flowering of plants, &c.), and in many cases we find it is so, that is, curves which represent the dates of flowering of plants will be found to show a certain agreement with the temperature curve of February-March, and with the sun-spot curve.

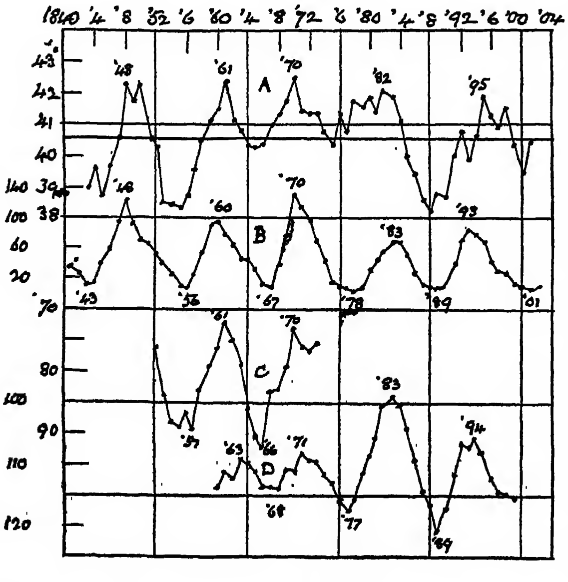
In the diagram are given two of these phenological curves (C and D). C is that for flowering of *Ribes sanguineum* in Edinburgh (1850–87), and D that for flowering of *Azalea pontica* at Parc de Baleine, Allier, in the heart of France (1858–1901). (The scales are separate.)

The date of flowering is given as the day-number in the year, and these numbers are smoothed with averages of

five. The curves are inverted, so that high points represent early dates and low points late dates.

Other examples might be given. This line of inquiry has been followed to some extent by M. Flammarion in France, and it seems desirable that attention should be given to it in this country by those interested in phenology.

The contrast above referred to between the relations of sun-spots and temperature in western Europe and those



in the tropics also calls for elucidation. Probably no meteorologist would now regard it (or other such contrasts) as fatal to the idea of sun-spot influence.

ALEX. B. MACDOWALL.

Retarded Motion of the Great Red Spot on Jupiter.

PERHAPS the most notable fact brought to light by observations of Jupiter during the present season is that the velocity of the great red spot has been again retarded. The rotation period of this well-known object has been as follows in recent years:—

	h.	m.	s.
1898	9	55	41·8
1899	9	55	41·9
1900	9	55	41·7
1901	9	55	40·9
1902 and to May 1903	9	55	39·0
May 26 to August 21, 1903	9	55	41·5

At the end of May last the longitude of the spot was about 30°, whereas at the present time it is 32°, indicating an easterly drift of 2°, whereas during the preceding twelve months the marking had shown a westerly drift of about 1° per month. The spot now follows the zero meridian (system ii. of Mr. Crommelin's ephemeris, *Monthly Notices* R.A.S., lxiii. p. 110, December, 1902) by about 53 minutes. A remarkable disturbance has recently occurred in the southern equatorial belt of Jupiter. In about longitude 140° to 175° (system i.) several nearly black spots have appeared, and the belt in this region is much torn and full of irregularities, changing from night to night, and evidently subject to extensive commotions.

W. F. DENNING.

The Spots on Saturn.

DURING the past two months about 75 transit times of these objects have been taken here. Several of the more conspicuous markings are moving slower than expected, and their positions appear to be well represented by a rotation period of about 10h. 39½m.

W. F. DENNING.

Bishopston, Bristol, August 25.

THE SOUTHPORT MEETING OF THE BRITISH ASSOCIATION.

SINCE the prospective programmes of the various sections of the British Association were obtained for last week's NATURE, the following additional particulars referring to the subsection of Section A, devoted to astronomy and meteorology, and the International Meteorological Committee have been received from Dr. W. N. Shaw, chairman of the subsection.

It is intended that the subsection shall meet on Friday, September 11, and on the following Monday and Wednesday. The proceedings may be expected to be especially interesting on account of the presence of a number of distinguished meteorologists from foreign countries who will be in Southport in connection with the meeting of the International Committee. It is hoped that arrangements can be made to enable the members of the committee to take part in the meetings of the subsection, although separate meetings of the committee must be held for the transaction of business.

The questions already proposed for discussion by the Committee include the initiation of international cooperation in connection with atmospheric electricity and solar physics, and its extension as regards terrestrial magnetism; the revision of the arrangements for the exchange of daily telegraphic reports, and the modification of some of the existing international conventions with regard to the observations made at stations of various orders and the method of recording them.

In the subsection on September 11, after an address by the chairman on methods of meteorological investigation, the president of the Association, Sir N. Lockyer, will read a paper on the correlation of solar and terrestrial phenomena, which will be followed by a discussion, as a preliminary to a proposal for putting the organisation of work in connection with that subject upon an international basis. Dr. Buchan will contribute a communication illustrating the distribution of rainfall in Scotland according to the succession of years of the sun-spot cycle. At the same session it is hoped that some of the members of the International Meteorological Committee who have taken a prominent part in the prosecution of researches in connection with that committee may be able to contribute papers. In particular the work of the committee on cloud observations has recently been brought to a conclusion, and a summary of the final results achieved would be very acceptable.

For any further available time on that or the other days there is already a substantial programme. Various astronomical papers have been referred to in the previous notice. The committees which have to present reports are those on kite observations, on the Ben Nevis Observatory, and on seismological observations, and any one of them, either of themselves or in connection with papers on special points associated with them, may give rise to valuable discussion. Prof. Hergesell, the chairman of the aëronautical committee, will be able to give the latest information as to the international investigation of the upper air, and Dr. Varley will exhibit the record obtained by him for Mr. P. Y. Alexander with an unmanned balloon that reached the extraordinary height of 70,000 feet on a journey from Bath in July. The kite equipment and method of investigation employed by Mr. Dines will be exhibited, if possible, in action.

Prof. Callendar will speak upon self-recording instruments, and thus open the way for the discussion of a subject which is of pressing importance in cooperative meteorological work.

The exhibition of objects of interest in connection with meteorology, terrestrial magnetism, and allied sciences has already been referred to in the columns of NATURE. Arrangements have been made with the view of exhibiting the formation and physical properties of the remarkable vortex ring of smoke produced by the discharge of a mortar of the same type as those which are extensively used in southern Europe with the object of mitigating hailstorms.

By way of illustration of the method adopted by the Meteorological Council for dealing with telegraphic weather reports, a weather chart for north-western Europe, with remarks and forecasts for the British Isles, will be prepared each morning during the meeting on the receipt of telegraphic information at Southport, and a limited number of lithographed copies will be available in the reception room.

THE OLDER CIVILISATION OF GREECE.[1]

STUDENTS of the older civilisation of Greece, which we usually know as "Mycenæan," will welcome the appearance of the eighth volume of the British School at Athens Annual, which, we are glad to say, this year is printed on much better paper than formerly, and shows a great improvement both in editing and arrangement. The volume contains the chief results of the excavations which were undertaken in Crete in 1902, both by the officers of the British School itself and by the Cretan Exploration Fund, of which Mr. A. J. Evans is the prime mover. More than a third of the book is occupied by an elaborate paper by Mr. Evans, who continues his annual description of the results of his excavations at Knossos; this is profusely illustrated by no less than seventy-four reproductions from photographs and line drawings, a map showing the state of the excavations at the present time, and two plates. Mr. Evans's paper is exceedingly interesting reading, and his discoveries appear to have been, as is usually the case, of first-class importance; we earnestly hope that good fortune may attend his labours in the future at Knossos as it has done in the past! It is, however, obvious that, for extensive excavations of this kind, which involve heavy and prolonged expenditure, increased funds are necessary. It is well known that Mr. Evans has contributed to the expenses of the work from his own private means far more than was right, but it is clear that no archæologist, however enthusiastic he may be, can continue to spend his own money indefinitely on researches which would, in any other country but England, be undertaken either by the Government or by some wealthy academy.

The most important objects described by Mr. Evans are:—(1) A series of tablets of porcelain mosaic representing houses and towers, which are curiously like children's dolls' houses, with a door in the middle and the windows divided by mullions. (2) A series of similar porcelain tablets with representations of warriors and animals. (3) A set of terra-cotta models of pillar-altars, with figures of doves perched upon the top of them. (4) Fragments of ivory figures of leaping youths, with the hair represented by bronze spirals let into the ivory. (5) A small shrine discovered *in situ* in the southern part of the palace. The shrine and its contents have been carefully kept in their original position, and a small house has been built over them to protect them from the weather. The contents consist of rude iconic figures of deities, and a horned altar, which is somewhat Canaanitish in type. These horned altars are familiar objects in Cretan diggings, and they are usually described by Mr. Evans as "horns of consecration." (6) Objects inscribed in ink with Cretan hieroglyphics. These are of great importance, for they show that the Cretans employed the Egyptian means of writing as well as the Mesopotamian; they used both pen and ink as well as clay tablet and stylus. (7) The sanitary arrangements of the palace, which appear to have been extraordinarily modern in character. The latrines were water-closets, which were provided with carefully constructed drains made of terra-cotta pipes, the sections of which remind one (see Fig. 7, p. 13) of a sanitary engineer's catalogue of the present day. The exigencies of space will not allow us to enumerate the minor discoveries, and we refer the reader to the Annual itself for a full account of them.

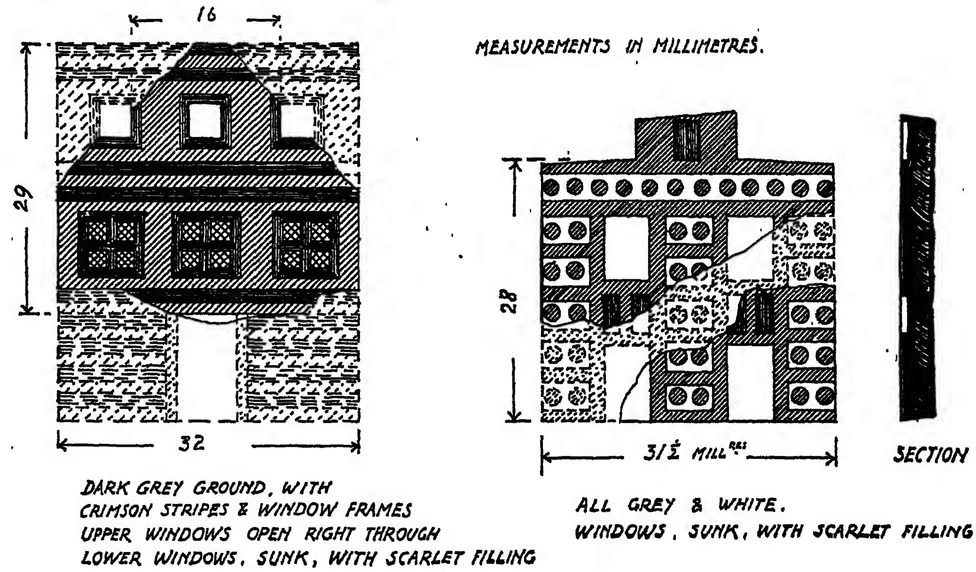


FIG. 1.—Porcelain Tablets in Form of Houses (slightly enlarged).

Mr. Evans ends his paper with some speculations as to the possible connection of Crete with Egypt as early as the time of the fourth and fifth dynasties, *i.e.* about B.C. 3700–B.C. 3200, and it is of interest to note that Mr. H. R. Hall, of the British Museum, publishes in this volume of the Annual a paper dealing more or less with this very subject. Mr. Hall traces the history of the connection between Egypt and the peoples of the Ægean, and the southern coast

[1] "The Annual of the British School at Athens." No. viii. Session 1901–1902. Pp. 348, 20 plates, and many illustrations. (London: Macmillan and Co., Ltd.)

of Asia Minor, from the periods of the sixth and twelfth dynasties down to the reign of Rameses III., *i.e.* for a space of more than 2000 years. The great value of his paper to Greek archæologists consists in the fact that he derives his materials from the Egyptian monuments alone, and he has shown pretty conclusively from the Egyptian records that the Mycenæans, or "Minoans," of Crete were in close communication with Egypt as early as the time of the eighteenth dynasty, about B.C. 1650 to B.C. 1400, and probably much earlier. We may note in passing a point of interest, namely, his identification of the true name of the Island of Cyprus in the time of Thothmes III., viz. Yantanay, which is undoubtedly the same as the Assyrian name for the island, "Yatnana." Mr. Hall also gives new material to the student of Mycenæan art in his identifications of Cretan vases among the tribute depicted on the walls of the tombs at Thebes, about B.C. 1550. The rest of his paper is occupied with an account of the relations of the Egyptians with the Mediterranean tribes who successively invaded Egypt under the nineteenth and twentieth dynasties. He proves that the period of peaceful relations between Crete and Egypt under the eighteenth dynasty was the period of the Minoan civilisation of Knossos and Phæstus, and that the post-Minoan, or true Mycenæan, period in Greece was the time when the peaceful relations of Cretan civilisation with Egypt had come to an end, and, in the author's words, "in the days of the degenerate Ramessids of Egypt, its place had been taken by wandering tribes, amid whose internecine struggles the older civilisation of Greece slowly degenerated and finally passed away.

FIG. 2.—Upper Part and Head of a Model of an Ape found at Mycenæ.

The excavations which have been carried on by the British School itself at Palaikastro, at the eastern end of Crete, are described by Mr. R. C. Bosanquet, the present director of the school. He has found there the remains of a palace and houses, some remarkable interments in painted terra-cotta coffins, and a great quantity of pottery of the pre-Mycenæan or Kamares type. We understand that Mr. Bosanquet's excavations this year have been even more productive than those of last year, and his exploration of the Eteokretan country has given us much new information about this remote but interesting portion of the island. Two or three years ago Mr. Bosanquet discovered on the site of Præsus, the ancient capital of the Eteokretans, another example of an inscription in the non-Greek language of eastern Crete. This is critically examined by Mr. R. S. Conway in this number of the Annual, but we think that his attempt to prove that the language is Indo-European is unsuccessful. Kretschmer has shown that the languages of southern Asia Minor, of which Lycian is the best known example, were not Indo-European, and legend connects the Eteokretans with Lycia. Of the Lycian language Mr. Conway naïvely admits (p. 156, note 2) that he has no knowledge, but yet criticises Kretschmer! The remaining article in the volume, which is by Mr. Marcus N. Tod, is of interest to classical scholars only. The above remarks are sufficient to indicate the interest and importance of the new volume of the British School at Athens.

THE MARQUIS OF SALISBURY.

THE death of Lord Salisbury has robbed us of a great statesman. He had been ill for some weeks and the peaceful end came during the evening of Saturday last. At the beginning of June of this year an attack of nephritis, complicated with a weakness of the heart, set in, and from this illness Lord Salisbury never recovered. Since the preceding Wednesday, when his heart began to fail, it was generally known that there was no hope, and the quiet, painless passing came as a fitting conclusion to a distinguished career, marked always as it was by a dignified reserve and an unusual love for seclusion.

Born in Hatfield on February 3, 1830, Lord Salisbury died in his seventy-fourth year. He was the direct lineal descendant of the great Lord Burleigh, and was educated at Eton and Christ Church, Oxford, where he graduated in 1850. The few years following his stay at Oxford were spent in travel, and included a somewhat prolonged visit to Australia and New Zealand. During this period he learnt from personal experience the dangers and charms of life at cattle stations and at the gold diggings. Returning in 1853, he was elected to an All Souls Fellowship, but as subsequent events showed he preferred the activity of politics to the quietude of university life. In the autumn of the same year he entered the House of Commons as Conservative member for Stamford, and for fifteen years he continued to represent this constituency, until, in 1868, on the death of his father, he took his seat in the House of Lords as Marquis of Salisbury.

It is unnecessary, even if it were appropriate, to give in these columns an account of the numerous incidents in the political career of this renowned statesman. The barest catalogue of the important offices of State occupied by him with consummate ability serves adequately to indicate how intimately his life has been intertwined with the history of the Empire during the latter half of the nineteenth century, and how large a part the dead statesman has taken in the government of the nation. He was twice Secretary for India and President of the Indian Council. In 1876 he was special Ambassador to the historic conference at Constantinople; and in 1878 Plenipotentiary at the celebrated Berlin Conference. Four times he was the Secretary of State for Foreign Affairs, and in this capacity more than any other, perhaps, he inspired the complete confidence of his countrymen. In 1886 he was First Lord of the Treasury, and three times he was called upon by his Sovereign to form a Cabinet. His premierships lasted respectively from 1885–6, 1886–1892, and 1895–1902.

But an account of Lord Salisbury's political career gives no proper idea of the versatility of his genius. When a member of the House of Commons he was actively engaged in journalistic work, and his contributions to the *Saturday Review*, the *Quarterly Review*, and other papers would have secured for a less gifted person a sufficiently high reputation. To men of science, however, the most interesting recollection in connection with Lord Salisbury is the fact that in 1894 he was President of the British Association, and that throughout his political triumphs his great pleasure was, in his leisure hours at Hatfield, to pursue scientific researches in physics and chemistry.

In commenting on the Presidential Address delivered by Lord Salisbury at Oxford in our issue for August 9, 1894, we remarked:—"Many of those who know Lord Salisbury only as a politician and as Minister for Foreign Affairs will be surprised at the wide range of thought and reading displayed in his

handling of the diverse topics which he passes under review." And though Lord Salisbury himself said in that address, "In presence of the high priests of science I am only a layman, and all the skill of all the chemists the Association contains will not transmute a layman into any more precious kind of metal," yet on that occasion he proceeded to give in a masterly fashion "a survey not of our science but of our ignorance." The references to the want of knowledge of the nature of the capricious differences which separate the atoms from each other; the description of the ether as "a half-discovered entity"; the explanation of the deep obscurity which at the time of the address still enveloped the origin of the infinite variety of life, and the impossibility of demonstrating the process of natural selection in detail, combined to make the Oxford British Association address comparable in importance with the great controversy at the same city when the Association met there thirty-four years previously.

The study of science was for many years the solace which Lord Salisbury sought from the cares of State, and it is far from fanciful to suppose that these investigations influenced his political outlook and contributed to his success in meeting the difficulties of government. But whether this is so or not, there can be no doubt that Lord Salisbury's acquaintance with physical and chemical science was of an intimate nature, and added greatly to the joy and comfort of the short years of his retirement.

Lord Salisbury held many other appointments and received numerous academic distinctions. Among these may be mentioned that from 1869 to the time of his death he was Chancellor of the University of Oxford, and his interest in higher education was also shown by the fact of his being a member of the Council of King's College, London. He was a Doctor of Civil Law of Oxford, and a Doctor of Laws of Cambridge University, as well as a Fellow of the Royal Society.

This brief notice of a great career may be fittingly closed with a paragraph from Dr. Traill's monograph. "Lord Salisbury's record is that of an English statesman who, while directing the affairs of his country abroad with singular skill and judgment, has also guided its domestic policy in the paths of wisdom and equity, and, though loyally submitting to the 'will of the majority' in all things lawful, has held it his first duty to maintain the just rights of every class, however small a minority it may constitute, in the State."

PROF. LUIGI CREMONA.

AN interesting account of the life and work of the late Prof. Cremona, by Prof. Blaserna, appears in the *Proceedings* of the Royal Society of Edinburgh (vol. xxiv.), an advance copy of which has been received. By permission of the general secretary of the Society, we print a free translation of Prof. Blaserna's contribution and extracts from a note appended to it.

Prof. Luigi Cremona was born at Pavia on December 7, 1830, and studied there until the year 1848, when he suspended his academic work to join the ranks of the Italian volunteers, and to take part in the heroic defence of Venice until the capitulation of that famous town. He then graduated in mathematics at Pavia, where he had among his teachers Francesco Brioschi, and among his fellow-students Eugenio Beltrami and Felice Casarati. Thereafter he taught in the Gymnasium at Cremona and in the Beccarian Lyceum at Milan.

In 1860 he was appointed to the new chair of higher geometry in the University of Bologna, then reorganised by the Italian Government, and thence he passed, in 1866, to the Polytechnic at Milan. When, after the year 1870, the Italian Government undertook the organisation of the great University of Rome, with its annexed engineering school, Cremona was called, in 1873, to be professor of higher geometry in the university and director of the engineering school, which he reconstructed and established in the old Convent of St. Pietro in Vincoli. The duties of this double post he discharged with fidelity and distinction to the last years of his life.

Although Cremona had been a pupil of Brioschi, an eminent analyst, his predilection was always for geometry, in which he may be said to have created a classical school. His numerous publications refer chiefly to the theory of algebraic curves and surfaces. All the problems that arose in this department of mathematics between 1860 and 1880 attracted his attention, and everywhere he left an indelible trace of the depth and the clearness which characterised his genius.

To general theory are dedicated the "Introduction to a Geometrical Theory of Plane Curves" (1862) and "Preliminaries to a Theory of Surfaces" (1866), two monographs in which he expounds, with originality of view and wonderful unity of method, results partly known and partly new. He demonstrated the fruitfulness of the theorems contained in the second of these memoirs by applying them to the study of surfaces of the third order, in the "Mémoire de Géometrie pure sur les Surfaces du troisième Ordre," which gained in 1886 the Steiner prize of the Academy of Berlin, and which will remain for all time a classic model of geometric research.

But the originality of Cremona appears still more distinctly in his study of the transformations to which his name is now attached. Already in the first half of the nineteenth century a theory had arisen of the projective transformations which change the points and straight lines of one plane into the points and straight lines of another plane, and side by side with these had also been examined the correspondences which transform straight lines into circles or conics. But the idea of treating from a more general point of view the transformations which change straight lines into algebraic curves of any order n whatever belongs to Cremona, who established the basis of this theory in two memoirs (1863–65), and afterwards extended it to space of three dimensions (1871–72), thus opening to geometers a vast field of research, which has not been exhausted at the present day.

While, by these works, of which I have mentioned only the most extensive, and by his splendid lectures, Cremona was firing the rising generation with the love of pure science, and thus exercising a great influence on original geometric research in Italy during the last thirty years, on the other hand he was never weary of showing his interest in the technical applications of mathematics. His little work on "Reciprocal Figures in Graphical Statics" is a beautiful example of this interpenetration of pure and applied science, an interpenetration which characterises another side of his broad genius. Always pursuing this order of ideas, he took assiduous care with his engineering students in Rome to keep science and practice side by side, inciting them to attain that just balance of different faculties of which he gave himself so fine an example.

Besides all this, Luigi Cremona was a statesman. Nominated a Senator of the kingdom in 1879, he took an active part in all the work of the Senate. He was, indeed, one of the most respected and influential of the

Senators, and his reports and speeches reveal a man of frankly liberal views and of firm and stable character He was, for a short time, Minister of Public Instruction in one of the ministries of the Marchese di Rudini.

The fame of Luigi Cremona is world-wide. Almost all the foreign academies elected him a fellow. His death (which happened on June 10 last) has been a loss not only for Italy, but for science universal, in which his discoveries will long secure him a place of honour.

In the course of a note appended to Prof. Blaserna's valuable statement of facts as to Cremona's career, Prof. Chrystal remarks:—

In the year 1884, Cremona, along with Hermite and his son-in-law Émile Picard, was my guest during the tercentenary festival of the University of Edinburgh. Besides these three distinguished mathematicians, the following were present at the festival:—Helmholtz, Bierens de Haan, Cayley, Sylvester, Lord Kelvin, Stokes, Salmon, Lord Rayleigh, and Tait. The majority of these dined one evening with Lord M'Laren, and it is scarcely probable that there ever was such a feast of mathematicians before or since. Of this brilliant band of nineteenth century men of science, there remain with us now only Kelvin, Rayleigh, and Picard.

NOTES.

THE ninth International Geological Congress was opened at Vienna on Thursday last, when Dr. Tietze, director of the Imperial Institute of Geology, was elected president.

A REUTER telegram from Cape Town states that the Cape Legislative Council has agreed to a motion in favour of addressing a communication to the Imperial Government on the subject of the adoption of the metric system.

ACCORDING to the *Athenaeum*, a resolution was passed at the conclusion of the recent geodetic congress at Amsterdam requesting the various nations to carry out extensive measurements of gravity from the Atlantic towards the east through the lowlands of Europe and Asia, as well as in the plateau around Thibet. A clear conception of the variations of weight and of the distribution of bulk in the crust of the earth would be gained thereby in connection with astronomical determinations of longitude and latitude.

Science states that the commission sent by the U.S. Marine Hospital Service to Vera Cruz reports three propositions as having been demonstrated beyond doubt, namely, (1) that the cause of yellow fever is an animal parasite, and not a vegetable germ or bacterium; (2) that the disease is communicated only by the bite of mosquitoes; (3) that only one genus of mosquitoes, *Stegomyia Fasciata*, is the host of the yellow fever parasite.

THE *British Medical Journal* states that Dr. S. R. Christophers, who was associated with Dr. Stephens in the investigation as to malaria conducted on the west coast of Africa and in the Indian cantonments, has been notified by the Indian Government that the medical authorities desire him to proceed at once to India, with the view of his again taking up special work relating to malarial infection. Dr. Christophers is, it is stated, leaving almost immediately to enter upon his duties.

ACCORDING to a Stockholm correspondent of the *Times*, the Swedish steamer *Frithjof*, which on August 17 started from Stockholm for the relief of Dr. Otto Nordenskjöld's South Polar Expedition, will take on board at Bremerhaven provisions for three years and wireless telegraphy apparatus. Such apparatus is also, it is stated, to be fitted on board the Argentine gunboat *Uruguay*, and it is thought that this vessel, which is iron built, will remain outside the ice while the *Frithjof* will push on as far south as possible. From Bremerhaven the *Frithjof* will go to Plymouth to coal, and then *viâ* Madeira to Buenos Ayres, where possibly an Argentine naval officer will join her. She will then go to Punta Arenas, whence her commander proposes to reach Snowhill, the supposed winter station of the Antarctic.

ON Saturday last the Canadian Government steamer *Neptune* sailed from Halifax, Nova Scotia, for Hudson Bay and Arctic waters on an expedition to last a year and a half. The object of the expedition is to conduct, on behalf of the Government, a botanical, geological, and natural history investigation. The party will take formal possession of the Arctic Islands and the shore of Baffin's Bay. The commander of the expedition will report on the alleged extensive American poaching in the Hudson Bay fisheries. The importance of the cod and halibut fisheries will be reported on.

A MESSAGE from Naples, dated August 22, states that the explosions of Mount Vesuvius are increasing in violence, and quantities of volcanic matter have been thrown to a height of about 200 yards. At half past 6 o'clock of the morning referred to, a slight earthquake shock was felt.

THE arrangements for the eighth International Geographical Congress, to be held next year at Washington, are, says the *Times*, taking shape under the care of a committee representing the ten geographical societies and mountaineering clubs of the United States, which have united to welcome the geographers of all nations to American soil. The congress will meet in Washington on September 8, 1904, and will hold daily sessions on September 9, 10, 12, 13, and 14. The subjects for treatment and discussion during the meeting at Washington are classified under the following heads:—(1) Physical geography, including geomorphology, meteorology, hydrology, &c.; (2) mathematical geography, including geodesy and geophysics; (3) biogeography, including botany and zoology in their geographical aspects; (4) anthropogeography, including ethnology; (5) descriptive geography, including explorations and surveys; (6) geographical technology, including cartography, bibliography, orthography of place-names, &c.; (7) commercial and industrial geography; (8) history of geography; (9) geographical education. The committee urges that early notice be given by those desirous of presenting communications or proposing subjects for discussion, July 1, 1904, being fixed as the latest date for submitting communications designed for printing in connection with the congress, and August 1 in the case of abstracts (not exceeding 1000 words in length) designed for insertion in the daily bulletin.

AN International Electrical Congress will be held at St. Louis, Mo., from September 12 to 17 of next year. The sections which have been proposed for the main body of the congress are:—*General Theory*.—Section A, mathematical and experimental. *Applications*.—Section B, general applications; Section C, electrochemistry; Section D, electric power transmission; Section E, electric light and distribution; Section F, electric transportation; Section G, electric communication; Section H, electrotherapeutics. Prof. Elihu Thomson has been elected president of the committee of organisation, and the general secretary is Dr. A. E. Kennelly, Harvard University, Cambridge, Mass.

THE *Times* Brussels correspondent states that the eleventh International Health Conference will be held in Brussels from September 2 to 8. One of the leading questions for discussion is whether the tuberculosis bacillus in the domestic animal is identical with that of the human species.

IN connection with an exhibition which is to take place at Milan in 1905, a national sanitary congress is to be held. The work of the congress will be dealt with in the following sections:—sanitary assistance, public hygiene, clinico-scientific and therapeutic, medical jurisprudence and accidents to workmen, professional interests.

A GENERAL exhibition arranged by the Central Association of Inventors, of Bayreuth, for the purpose of facilitating the sale of patents and copyrighted patterns is to be held during September and October next at Nuremberg. There are, it is stated, more than 200,000 copyrighted patterns in Germany and more than 140,000 patents, but one-half of these are not in public use, the reason being that the inventors are not able to exploit their inventions. It was because of this that the Central Association came into being some years ago. Its purpose is to assist the members to make their inventions profitable to themselves, the majority of inventors not having the means to do so. The Association furnishes space to inventors without means free of cost, and charges no fees for effecting a sale.

ACCORDING to a Reuter telegram from Berlin, a number of mining officials will, at the instance of the Minister of Commerce, shortly be sent to this country to make a thorough study of the hygienic and sanitary arrangements in mining districts.

THE *Electrician*, quoting from the *Western Electrician* of Chicago, states that preliminary reports have been given concerning wireless telegraph experiments which have been conducted on board the training ships *Prairie* and *Topeka*, in conjunction with shore stations, by the Navy Department of the United States during the last year. The reports state that the Slaby-Arco system is well suited for naval purposes, and has been adopted by the United States Navy. It was tested in competition with French, German, and English devices, not, however, including the Marconi system. Satisfactory terms, it is stated, could not be made with Mr. Marconi for the installation of his instruments on the war ships, and further negotiations were discontinued. Twenty sets of Slaby-Arco instruments have been installed on eight war vessels, which used them in the fleet manœuvres.

A TELEGRAM from New York, through Laffan's agency, states that the advisory board of the American scientific expedition to Babylon has been compelled to abandon its plan of extensive excavations at that place, preparations for which have been made during the last three years. The abandonment is due to the persistent refusal of the Porte to permit the American society to carry on such work, although it has readily authorised excavations by other nations.

THE collections made by Mr. M. J. Nicoll, who accompanied Lord Crawford, as naturalist, in the R.S.Y. *Walhalla* during his recent tour round the world, have arrived at the Natural History Museum, South Kensington, and contain about 1500 specimens. The *Walhalla* remained so short a time at most of the places where she stopped that it was not possible to procure a large number of examples of terrestrial animals; but about 250 bird-skins were brought home. The principal collections were made in the Magellan Straits, at Valparaiso, in the Samoan and Fiji groups of the Pacific, and in Torres Straits. Mr. Nicoll is now engaged in arranging and naming the specimens.

SEVERAL living specimens (three of which have arrived safely) of the wild guinea-pig of Brazil have, according to *Science*, recently been sent to the zoological laboratory of Harvard University by Mr. Adolph Hempel for the purpose of experimental studies in heredity.

DR. CARROLL gives an interesting *résumé* of our knowledge of the mode of transmission of yellow fever (*Journ.* Amer. Med. Assoc., May 23). He points out that the mosquito theory has been proved to be true, and that the non-communicability of the disease from person to person, and by means of fomites, has been demonstrated. Yellow fever has been eradicated from Havana, one of its endemic homes, by the institution of measures directed against the mosquito, after extreme cleanliness and energetic disinfection had proved dismal failures.

THE specificity of anti-venene, the anti-serum for snake venom, has been a matter of controversy for some years. Calmette originally asserted that anti-venene was not specific, that is, cobra anti-venene, prepared by injecting an animal with increasing doses of cobra venom, though most active against cobra venom, would also antagonise other venoms. Martin, and more recently Tidswell, in Australia, questioned the correctness of this view, and Captain Lamb, I.M.S., has now proved beyond doubt that anti-venomous sera are just as specific as any other antisera, *e.g.* diphtheria or tetanus (*Sc. Mem.* of the Gov. of India, New Series, No. 5). He has tested the neutralising properties of several anti-venomous sera towards the venoms of many species of venomous snakes, and in no case was any neutralising power exhibited by a serum except towards the venom with which it had been prepared.

THE annual report issued by the superintendent of the Botanical Department in Trinidad bears testimony to the useful work which is carried on at the St. Clair experiment station. The Lagos "silk rubber" plant *Funtumia elastica* continues to be in demand, as the points in its favour are suitability to the climate, easy coagulation, and good rubber yield at an early age. The experiments with seedling sugar-canes are unfortunately limited by the small amount of space available for growing plots, but the demand for canes to the full extent of the available supply is a sufficient guarantee of the success of the undertaking. The cultivation of cotton in the West Indies would be the revival of an old industry. Through the cooperation of the Cotton Growers' Association, a quantity of seed has been provided for distribution, and prizes are offered for the best results.

THE botanical features of that district comprised in the Delta of the Ganges known as the Sundribuns are so unique that even after the surveys by Prof. Heinig and Mr. C. B. Clarke there still remains scope for the account which is presented by Dr. Prain in the *Records* of the Botanical Survey of India. This includes the first complete list of plants gathered in the district, with a guide to the genera and species, as well as a summary of the principal ecological associations, and observations on the manner in which they may have originated. First in point of interest comes the mangrove vegetation, which includes a heterogeneous collection of plants, many of which are characterised by the development of root suckers having a respiratory function; further, the collections of plants found at the sea face and in the clearings present problems in connection with the dispersal of species.

THE causes of acceleration and retardation in the metamorphosis of *Amblystoma tigrinum*, the adult form of the Mexican axolotl, form the subject of an article by Mr. J. H. Powers in the June number of the *American Naturalist*. According to the author, previous observers have been in error in attributing the retention of the larval form to inability to leave an aquatic life, and, conversely, the early acquisition of the adult condition to removal from water. The real factor in the case, he believes, is nutrition. A paper by Mr. J. H. Lovell, in the same journal, on the colours of northern gamopetalous flowers and their relations to bees and other insects, contains much matter of interest alike to the botanist and to the entomologist. The sequel will be published in a later number.

To vol. ii. No. 5 of *Marine Investigations in South Africa*, Dr. J. D. F. Gilchrist contributes some important notes on the development of South African fishes. The publication of these notes, which are confessedly crude and imperfect, would have been deferred until fuller investigations had been undertaken were it not for the circumstance that they have an important bearing on certain disputed points connected with the Cape fisheries. Many of the fishermen urge, for instance, that the spawn of several of the commoner food-fishes is developed on or near the sea-bottom, and is, in consequence, seriously damaged by trawling. To this the author replies that, since in northern waters it has been demonstrated that only one valuable food-fish, the herring, has deep-lying spawn, and since the Cape seas are the home of only a small species of herring of little or no commercial value, it is probable that the damage done by trawling in South African waters has been largely overestimated.

A PRELIMINARY report upon "Trypanosomiasis of Horses ('Surra') in the Philippine Islands," by Messrs. Musgrave and Williamson, has been issued by the Government Laboratory, Manila. The disease seems to have been recently introduced into the Philippines, for careful investigation has failed to show any evidence that it existed there before May or June, 1901. It is transmitted through the bites of insects, and until the exact species are discriminated, for preventive measures all insects should be considered as carriers of the infection. In Manila a certain number of the rats have been found to be infected with the horse trypanosoma. An account is given of the symptoms of the disease and of the preventive measures to be adopted, the most important of which is the prevention of the access of all flies and insects.

A SHORT time ago M. Blondlot announced the discovery of a new form of radiation found with Röntgen rays, and possessing the power of penetrating black paper and many metals. The rays could be reflected and refracted by quartz lenses, and were without photographic action; they could, however, be detected by their power of increasing the luminosity of small electric sparks or of a colourless "blue" flame. The rays were subsequently shown by M. Blondlot to be produced by an Auer burner. Following up his researches on these *n* rays, M. Blondlot has been led to discover some remarkable properties which they possess; these are communicated in a recent number of the *Comptes rendus*. It seems that the rays are capable of increasing the illumination given by an incandescent surface on which they fall, and this without any increase of temperature. An experiment which seems conclusive is quoted; a platinum wire which was heated to a dull red was subjected to the action of the rays, and whenever these were allowed to fall on it the incandescence was visibly increased. An auxiliary electrical circuit afforded a means of measuring the resistance, and hence the temperature of the wire, and this showed that the rays produced no increase in temperature; an increase of temperature too small to produce a visible effect in the incandescence of the wire was easily detected by the measuring circuit. This result is particularly interesting, not only in reference to the *n* rays of M. Blondlot, but in reference to theories of incandescence and light emission generally, as it seems possible that these rays may be able to throw some light on the many difficult problems that beset this subject. The remarkable properties that this radiation seems to possess promise to make it of unusual interest, and possibly also of great utility.

IN the *Gazette de Lausanne*, M. F. A. Forel directs attention to what appears to be a recurrence of the coloured circle round the sun (Bishop's Ring), similar to that which was observed after the Krakatoa explosion in 1883. The present phenomenon is paler than that first described by Mr. Bishop, and is supposed to be connected with the eruption of Mont Pelée in May, 1902. M. Forel states that it can only be seen at an altitude of not less than 2000 metres; it was first seen by him on August 1, and he points out that it would be very interesting if alpine climbers, or balloonists, would state when the ring was first observed by them, and whether its appearance is intermittent or continuous.

A CORRESPONDENT of the *Times* directs attention to a supposed cure for the mysterious malady known as mountain sickness. The discoverer of the specific is a Russian topographer named Passtoukhof, who, for some years past, has been making ascents in the Caucasus, where he has climbed the Grand Ararat, Mount Kasbek, and Mount Elbruz. At such high altitudes as these it is easy to understand that the question of mountain sickness becomes a serious one, and on more than one occasion M. Passtoukhof has found not only himself, but all the other members of his expedition, completely prostrated by it. On one of these occasions it occurred to him to try the experiment of lighting his spirit lamp and making some tea, which he administered to himself and his companions in an almost boiling condition, with a result that far exceeded his expectations. Almost immediately the more serious symptoms disappeared, and in a short time all the members of the expedition found themselves well enough to continue the ascent. Later on M. Passtoukhof repeated this experiment of using boiling tea as a remedy for mountain sickness, with results so invariably successful that he now feels justified in considering that it may really be regarded as a specific.

A CORRESPONDENT directs our attention to the fact that one feature of the programme at present in force at the Alhambra is an exhibition of the microbioscope. We are glad, like our correspondent, that science is being introduced—even in the form of amusement—to those who, in ordinary circumstances, take no interest in scientific matters, and think with him that more might be done even with existing resources to bring a knowledge of the advances of science under the notice of the people. "The music halls are," says our correspondent, "being increasingly used for good music; why not for good science? The managers will put money into it if the public respond, and no objection will be made to raising the tone of their programmes if the houses fill. Those interested in science need not spend the evening there; they could go to see just what concerned them."

THE Engineering Standards Committee has just issued "standard sections and specification" for tramway rails. If the series of rails be adopted, it should be easier for the British manufacturer to hold his own against foreign competition, which, in the case of tramway rails, is particularly severe.

WE have received the first parts of the monthly *Bulletin* of the Philippine Weather Bureau for 1903, prepared under the direction of the Rev. José Algué, S.J., director of the service. This bulletin, modelled on the plan of the United States meteorological publications, contains valuable climatological observations and general notes on the weather and crops. The report for 1902 contains an interesting account of the establishment and development of the service under the Spanish Government, and of its reorganisation and improvement under the United States. Meteorological observations were begun in Manila in 1865, and after many years of assiduous study of the behaviour of the typhoons of the eastern seas, Father Faura, the first director of the observatory, commenced his predictions of the approach of typhoons in July, 1879. These storm warnings have been the means of saving much life and property, not only in the Philippine Islands, but on the Chinese coasts. Their value is now fully recognised by the United States Government and by the Colonial Secretary and Chamber of Commerce of Hong Kong. On the recommendation of the chief of the U.S. Weather Bureau, a network of subsidiary stations has been established in the archipelago which will doubtless render invaluable service to our knowledge of the meteorology of the Far East.

A PAMPHLET of sixty-nine pages, extracted from the report of the expedition of the *Stella Polare* in 1899–1900, deals with the magnetic observations undertaken in the Bay of Teplitz by Captain Umberto Cagni. These observations were reduced by Prof. Luigi Palazzo, who gives the following results for July, 1899, and June, 1900:—Declination, 21° 10′ and 21° 18′ east; inclination, 83° 25′ and 83° 1.2′ north; horizontal intensity, 0.06846 and 0.06855; vertical intensity, 0.59319, 0.55990; total force, 0.59713, 0.56409. The principal instruments used were a unifilar Schneider magnetometer and a Kew inclinometer, but great difficulties were experienced in making the observations; among other inconveniences, snow was carried into the temporary observatory, and succeeded in penetrating through every crack or crevice.

SOME recent researches in the comparatively modern study of experimental phonetics are given by Prof. E. W. Scripture (Yale) in the *Medical Record* (February 28), and *Die neuern Sprachen* (January). In the former paper, Prof. Scripture describes the different methods that have been employed for registering the sound curves of the human voice. The method preferred by the author is to obtain a gramophone or phonograph record of the voice and to trace off an enlargement of the fluctuations either by mechanical or by photographic methods. In the second paper, Prof. Scripture describes a complete record of the melody of the Lord's Prayer as recited in the style characteristic of the eastern part of the United States. A diagram is given showing the main variations of pitch. An investigation in another branch of physiological acoustics, dealing with the audibility of vowel sounds under pathological conditions, is given by M. Marage in the *Comptes rendus* (February).

THE additions to the Zoological Society's Gardens during the past week include two White-crowned Mangabeys (*Cercocebus oethiops*) from West Africa, presented by Mr. C. R. Farquharson; an Ocelot (*Felis pardalis*) from Rio de Janeiro, presented by Mr. John Gordon; a Grand Eclectus (*Eclectus roratus*) from Moluccas, a Black-crested Cardinal (*Gubernatrix cristatella*) from Paraguay, a Red-headed Cardinal (*Paroaria larvata*), a White-throated Finch (*Spermophila lineola*) from Brazil, presented by the Right Hon. Earl of Crawford, K.T.; a Brown-throated Conure (*Conurus oeruginosus*) from South America, presented by Mrs. M. Moir-Byres; a Barred Dove (*Geopelia striata*) from India, a West African Love-bird (*Agapornis pullaria*) from West Africa, presented by Sir Arthur Bigge, K.C.B.; a Common Snake (*Tropidonotus natrix*), British, presented by Mr. Oliver Roberts; a Yellow Baboon (*Papio cynocephalus*) from Africa, a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, a Lion Marmoset (*Midas rosalia*) from South-east Brazil, an Echidna (*Echidna hystrix*) from New South Wales, two Stanley Parrakeets (*Platycercus icterotis*), two Tree Sparrows (*Passer montanus*), three Limbless Lizards (*Pygopus lepidopus*), a Muricated Lizard (*Amphibolurus muricatus*), a Cunningham's Skink (*Egernia cunninghami*) from Australia, a Lesser White-fronted Goose (*Anser erythropus*), two Jackdaws (*Corvus monedula*, var.), European; an American Glass Snake (*Ophiosaurus ventralis*), a Hog-nosed Snake (*Heterodon platyrhinos*), two Couch's Snakes (*Tropidonotus ordinatus couchi*) from North America, deposited; nine Summer Ducks (*Aex sponsa*) from North America, purchased.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER:—

Sept. 3. 8h. Saturn in conjunction with moon. Saturn 5° 26′ S.
5. 9h. 26m. Minimum of Algol (β Persei).
7. 5h. Mercury at greatest eastern elongation (27° 0′).
11. 18h. Jupiter in opposition to the sun.
12. Saturn. Polar diameter = 16″·3, outer minor axis of outer ring = 14″·39.
15. Venus. Illuminated portion of disc = 0·002; of Mars = 0·891.
17. 9h. Venus in inferior conjunction with the sun.
" 13h. 53m. to 14h. 36m. Moon occults α Cancri (mag. 4·3).
20. Sun totally eclipsed, invisible at Greenwich.
21. 7h. 13m. to 10h. 22m. Transit of Jupiter's Sat. III. (Ganymede).
23. 18h. Sun enters Libra. Autumn commences.
25. 11h. 9m. Minimum of Algol (β Persei).
27. 7h. 55m. to 11h. 2m. Transit of Jupiter's Sat. IV. (Callisto).
28. 7h. 58m. Minimum of Algol (β Persei).
" 10h. 30m. to 13h. 40m. Transit of Jupiter's Sat. III. (Ganymede).
30. 13h. Saturn in conjunction with moon. Saturn 5° 32′ S.

NEW TABLE FOR EX-MERIDIAN OBSERVATIONS OF ALTITUDE.—In existing tables for obtaining the difference between the observed and meridian altitudes, when determining latitude by ex-meridian observations, one has to refer to *two* separate tables, using as arguments declination, hour angle and approximate latitude. To remedy this Mr. H. B. Goodwin, R.N., has just published a pamphlet (Griffin and Co., Portsmouth) showing how the problem may be solved by the use of *one* table only, which is included in his pamphlet, using approximate latitude and azimuth.

The principle on which the method is based is that a body near the meridian may be regarded as changing its altitude with a uniform rate of change, and at any one interval we may take the *mean* rate of change as representative; and obtain the "reduction" to meridian altitude from the formula $dz = \sin A \cos l . dh$, where dz is the change of altitude and dh the contemporaneous change of hour

angle; dz for each half degree of latitude and azimuth is given in the table. All that one has to do to obtain the "reduction" is to take the approximate azimuth from any azimuth tables—and this has to be done for another part of the problem—then take out the rate of change, dz, from the Goodwin table and multiply this by the number of minutes in the hour angle.

RETURN OF BROOKS'S COMET.—A telegram from Kiel announces that Brooks's comet was observed by Prof. Aitken at the Lick Observatory on August 18, and that the position of the comet at 12h. 17·4m. (Lick M.T.) on that date was R.A. = 21h. 2m. 51·3s., Dec. = $-27° 4' 19''$. This position agrees closely with that given by an ephemeris computed by Herr P. Neugebauer, and published in No. 3868 of the *Astronomische Nachrichten*. The following is an extract from this ephemeris:—

Ephemeris 12*h.* (*M.T. Berlin.*)

1903	True α h. m. s.	True δ ° ′ ″	log r	log Δ

According to Aitken's determination of the comet's position, as given above, this ephemeris needs a correction of +22·58s. in R.A. and $+1' 41''·2$ in Dec.

Although not a bright object, this comet is of historical interest, because when it was first discovered by Brooks, in 1889, it was held to be a good illustration of the "capture theory" of comets, and was looked upon as identical with Lexell's lost comet of 1770, which had been "captured" by Jupiter. This belief was, however, discountenanced by the subsequent researches of Dr. Poor, of Baltimore. In 1889 Barnard observed the comet as double, and found that the two parts were slowly separating.

This comet has a period of 7·096 years, and was duly observed in 1896, when it performed its perihelion passage on November 4. For the present return the comet takes the designation 1903 *d*.

EPHEMERIS FOR COMET 1903 *c*.—An ephemeris for comet 1903 *c* is given in No. 3890 of the *Astronomische Nachrichten* by Herren M. Knapp and W. Dziewulski.

The comet is now too near the sun to be observed, but it will be observable by astronomers residing in the southern hemisphere after the middle of September.

α CORONÆ A SPECTROSCOPIC BINARY.—Using the 80cm. refractor and the No. 1 spectrograph of the Potsdam Observatory, Prof. Hartmann has determined that the radial velocity of α Coronæ Borealis varies from −20km. (May 28, 1902) to +38km. (June 3, 1902). The observations extended over the period May, 1902–July, 1903, and the respective velocities were determined from measurements of the lines Hβ, Hγ, Hδ, λ 4481 (Mg) and λ 3934 (Ca). The period of the binary is given as about 17 days (*Astronomische Nachrichten*, No. 3890).

THE ALLEGHENY OBSERVATORY.—In his report for 1902 the director, Prof. F. L. O. Wadsworth, laments the fact that the new observatory buildings and their equipments are not yet completed, and especially urges the necessity for mounting and housing the new 30-inch refractor, the discs for which have already been received from Mantois, of Paris; for this purpose a fund of sixty-five thousand dollars is required, none of which is yet subscribed or provided for.

An excellent electrical equipment for lighting and heating, and for all kinds of experimental work, has been donated by Mr. Westinghouse.

An efficient time service was maintained throughout the year 1902 in spite of instrumental difficulties. General observational work has had to be suspended pending the removal to the new observatory. A large number of mathematical researches have already been carried out, and others are suggested for future attention, by the director.

The latter part of the report is devoted to an outline of the work it is proposed to do when the new observatory is in full swing; this work includes exhaustive daily observations of all the solar phenomena and seismographic, gravitational, and magnetic observations.

THE RELATIONS BETWEEN SCIENTIFIC RESEARCH AND CHEMICAL INDUSTRY.[1]

THE particular branch of science with which I have been asked to deal at this meeting of university extension students—viz. chemistry—is perhaps better calculated to illustrate the intimate connection between scientific research and *productive* industry than any other subject. I emphasise the term *productive* industry because it is desirable to distinguish between productiveness and trade, *i.e.* buying and selling. With the latter I have nothing to do beyond pointing out the very obvious principle that, without something to buy or sell, there would be no commerce, and consequently productive industry must be put into the first rank. Now chemical products of various kinds are absolutely indispensable to all civilised nations. You may remember that many years ago Lord Beaconsfield said that the state of trade could be gauged by the price of chemicals. A writer in the *North American Review* in 1899 published an article in which he laid it down that the nation which possessed the best chemists was bound to come to the forefront in the struggle for industrial supremacy. Of course, "there is nothing like leather," and I am bound to agree with him. Had he been an engineer or an electrician he might perhaps have said the same for mechanical or electrical engineering. At any rate, it is perfectly safe to generalise his statement, and to declare that the nation which possesses the most highly trained technologists is bound to take the lead.

In so many ways does chemistry come into contact with nearly every branch of industry that it is difficult to know where to draw the line in giving actual illustrations of the industrial results achieved through chemical research. It is not possible logically, for example, to distinguish between the results obtained through research directed towards the solution of a particular industrial problem and the results obtained as by-products in the course of purely scientific investigation. Industry has been advanced, and always will be advanced, by both methods. Bearing in mind also that chemistry, in its widest sense, is essentially the science of matter—at any rate until the physicist has electrified matter into his own domain—it is evident that we are concerned not only with the production of useful materials for direct consumption, but also with the production of materials required in other industries. Thus chemistry affects engineers through the metals, cements, and other materials used for constructive purposes, and through the fuels used as sources of energy; it affects the agriculturist on account of the relationship between the growing plant and the composition of the soil, as well as through the relationship between the composition of crops and their value as food-stuffs; it supplies materials for the pharmacist, for the manufacture of pottery, glass and soap, for the paper maker, for the dyer and colour-printer, for the bleacher, tanner, brewer and spirit distiller; it furnishes the explosives used in modern warfare, and it supplies photography with all the materials necessary for the practise of that art. Among later developments it may be claimed that the modern science of bacteriology is the outcome of chemical research, and the manufacture of anti-toxins—the industrial result of this science—has until quite recently been in the hands of the chemical manufacturers. I may remind you also that many important products such as sodium, aluminium, phosphorus, calcium carbide, caustic soda, and chlorine are manufactured by electrical processes, so that the demand for these products has given an impetus to the development of applied electricity.

1 A Lecture delivered at the University Extension Meeting at Oxford on August 3, by Prof. Raphael Meldola F.R.S.

It is obviously impossible in view of the enormous range of industry in which chemistry is directly or indirectly concerned to do more on the present occasion than take a cursory glance at a few of the more striking cases illustrative of the connection between research and industry. As an example of the creation of an industry through research directed towards a special end, attention may be directed to the manufacture of optical and other glass at Jena. The history of this branch of manufacture, and the results achieved, have been fully described by Dr. Hovestadt in a work published three years ago, and of which a translation, by Prof. and Miss Everett, has been recently published in this country. I must refer you to this work for full particulars. The physical requirements to be complied with in order to produce the most perfect glass for the construction of lenses for optical instruments had long been known, and many attempts had been made to realise these conditions in practice. A visit to the international exhibition of scientific apparatus in London in 1876 led Prof. Abbe to direct attention once again to the fact that the future perfection of the microscope lay with the glass-maker, and in 1881 he, in conjunction with Schott, commenced a set of experiments having for their object the production of a series of glasses of known composition, the optical properties of which were concurrently determined by measurements made by Prof. Abbe. The experimental meltings were enlarged in scale the following year, and an experimental laboratory established for the continuation of the work at Jena. A chemist was added to the staff, and thus there were cooperating in this industrial research a glassmaker, a chemist, and a physicist. Before the end of 1883 the results had been so far successful that the Jena laboratory was in a position to make known to the world the processes for the "rational manufacture of optical glass." At this stage the experimenters were persuaded to put the results of their labour into practice, and the instrument makers, Messrs. Zeiss, having joined in, the Jena glass factory for producing optical glass on the commercial scale was established towards the end of 1884. In the first catalogue published by the Jena Works in 1886, we are told that forty-four optical glasses, nineteen being new in composition, were included. By 1888 the undertaking had been so successful that a supplementary catalogue was issued containing twenty-four additional glasses, of which thirteen were new, and in 1892 a second supplement announced the manufacture of eight more kinds of glass, of which six were new. Consider what this piece of work, prompted by science, fostered by the State, and carried out by a university professor in conjunction with a technologist has done for German industry. In the early stages of the experiments, before commercial results had been obtained, the experimenters were subsidised by the Prussian Education Department and by the Prussian Diet with a wise forethought which subsequent events have amply justified. Need I remind those who have come here to hear about bacteriology from Prof. Sims Woodhead how that science has advanced *pari passu* with the perfecting of the microscopic objective? The Zeiss instruments are now world-renowned, for it is obvious that a command over the processes for making glass with any particular optical properties that might be desired would enable the instrument maker to produce lenses suitable for other purposes, such as telescopes, field-glasses, photographic cameras, &c. I am afraid to dwell too much upon the perfection of the lenses of the Jena instruments because I lay myself open to the charge of holding a brief for a particular firm. If you want to know more fully what this optical glass industry has done for Germany, I refer you to the report on instruments of precision published in connection with the German exhibit at the Paris International Exhibition of 1900. As a further outcome the study of the properties of glasses of known composition in connection with their thermal and electrical behaviour has led to the manufacture of glass especially suitable for making thermometers, as also for electrical insulation, for the construction of the vacuum tubes used for producing Röntgen rays, and for the vessels employed in chemical laboratories. In brief, the manufacture of the finer kinds of glass has been placed upon a strictly scientific footing as the outcome of scientific research.

The next illustration which I propose to make use of refers to the applications of chemistry to agriculture. The growing plant, as you are aware, requires food for its growth just as much as the growing animal. Take an extreme case, and consider the size and weight of an oak tree as compared with the acorn from which it arose. This enormous accumulation of matter represents the assimilation of gaseous food in the form of carbon dioxide from the air through the leaves, and of water and nitrogenous and other mineral matter through the roots. It was the great German chemist Liebig who first established this broad principle of plant growth by systematic experiments upon various crops, and his results were given to the world in a work published in 1840, the English edition, edited by Lyon Playfair (afterwards Lord Playfair), bearing the title "Organic Chemistry in its Applications to Agriculture and Physiology." Perhaps few students consult this work now, but it was, strictly speaking, epoch-making on its appearance, because it brought the chemist into direct relationship with the farmer, and the consequence has been an enormous increase in the food-raising capacity of the soil. It is not necessary to inquire closely here into the motives that prompted Liebig's investigations—whether his work comes under the category of scientific researches directed towards a practical end, or whether he began with a desire of ascertaining abstract truth in the first place, and then found that his results were capable of practical application. It is quite immaterial from the present point of view how this work originated, because we are considering only the bearing of the results upon industry. It is evident that if a growing plant requires certain elements, such as potassium, sodium, phosphorus, nitrogen, calcium, magnesium, sulphur, chlorine, iron, &c., and if the soil by previous crops has been exhausted of some of these elements, it will not be possible to raise subsequent crops on this impoverished soil unless the necessary elements are supplied. In other words, the requisite elements must be added, and added in the form of compounds which the plant can make use of. Thus the great industry of crop-raising, and as connected therewith the feeding of farm stock, was shown to depend ultimately upon the chemical composition of the soil, and the manufacture of artificial manures or fertilisers has been the practical outcome of Liebig's researches.

Let us consider, further, the industrial results so far as these have influenced chemical manufactures. Prof. Warington can tell you all about the agricultural results. The elements which are most likely to fail, and which, in fact, have generally to be supplied, are potassium, phosphorus and nitrogen, excepting, of course, in the case of those particular leguminous plants which have developed a special means of fixing atmospheric nitrogen. Chemistry having thus been called upon to supply the agriculturist with compounds containing potassium, phosphorus and nitrogen, the first development which may be ascribed to Liebig's influence is the Stassfurt salt industry in Prussia, where immense deposits of salts containing potassium were known to exist. Similar deposits are found in Anhalt. The mining of these salts was commenced in 1860, and has proved an immense source of wealth to Germany, the total value of the Stassfurt and Anhalt salts produced down to 1890 being estimated at 11,500,000*l.*, and since that time the output has gone on increasing from year to year. It is not necessary to weary you with statistics, but it is important to note how the demand for potassium salts for agricultural purposes has given rise to a great industry, for the natural salts, consisting chiefly of carnallite, a double chloride of potassium and magnesium and kainite, a double sulphate of potassium and magnesium with magnesium chloride, have to be submitted to various processes in order to separate the constituents, and the Stassfurt salt factories are now supplying Germany, as well as exporting large quantities of potassium chloride and sulphate, magnesium chloride and sulphate, potassium carbonate, caustic potash, &c.

In a similar way the demand for phosphates has given rise to the utilisation of every available source of these compounds. Calcium phosphate is found as the mineral apatite, a double calcium phosphate and chloride or fluoride occurring in vast deposits in America, and also in a less definite form in Canada, the West Indies, France, Belgium,

and Germany. In this country calcium phosphate occurs in the form of coprolites, supposed to be the excreta of extinct saurians, in Cambridgeshire and elsewhere. All these natural phosphatic mineral deposits are mined, and have become valuable assets to the countries possessing them. The conversion of the minerals into a form suitable for the nutrition of crops is a branch of chemical industry involving the use of sulphuric acid for the conversion of the natural phosphate into the more easily assimilable form known as superphosphate. The greater part of the world's output of natural phosphates finds its way to Germany to undergo this treatment, the annual consumption of artificial manure in that country being estimated at something more than two million tons at a cost of about 5,000,000*l.* The mineral portion of the bones of animals, as you are no doubt aware, also consists largely of calcium phosphate, and before the mining of the mineral phosphates the conversion of bone ash into superphosphate was carried on on a very large scale. Bone ash is supplied now in large quantities from South America, but not much is converted into superphosphate, as the bones, after removal of the fat and the size (for glue), are capable of being finely ground, and are available for manure in this form.

Here is surely a romance of chemistry! The phosphates contained in the vegetation of the South American pampas go to build up the bony framework of the cattle which graze thereon. The skeletons of these beasts ultimately supply, let us say, the growing crop of a beet sugar manufacturer in Germany with phosphates. The phosphates picked out of the soil by South American vegetation concentrate in the bones of cattle, and are then sent into circulation in German beet. Or, even more striking, the phosphates accumulated by the great lizards of a remote geological age are now circulating through growing crops. This circulation of matter through the intervention of the living organism is an every-day story to the chemist. To our greatest poet apparently it was also known:—

"Imperious Cæsar, dead and turn'd to clay,
Might stop a hole to keep the wind away:
O, that that earth which kept the world in awe,
Should patch a wall to expel the winter's flaw!"

But we must descend from romance to reality. The deposits of sea birds also contain phosphates derived from the fish upon which they feed, and these deposits often accumulate in such large quantities as to make them available for agricultural purposes. Under the name of guano, immense quantities of this material, which contains both phosphates and nitrogenous matter, are exported from Peru. There is subject-matter for philosophising here, also, about the circulation of phosphates from marine organisms through birds into growing crops, and so forth, but time will not admit of many side disquisitions if I am to keep to my text. As another source of phosphate, it is of interest to know that the basic slag obtained in the Thomas-Gilchrist process of making steel is now largely used, so that the work set going by Liebig has, among its latest developments, led to the utilisation of a waste product of the steel industry.

Excepting in the case of leguminous plants, which are capable of utilising atmospheric nitrogen by a process which it does not come within my province to explain, the ordinary source of nitrogen for growing plants is a soluble nitrate, and if the soil is poor in such salts, they must be supplied either directly or indirectly through salts of ammonia, which are converted into nitrates in the soil by bacterial action in a way that nobody is better able to explain to you than Prof. Warington. The great natural deposits of sodium nitrate which occur in Chile and Peru supply practically all the nitrogen applied to the soil in this form for fertilising purposes. With respect to ammonia, the destructive distillation of coal for the manufacture of gas and tar products, or for the production of coke, furnishes practically all the salts of this base required for agricultural and other purposes. The vital importance of assimilable nitrogen to growing crops has led the chemist also to study methods for the fixation of atmospheric nitrogen so as to render this element available for such purposes. It has long been known that nitrogen and oxygen can be made to combine under the influence of the electric spark. This, as you may remember, is one of the methods used by Cavendish in his classical researches on the composition of the air, and it was used also by Lord Rayleigh to separate atmospheric nitrogen from argon. Sir William Crookes has shown that the combustion can be brought about by the electric flame with such facility as to render the production of nitrite and nitrate by this process an industrial possibility, and the manufacture has actually been started in America by utilising the Falls of Niagara for the generation of the necessary electric power. Still more recently it has been found by Caro and Frank that when lime and coal are heated in the electric furnace, the calcium carbide fixes atmospheric nitrogen to form a compound known as calcium cyanamide, and this decomposes in the soil with the liberation of ammonia, so that the nitrogen of the air is thus rendered available for plant nutrition by an electro-chemical process. The manufacture of this "Kalkstickstoff" is in the hands of the electrical engineering firm of Siemens and Halske, in Berlin.

There has been no straining of facts on my part in this sketch—necessarily brief—of the industrial results of Liebig's work. The establishment of the fundamental truths was a piece of pure scientific research. Had it not been made known by the irrefragable proofs furnished by scientific method that such and such elements were essential for plant growth, the mineral resources of the earth would have remained unused for this purpose. The minute percentage of nitrogen locked up in the fossilised vegetation of the Carboniferous period would never have been isolated in the form of ammonia and applied to the soil for the nourishment of the crops raised by the present day agriculturist. The successful cultivation of the beet as a source of sugar has been made possible by this knowledge, and it may be of interest to add that the further scientific study of the cultivation of that root in Germany has led to the yield of sugar being increased from 5¾ to 13 per cent. during the period commencing about the year 1840 and ending at the present time. The economic result of this industry upon our own sugar-growing colonies is a fiscal question which does not come within the province of this address.

Equally instructive as illustrating the connection between scientific research and industry is the production of alcohol and other valuable products through the agency of living organisms. The spontaneous conversion of saccharine solutions, such as the juice of the grape, into solutions containing alcohol, with the concurrent development of gaseous carbon dioxide, is among the earliest recorded observations in applied organic chemistry. The various theories which were from time to time advanced to explain what is called "fermentation" are now of historical interest only. It is to the researches of Pasteur that we are indebted for the placing of the fermentation industries on a scientific foundation. This illustrious chemist, who as far back as 1860–62 had successfully disproved the so-called "spontaneous generation" by showing that the ordinary air was always charged with living germs, turned his attention to the diseases of wine, with the object of assisting an industry of great national importance in France. His "Études sur le Vin" was published in 1872. A greater work—the great classic of the science of fermentation—appeared in 1876 under the title "Études sur la Bière." In this work it was definitely proved that the transformation of sugar into alcohol is a biochemical change; that the yeast which produces this change, and of which the organised nature had long previously been suspected, is, in fact, a low form of vegetable life allied to the fungi, and that it multiplies and grows at the expense of the sugar and other materials contained in the fermenting liquid, the alcohol and carbon dioxide being the products of its activity. It is now known, through the work of Buchner, that this chemical transformation of sugar into carbon dioxide and alcohol is the result of interaction between the sugar and a certain definite substance—an unorganised ferment—which is formed by the living yeast cell, and which can do its work independently of the cell in which it originated.

The scientific development of the fermentation industries followed from this and other work of Pasteur's. The names of those who have taken part in these later developments are numerous and illustrious, but want of time prohibits a detailed survey of this most fascinating chapter

of biochemistry. The leading idea that the formation of alcohol is a biochemical process depending upon certain organisms, or, as we may now say, upon the products of certain organisms, carries with it, as a necessary consequence, the conclusion that the industrial production of alcohol—whether for brewing or spirit distilling, or for the chemical manufacturer—is not an empirical or rule-of-thumb operation depending upon unknown conditions, but a definite chemical change produced in a definite way by a definite organism (yeast), and just as much under control as any other chemical operation. The chemist and the brewer have thus also been brought into association. The recognition that definite chemical transformations can be effected by microscopic forms of life which resulted from Pasteur's studies in wine and beer has had such far-reaching consequences that it is impossible to overestimate the importance of this work for the well-being of humanity. I should be encroaching upon the domain of Prof. Sims Woodhead were I to do more than remind you of the growth of that modern science—the most humanitarian of all the sciences—bacteriology, out of this fundamental conception. Keeping to the main topic of industrial results, one outcome has been, as I have said, to bring the operations of the brewer under scientific control. The organism, the yeast introduced into the vat to induce fermentation, must undergo careful microscopic examination to see that it contains no deleterious organisms, *i.e.* no organisms which would give rise to products other than alcohol. The water used by the brewer must be analysed to ascertain whether it contains the necessary mineral constituents for the nourishment of the yeast, because this plant is subject to the same conditions of growth as any other plant. Instead of obtaining its carbon from carbon dioxide, however, it can utilise sugar for this purpose, and it decomposes the sugar into carbon dioxide and alcohol in the way indicated.

The recognition of yeast as a vital chemical reagent which is apt to contain impurities in the form of wild or stray organisms which may damage the contents of the brewing vat, has led further to the introduction of the process of brewing by what is known as "pure culture yeast." This industry, of which the home is chiefly on the Continent, depends on the use of a yeast cultivated in the first place from a single cell of some particular species or variety or race by methods similar in principle to those adopted by the bacteriologist, the cultivation being carried on from generation to generation in carefully prepared solutions containing the necessary nutrient materials, sugar, nitrogenous matter, mineral salts, &c., and previously sterilised by heat so as to destroy every other form of life. The brewer can now be supplied, as the outcome of a series of brilliant investigations by Hansen, of Copenhagen, to whom he is indebted for this purification of the biological foundation of his industry, with a cultivated yeast as pure in strain as a pedigree horse or a particular breed of dog —a yeast which, by virtue of its purity, can be depended on for giving constant results in the brewing vat. This is another illustration of the relationship between research and industry.

Consider, in the next place, the sugar which the yeast decomposes by virtue of its zymase. In an ordinary brewing operation the liquor which is fermented is not supplied in the first place with sugar as such, but the starch contained in the barley grain is ultimately broken down, as chemists say, into sugar by virtue of certain processes which I cannot stop to explain. But the broad fact is that yeast cannot feed upon starch, but only upon sugar, and, in fact, only upon certain kinds of sugars, and the starch which is stored up in the barley is the raw material which ultimately supplies the necessary kind of sugar. So that starch, which, as you know, is a substance very widely distributed in the vegetable kingdom, can be extracted if necessary from the seeds or tubers which contain it, and converted into sugar by chemical processes, and then used for the production of alcohol. An important industry is flourishing in Germany at the present time for the production of alcohol from potato-starch. In Berlin a few weeks ago we were shown over a large establishment entirely devoted to the fermentation industries, and potato spirit and other products from the potato were the most conspicuous features of the exhibition. Now alcohol is a substance of great importance for chemical industry in many directions, and its inflammability makes it valuable as a fuel, so that the problem of the cheap production of alcohol is worthy of the serious attention of investigators. It is interesting to contemplate the period when our natural sources of fuel, coal and petroleum, are all exhausted, and when we may have to fall back upon the vital activity of a lowly form of vegetable life to supply us with liquid fuel. Scientific research has helped here, also, to call a new industry into existence, because the cost of alcohol, like that of any other chemical product, is obviously dependent upon the yield, *i.e.* upon the quantity obtainable from a given weight of raw material. I must claim your indulgence while I trace in brief outline one of the most beautiful of the modern industrial developments of the principles of fermentation.

It had long been known that in Java an alcoholic beverage, known as arrack, was prepared by fermenting molasses with a peculiar ferment prepared by a special process from rice. From what has been previously said, you will understand that the starch contained in rice is not, as such, available for direct alcoholic fermentation. A detailed scientific investigation of the starch-fermenting materials used in Java and elsewhere in the Far East has revealed the fact that these ferments owe their activity to the joint action of two out of several different organisms which are contained in them. One of these is a mould fungus which has the property of saccharifying starch, *i.e.* breaking it down into sugar, and thus rendering it available for the growth of the other organism, which is a yeast capable of exciting alcoholic fermentation in the usual way. Now the principle revealed by the scientific study of these eastern ferments has been developed into an industrial process for producing alcohol from starch of any origin, such as from maize, rice, potato, &c. The operations, in the briefest possible terms, consist in saccharifying the prepared starch by a pure culture of mould fungus, and then fermenting by means of yeast. The problem of increasing the yield of alcohol has thus been solved; not only is the spirit obtained in more concentrated form, but the actual percentage of alcohol furnished by a given weight of starch is much greater than has ever been obtained by any of the older processes of fermentation.

I have left but little time for dealing with an industry with which I have had long personal connection—the manufacture of colouring matters and other products from coal tar. The relations between scientific research and this industry are so intimate, and are so frequently referred to in public, that it has become a kind of stock example for the use of those who wish to emphasise the interdependence of science and industry. The history of this industry, moreover, is particularly instructive from our present point of view, because it originated in this country in 1858 and flourished here for a period of about twenty years, and then began to decline. The chief centre of activity for the production of coal tar products at the present time is Germany, where there are six large factories and a number of smaller ones. The aggregate capital of the six large factories amounts to some 3,000,000*l.*, and they give employment to about 20,000 people, including chemists, engineers, clerks and travellers, dyers and draughtsmen, workmen, &c. These large firms pay dividends varying between 5 and 25 per cent. upon their capital. The total value of the tar products manufactured in Germany exceeds 10,000,000*l.* annually, and she supplies by far the largest proportion of the dye-stuffs used throughout the world. When, in 1886, I proclaimed our approaching fate with respect to this industry, I found that we were then using about 90 per cent. of German and other foreign colouring matters in this country, and my friend, Prof. Arthur Green, of the Yorkshire College, finds that things are in about the same state at the present time.

The coal tar colour industry arose, in the first place, from an observation made by Dr. W. H. Perkin in 1856 in the course of a research having for its object the synthesis of quinine. He did not succeed in producing the alkaloid, but he noticed that aniline, when oxidised, gave a colouring matter, which he manufactured and introduced under the name of "mauve," and so laid the foundations of an industry which has developed to its present colossal dimensions. The art of the dyer and calico-printer has been

absolutely revolutionised by the introduction of the synthetical colouring matters prepared from coal tar. Of these more than 500 are now available—each one a distinct and definite chemical compound with characteristic colour; each one with properties rendering it suitable for application to particular classes of fabrics. Every range of colour, including the deepest black, can be imparted, and every degree of brilliancy or dullness, of fastness to light, to washing and bleaching agents, &c., can be realised as required. The natural dye-stuffs, such as madder, which supplied alizarin for Turkey red; the cochineal insect, which furnished a red dye; the lichens and dyewoods, which were used by the old-time dyers, have been displaced, or are on the way to displacement, by the tar products. The most important of all the natural colouring matters, indigo, is, as you know, among the latest of the achievements of industrial synthetical chemistry, and a great industry worth some 3,000,000*l.* annually to our Indian Empire is threatened with extermination by the German manufacturers. Not a month passes without the introduction of new colouring matters, and so enterprising are the German colour makers that their pattern-books are issued with full directions in various languages, and trained chemists in their service will give personal instructions to our dyers in the application of new and unfamiliar colouring matters.

It is impossible to do more than allude in passing to the enormous influence of this greatest and most refined of all the chemical industries upon every other department of chemical manufacture. It has reacted, and is reacting, with ever multiplying ramifications upon the manufacture of the raw materials such as acids and alkalis, it is revolutionising the methods for producing sulphuric acid, it is pressing into its service electrolytic processes, and it has created new branches of engineering for the construction of special plant and machinery. The utilisation of the infinity of compounds present in the tar is no longer restricted to the production of colouring matters. Valuable medicinal preparations, photographic materials, perfumes, antiseptics, the sweet-tasting saccharin, which is 300 times sweeter than sugar, an artificial musk which exceeds in intensity of odour any natural musk, are among the manufactured products from coal tar. The industry is the direct outcome of scientific research; it has been developed by research, and is being still developed by research. Both methods referred to in this address have been, and are, at work. The by-results of pure scientific investigation are seized upon whenever they show the slightest chance of being industrially useful. Saccharin is such a by-result. The chemical reactions which culminated in the industrial production of indigo were published by their discoverer, the late Dr. Heumann, as an academic discovery in the first place, and were developed industrially by the "Badische Anilin und Soda Fabrik" of Ludwigshafen. By the other method whole armies of highly trained scientific chemists are constantly at work in the splendidly equipped research laboratories of the German factories investigating new products and processes with the direct object of their ultimate industrial application. Nor must it be forgotten that under the term "research" used in this connection is comprised also theoretical research. A close study of the history of this industry will show how throughout it has been vitalised by theoretical conceptions concerning the chemical structure of the molecules of organic compounds, and especially by the so-called benzene ring theory of Kekulé, now so familiar to chemical students. The force of illustration of the connection between science and industry can, perhaps, go no further than in this case, where a purely abstract conception based on a knowledge of the properties of the atom of carbon has reacted upon a branch of manufacture to its lasting benefit.

I have thought it best to limit my treatment to the record of bare facts in order to bring home to you in a concrete way how chemical industry and chemical research are interdependent. Four groups of industries have been dealt with; it would have been easy to subdivide the subject and to deal with four dozen. I must confess that I am getting rather tired of what may be called the platform treatment of education in applied science, which consists in general of the purely clerical or office-boy work of compiling information—doubtless very valuable in its way—concerning the number of schools in foreign countries, the acreage of land which they cover, their cubic contents, cost of erection and maintenance, the number of professors and staff, and the number of students which they turn out annually. The reason why this kind of information is getting stale and wearisome is because it produced at first no effect at all in this country, and then it led to a reckless expenditure in bricks and mortar, and the starting of institutions which are inadequately endowed, insufficiently maintained, and altogether lower in their working capabilities than the continental institutions which prompted their foundation. I thought, therefore, that it might be more acceptable if, instead of dealing with the usual generalities of the statistical order, I sketched the history of a few specific industries. If it appears that Germany has played a very prominent part in these histories, all I can say is that there has been no intentional selection on my part, but it is entirely due to the circumstance that it is to that country more than to any other that industry owes its advancement by scientific method. The preeminence of Germany in chemical industry is sufficiently notorious, as our own manufacturers know to their cost. The most striking feature of the exhibition at Paris in 1900, when, as a member of the International Jury for Chemical Products, I had occasion to examine the exhibits of all countries, was the collective exhibit of chemical products displayed by some ninety German firms. This splendid collection, which revealed more than anything the enormous advances made in chemical industry by Germany, is now deposited in a special building in the grounds of the Technical High School at Charlottenburg.

So much has been said and written about the causes of this wonderful development of German chemical manufactures that I hesitate to add anything more to the discussion. Certainly it is not possible to add anything new. Those who, like Prof. Michael Sadler and Dr. Rose, have made a special study of German educational systems have placed before the public valuable reports in which these causes are fully discussed from the educational point of view.[1] In the official report to the French Government on the products of Class 87, Prof. Haller, the secretary to our jury and author of the report, has devoted a whole section to the "Causes de la Prospérité de l'Industrie chimique Allemande." The general conclusion to which we have all come concerning this remarkable industrial development is that it is mainly due to the higher educational level in Germany with respect more especially to the highest scientific instruction in the universities and technical high schools. It is perhaps permissible to go one stage further back, and to say that this advanced scientific education is in itself the expression of the public faith in such education, and the recognition by the State of the industrial value of such training. It has been well pointed out that the money invested by the German nation in founding and maintaining the chemical chairs at the universities and technical high schools is now worth some 50,000,000*l.* annually to the country in this branch of industry alone. More especially, also, it may be claimed that the recognition of the value—the indispensable value—of scientific research to industry by the manufacturers themselves has been one of the most potent factors in developing German chemical industry, and the lack of such appreciation on the part of our own manufacturers has been one of the chief causes of their decadence.

In so far as the subject under consideration is an educational one, it comes within the province of a gathering of students held under the auspices of the most ancient seats of learning in this country. At any rate, the topic is one of such supreme importance to the welfare of this nation that I could not resist the invitation to take part in your proceedings, because the question is one which has been for years undergoing the most serious consideration by those who have, like myself, been connected on the one

[1] See especially vol. ix. of the special reports issued by the Board of Education, entitled "Education in Germany," by Prof. Sadler. Also Dr. Rose's diplomatic and Consular reports, issued by the Foreign Office, No. 561, "Chemical Instruction and Chemical Industries in Germany"; No. 591, "German Technical High Schools"; No. 594, "Agricultural Instruction in Germany and the Development of German Agriculture and Agricultural Industries."

hand with manufacturing industry and on the other hand with the teaching of science. Whether the old universities are desirous of making a new departure and of enlarging their spheres of activity so as to bring them more into harmony with the practical requirements of the age I have no authority to discuss. Certainly Cambridge, by the establishment of departments of engineering and agriculture, has made a distinct advance in this direction. At any rate, it may be taken as a sign of the times that the relationship between science and industry has been made a special feature of this year's university extension meeting, and the outer world will no doubt take due cognisance of the circumstance that a subject has been chosen for consideration which, in this country, is generally considered quite remote from the higher ideals of university education.

It is evident from what has long been going on in Germany and America, and from what is now taking place with regard to education by our newer universities here, that applied science is, or can be, brought within the province of university education. Of course, if the view be held that science is degraded by being turned to practical account, then we must not look to the universities for the training of our industrial leaders. It is impossible, however, to note the progress of events since the coalescence of science and industry abroad without coming to the conclusion that the position of a nation in the scale of civilisation will be measured in the future by its productive energy—by the capacity of its workers to evolve new ideas and to carry them out practically; by the number, zeal and originality of its scientific workers, and by their mastery over the resources of nature. I do not mean to imply that the old universities have done nothing towards the education of scientific thinkers and workers. What strikes outsiders like myself is the very small part that these universities are taking in the modern equipment of the great industrial army of Britain as compared with the work being done by foreign universities for their respective countries. In view of the industrial struggle between nations which has arisen through the discoveries of modern science—a struggle which is bound to become keener with the progress of science—it cannot be seriously maintained that the material welfare of our country is beneath the dignity of even the most profound academic scholar. The old definition of a university as an educational centre for the cultivation of useless knowledge no longer holds good. If there are universities which still cling to this tradition concerning their functions, it may safely be predicted that their influence in moulding the future life of the nation is destined to shrink to smaller and smaller dimensions.

The part played by the German universities and technical high schools in the training of technologists is now so well known in this country that a detailed restatement of the facts is hardly necessary. I may remind you that their twenty universities, with foundations dating from the fourteenth to the beginning of the nineteenth century, for many years supplied the factories with men thoroughly trained in science, and capable of applying their knowledge to industrial processes. With the development of manufacturing industry along scientific lines it was found necessary to provide more specialised education, and during the first half of the nineteenth century trade schools or polytechnics were called into existence in nine different centres. Of course, you know that our polytechnics here have very little analogy with the German institutions of that name. The polytechnics were in time found inadequate to meet the growing requirements of German industrial training, and their functions were accordingly enlarged and their educational status raised. Out of these nine polytechnics or trade schools have arisen nine technical high schools, and two more such schools are now in course of erection. Thus in Germany both universities and technical high schools are catering for the scientific needs of the national industries. I may add that a few years ago there was a serious discussion in Germany among certain educational bodies and industrial organisations as to whether the State should not be asked further to strengthen the scientific faculties of the universities by creating chairs of technical or applied chemistry, and although there has been no practical outcome of this movement as yet, it is an instructive illustration of the spirit which is abroad in that country.

There is very much misapprehension here concerning the nature and functions of the German technical high schools. They are not glorified polytechnics of our own type for teaching handicrafts to artisans or smatterings of science to ill-prepared students. They are institutions of university rank—their education is of university standard, and their professors stand on a level with the professors of the universities. Their students are not admitted until they have reached a high standard of general secondary education. Their courses of instruction are as purely scientific as the university courses, and the only difference between the two kinds of education is that the technical high school is all scientific, and the various sciences are taught both theoretically and practically with a view to their ultimate industrial applications. It is a "technical education" in the highest and best sense, and not in the narrow—I may even say degraded—sense in which the term is so frequently used in this country.

The question of the hour which the old universities have now to face is whether they are willing to take part in the newer education required by our industrial leaders, whether they are prepared to strengthen and develop the teaching of those physical sciences which underlie productive industry, and to recognise the claims of the applied sciences as subjects worthy of inclusion in their curricula. There will, of course, be a divergence of opinion with regard to this question. There will be the old, old conflict between the advocates of the "humanising" influence of the ancient classical studies and the supporters of modern scientific education. So far as my opinions are worth anything, I cannot see, and I never could see, why a study of nature at first hand should be less "humanising" than the study of those classical subjects which have so long held the field. I admit that the teaching of the physical sciences as they should be taught at the present time in any institution of university rank is more costly—that the equipment consists of something more than a library, and that their teachers, to be effective, should be themselves active investigators, inspiring originality and a desire for creating new knowledge in their students. I can understand that a subject which to the classical don wears the aspect of a financial ogre should be kept down as long as he has a preponderating influence in regulating the affairs of his university. But this is a matter of expediency, and not a real conflict between fundamental principles. I cannot find that the classical teaching of the American or German universities has been impaired by the splendid development of their scientific faculties; neither does it appear that the human products of their scientific activities are in the least degree inferior as men to their classical scholars. Of course, I am a special pleader, and I am making the best use of my opportunities, and I repeat that I never could see where any antagonism existed between the older and the newer studies excepting in the struggle for financial means. There are many educational authorities here and abroad who will tell you that the scientific development of the German universities has reacted upon and improved the classical teaching by an infusion of scientific method into the latter. Moreover, it must be remembered that we who are advocates for the new education are not clamouring, as many people think, for the abolition of the old studies. I for one should deplore any falling off in the prestige of the old universities as seats of classical learning. Neither is it suggested that our future leaders of industry would never at any period of their studies derive benefit from that particular kind of culture which the ancient literature is capable of imparting. I firmly believe they would; but the question as to when and how would open up the whole field of education, elementary, secondary, and university, both pre- and post-graduate, and I should find myself floundering among shoals and quicksands in no time. The ideal university is one that offers facilities for both the older and the newer education; they are not mutually exclusive—they can, and do, thrive side by side elsewhere, and there is no reason, at any rate no theoretical reason, why they should not do so here.

The form in which the question may be put is therefore whether, given the means, the older universities should

develop their work in the direction of applied science. A large body—I cannot say how many—of outsiders who are well-wishers of these universities is of opinion that they should, and there is an idea abroad that they are suffering financially now from having neglected this side of education in the past. There was, for example, a leading article in the *Times* of May 25 in the course of which the writer suggests that they may have suffered through having a false reputation for being very wealthy bodies, and he adds:—"Or is it perchance, because the modern millionaire, being a man of his age and an Englishman to boot, has no great belief in the economic value of knowledge as such, and no great confidence in the capacity of our ancient universities to adapt themselves to the needs of the coming time?" Now, so far as the chemical manufacturers of this country are concerned, I can say with some personal experiences of my own that they certainly have shown no great belief hitherto in the economic value of scientific knowledge, as they now know to their own cost. But if, to make a purely hypothetical conjecture, some beneficent millionaire were to test the capacity of our old universities for undertaking this kind of work, and were to offer adequate means for the purpose, I feel pretty confident, from what I know of the spirit which dominates their governing bodies, that such an offer would be accepted both at Cambridge and here at Oxford with few dissentients. If such a departure were placed within their power, I think that that great public which glories in the past achievements of these universities would rejoice in their new development. And I will further add that the creation of chairs of applied science would react upon and strengthen the teaching of all those sciences which are in any way connected with industrial productiveness.

Of course, this is all hypothesis—the most nebulous of hypotheses. We all know, unfortunately, that the financial resources of the universities have been, and are, inadequate for the purpose of enabling them to meet the requirements of modern scientific education, either in the way of staff, accommodation, or equipment. It can be said, and justly said, that so long as these universities are without the means of developing their schools of pure physical science to an extent worthy of their reputation, it is useless to talk about developing the teaching of applied science. So it may be. But I remind you that we are still in the region of hypothesis, and the captious critic might retort by saying that they have not done even as much as they might, and could, have done for the proper development of scientific teaching with the means already at their disposal—that they are still overweighted by ancient tradition, and that their internal scientific forces are still feeble as compared with the preponderating forces of the advocates of the older culture. There is no time, even if I knew enough about the inner mechanism of university administration, to discuss this aspect of the question, but if you want to know an American view of the case—a strong view!—I would invite attention to an address by Prof. Victor Alderson, Dean of the Armour Institute of Technology, delivered before the Chicago Literary Club in October last year, an abstract of which was published in NATURE of February 12.

The question of the recognition of applied science by our old universities must, as I said, be faced—the time is at hand for them to consider seriously whether it is desirable that they should cater for the training of those who are destined to be the founders and upholders of our national prosperity. The longer this question is shelved the smaller will grow the chances of their being able to participate in the work. At present we in this country are not up to the German level so far as concerns the higher technical training of industrial leaders. Our universities, in other words, have not yet had to encounter the full force of competition with newer institutions of the rank of the technical high schools. We have but very few, if any, schools of this status here now, but if I read the signs of the times correctly, the differentiation between the old and the new education—which has already become well marked—is bound with the progress of science to become more and more strongly pronounced. Our newer universities—especially those in large manufacturing centres—will be driven more and more into the teaching of applied science, and our polytechnics and technical colleges will perforce have to raise their educational standard. The effect cannot but be to cause the older universities to become of smaller importance in the general scheme of national education as time goes on. That is why I have taken advantage of the opportunity which has been placed in my hands for raising this note of alarm, because even if nothing practical results from this meeting, it may at any rate be useful to let it be known that many of us desire to see the most ancient and the most renowned of our educational foundations doing more for the education of a nation the prosperity of which is so largely dependent on productive industry.

Whether as the outcome of the lectures delivered and the conferences held during this meeting the attitude of the universities towards applied science undergoes modification or not, the ventilation of opinions cannot but be of advantage in many ways. If, for example, it is made manifest that the current of national thought is moving slowly—alas! very slowly—towards the recognition of science as the main factor of industrial progress, it may help to emphasise the necessity for strengthening and developing the teaching of pure science. If the beneficent millionaires are not forthcoming for the purpose of endowing applied science, there is, at any rate, ample scope for their beneficence in the endowment of pure science in our old universities. A school of active science workers would—to use a quasi-scientific expression found in the pages of many writers of fiction—"galvanise into life" the science teaching of the schools. If you can only help to mould the public mind into the belief that science is a living reality veiling truths of inestimable value to humanity from every point of view, moral, social and material—truths that are to be wrested only by conscientious, laborious and persistent *research*—you will be assisting a great cause. If you will proclaim this doctrine from the house-tops and assist in sweeping away that dust heap of formal text-book knowledge which passes for science in our examination rooms you will be doing something towards raising the general level of opinion in this country. We need it badly! Think of all the creative intellectual power running to waste—the unrealised assets in the way of originality of thought which Great Britain might have at her disposal if the brain power of her teachers and students were only diverted into the right channels. The old universities, by virtue of their prestige, their traditions, and their past achievements, have still a powerful hold upon the public mind. They must open their doors still more widely to science if they wish to retain their hold. If their means are at present insufficient to enable them to meet the requirements of the age, they can still forward the national cause by upholding the dignity of science, by insisting upon originality of thought as an essential qualification for its successful teaching, and by helping to dispel the notion that it undergoes degradation by being applied to human welfare. It must be realised, and it cannot be realised too soon, that the peaceful campaign of industrial competition requires leaders well trained in scientific method, and not crammed with mere formal book learning—men as alert in mind and resourceful in meeting difficulties, as upright in principle, as keen in enthusiasm, as far-seeing in imagination, and with as intimate a knowledge of human nature as the statesmen, warriors, divines, lawyers, and schoolmasters which these old universities have given to their country. The victory of the future is with that nation which enables her children to approximate more closely towards Tennyson's ideal:—

> ". . . the crowning race
> Of those that eye to eye shall look
> On knowledge; under whose command
> Is Earth and Earth's; and in their hand
> Is Nature like an open book."

IRRIGATION WORKS.

INDIA.

IN a recent number of the *Revue générale des Sciences* is an article on irrigation in India which is interesting as showing the impression made on the mind of a foreigner after an inspection of the great works that have been carried out under the British administration for mitigating the

effects of famines and improving the condition of agriculture. In a report published a few years ago by Mr. Deakin, the Minister of Water Supply in Victoria, under the title of "Irrigated India," Mr. Deakin stated that, in his opinion, after an inspection of the irrigation works in Italy, Egypt and America, he was satisfied that there was no canal system in the world that could hold comparison with that of India, and expressed his surprise that so little was known of it. The area of land irrigated in India by canals amounts to about 30 millions of acres, six times that of Egypt, and nearly double that of the whole of the rest of the world. M. Chailley Bert, the writer of the article under notice, after spending considerable time in inspecting the various irrigation works, seems to have come to very much the same conclusion. He expresses his opinion that, after the principles of the general administration of the country, and the conduct of the English in India, there is nothing of more interest and more worthy of observation than the system of irrigation, the methods pursued in carrying out the works, and the results that are obtained.

From all time there has existed a close relation in India between famine and irrigation. The ancient rulers of India have left everywhere traces of the great works which they had carried out for overcoming the want of rain and providing against the constant recurrence of famines; and since the English administration irrigation has been forced to the front by the terrible famines which periodically visit a portion of this vast territory, in every instance caused by deficient rainfall, which sometimes lasts for two or three consecutive years. The great famine of 1837 in Bengal led to the project of the Ganges Canal, which has now 5500 miles of main canals and branches; that of 1853 to the works at Madras; that of 1859 to the works in the north-west. The famine which desolated Orissa and the north of India in 1864, when a million of the inhabitants lost their lives by starvation notwithstanding the expenditure of 1½ millions of pounds in combating the famine, and also more than 3 millions in works of irrigation, resulted in the policy of systematically carrying out extraordinary public works by which it was contemplated to spend half a million a year in developing irrigation for the purpose of preventing the recurrence of these terrible disasters. During the terrible famine of 1876, for which a large relief fund was raised, 5¼ millions of lives were lost, although the Indian Government expended 11 millions in relief.

The rainfall of India is very various, amounting to 200 inches in a year in some districts, while in others the fall does not amount to more than from 2 to 10 inches; and over a vast area the land is dry and sterile, except where the rivers have been canalised, or the rain coming from the mountains has been caught and stored in reservoirs.

The peasants inhabiting these districts are described as being utterly improvident, and population goes on increasing at an enormous rate. The dry and unfertile years find them without any resources, and when famine comes untold misery ensues, and the population is decimated by starvation and death.

A vivid description is given by M. Chailley Bert of the irrigation works undertaken for the relief of the inhabitants in the great famine of 1901 in the Presidency of Bombay. Here five camps were established where provision was made for 10,000 people who were engaged in the construction of a reservoir. To this camp came a mass of people of all ages and conditions, old men, women, and children, besides the actual work people, driven from their homes by misery and starvation. To deal with this multitude a complete system of feeding and hospital requirements, sanitation and the care of children had to be provided, while all the able-bodied were organised into an army of workers. The writer says that no description can correctly give an idea of the complete system of organisation and order of this installation, and he seemed to be greatly impressed with the fact that the whole management was carried out by native functionaries under the direction of a single English engineer, with the occasional visits of the collector of the district and his assistants.

It is pointed out in the article that irrigation, besides providing a means of meeting the sterility due to the absence of rain, adds very greatly to the fertility of the land, in some cases doubling, and in others increasing the yield fourfold, and increasing the value of the land from 2*l.* or 3*l.* an acre to ten or twelve times that amount. Irrigation also permits the cultivation of the more valuable crops, such as rice, wheat, sugar cane, and indigo, and it also leads to other works which assist in the mitigation of famines, such as roads and railways for the conveyance of the produce of the irrigated lands.

The Indian Government has already expended upwards of 23 millions sterling on irrigation works, providing water for 13 millions of acres at an average cost of 35*s.* an acre.

SOUTH AFRICA.

At the meeting of the South African Science Association held in May last, amongst other subjects discussed, the most important in the interests of the country was that relating to irrigation, which Sir Charles Metcalfe described as the most prominent question of the day. In a paper read by Mr. Westhofen, the author stated that, owing to the insufficiency and uncertainty in the distribution of the rainfall, it was absolutely necessary that irrigation should be resorted to if the country is ever to be made a self-supporting one. Thousands of square miles of the most fertile land are lying waste owing to the want of this most essential adjunct to agriculture. The institution of a proper system of irrigation has hitherto been hindered by want of capital, want of experience, and ignorance of the best methods of storing water and applying it to the greatest advantage. Irrigation is no new thing in Africa. In Rhodesia there exist the remains of ancient works, and for miles and miles may be seen the traces of skilfully engineered irrigation canals. No information exists as to who carried out these works. In a rude way the natives of the Zambesi at the present day obtain from two to three crops off their land by employing a simple system of irrigation. As an example of what might be done, and as a public object lesson, a large reservoir containing 1000 million gallons of water was constructed by Mr. Rhodes at Matapos, the water in which is held up by an earthwork dam 100 feet high.

While thousands of acres of fertile land are lying waste in Africa for want of irrigation, food to the value of 2¼ millions of pounds is imported through Cape Town.

Before an efficient system of irrigation can be organised, legislation is required to define the water rights. Sir W. Willcocks, in his report on the subject, suggested that all rivers and streams should be proclaimed as public domain and become the property of the nation.

The forestry of the country was also dealt with in a paper by Mr. D. E. Hutchins, who showed that while at one time there is evidence that Africa was a well-wooded country, the forests of to-day consist generally of nothing but stunted evergreen trees confined to sheltered kloofs. There are now, however, Government forests worked systematically by the Forest Department, but so scarce is the supply that the imports of commercial timber amount to half a million pounds. It was stated that the special sleeper plantations established by the Cape Government Railways cost 60,000*l.*, and that in twenty-five years they were estimated to bring in a revenue of 100,000*l.* a year. There is no doubt that the encouragement of the growth of forests will have a material effect in conserving the rainfall of the country.

NEW MEXICO.

In the report issued by the New Mexico College of Agriculture for April, an account is given of the experiments carried out for pumping water for irrigation from wells. New Mexico has a genial climate and fertile soil, but the amount of rainfall is light, averaging not more than from 8 to 16 inches a year. Irrigation, therefore, becomes a necessity. It was with a view to demonstrate the practicability of providing such a supply of water from the underflow that the experimental work was undertaken. The strata consist of sand and gravel, with occasional layers of clay. The Rio Grande Valley is underlaid with gravel beds sufficiently thick to procure from them an ample supply of water at a depth of from 20 to 80 feet. There are two methods of obtaining water from the underground supply. One by sinking a well down to the water-level, and then forcing perforated pipes to some depth below this. The experimental station well was sunk 48 feet deep, with six-

inch pipes driven 21½ feet below this. The other method is by driving tubes varying from 3 to 6 inches diameter down from the surface some distance into the water-bearing surface. With tube wells as small as 3 inches in diameter, the perforated portion at the lower end is driven with the pipe, but with larger tubes the open pipe is first sunk, and the strainer or perforated part lowered inside; the tube is then jacked up until the perforated tube is exposed. The pipes are sunk by means of a sand bucket, which consists of a cylinder 3 to 5 feet long, the diameter being a little smaller than that of the tube, provided with a plunger and valve at the bottom. The cylinder is forced into the ground, and then the plunger is driven down to the bottom, and when drawn up sucks the sand and small stones into it. It is then raised to the surface and emptied. In some cases pressure has to be exerted by means of weights or levers to force the bucket down, and it is continually turned round by means of clamps. In favourable ground it will sink at the rate of 1 foot a minute. Owing to the quantity of fine sand in suspension in the water, centrifugal pumps for lifting the water were found to answer best. Where wells are used the suction pipe draws from the water at the bottom, but with tube wells the suction pipe is attached to the top of the tube.

FORESTRY IN THE UNITED STATES.

THE bulletins, professional and hydrographical papers, which form part of the serial publications of the United States Geological Survey, treat of a variety of subjects, among which forestry figures conspicuously. Five beautifully illustrated volumes, accompanied by carefully prepared and coloured maps, have recently been received. The statistics and information collected from various sources by well-trained experts and specialists are put forth in a very plain and comprehensive manner.

The first paper is by Mr. Henry Gannett, and treats of the forests of Oregon. It deals very concisely with the composition and character of the different forests and woodlands in the State. At the outset a land classification table is given, which shows total area, merchantable timber area, open country, burned, cut, and barren areas.

As the author remarks, "the most startling feature shown by the land classification map of this State, is the extent of the burned areas." A point worthy of note, to which the author directs attention, is that "the burns are greatest and most frequent in the most moist and heavily timbered parts of the State, and are smaller and fewer where the rainfall is less and where the timber is lighter," the reason being that the density and abundance of the undergrowth forms excellent fuel for the fire, and vastly increases its heat and destructiveness. Of the total timbered areas, not less than 18 per cent. has been thus destroyed. This represents a total of 54,000 million feet in the State, with an estimated value of 54 million dollars, which the author very truly remarks is too much to lose through carelessness. However, as the region of the fire area is well watered, reafforestation appears to be progressing favourably, especially where the burns have not been extensive; but, where many square miles have been involved, the lack of seed has retarded the process considerably. The dangerous fire season is autumn, when most things are dry. However, the magnitude of such devastations appears to have been worse prior to and during the days of early settlement—from 1843 to 1870. The rest of the paper consists of extremely valuable notes accompanied by tables which give a classification of the lands together with the amount and classification of timber for each county in the State. There is no extraneous matter brought in—each sentence is pithy and to the point. The text, accompanied as it is by illustrations and maps, gives as perfect an idea of the character and stand of the timber of Oregon as can well be conceived.

The next professional paper (No. 2) of the series is by the same author. It deals with a revision of the estimates of the standing timber and its distribution in the State of Washington. These forests consist mainly of red fir (*Pseudotsuga taxifolia*), mingled with spruce, hemlock, and cedar. They are the densest, heaviest, and most continuous in the States, with the exception of the red wood forests of California. The author's general description is followed by a summary of the standing timber in Washington, after which each county is taken up separately and in detail.

The revised estimate shows an increase over that given in a former report; this is due to the inclusion of species which have now come into use, and also such species as are of known value though at present not utilised.

The next report (No. 3) of the series is by Mr. Fred G. Plummer. It deals with the forest conditions in that part of the Cascade Range lying between the Mount Rainier and Washington Forest Reserve. The land classification map which accompanies this report covers 2,800,000 acres, but after deducting the naturally timberless areas, such as arid lands, lakes, and glaciers, also the area destroyed by fire (8 per cent.) and logging (1·64 per cent.), there remains an area of 2,292,820 acres which can be called timber lands. After dealing with general matters, the author gives a list of trees and shrubs of central Washington, which is followed by a very useful and instructive table showing the distribution of species by zones of altitude. Then comes a detailed record of the amount of vegetable growth supported by an acre of average soil of the Cascade Mountains. The defects and diseases of timber trees, also the market prices of lumber, receive due attention. The bulk of the report is taken up with detailed descriptions of the various watershed areas. At the end of the paper irrigation, grazing, and mineral springs are reported upon. The author's remarks on irrigation are interesting, as they show what can be done in the way of reclaiming and utilising arid tracts for agricultural purposes.

Report No. 4 of the series deals with the conditions of the Olympic Forest Reserve, Washington, and has been prepared from field notes taken by Messrs. Arthur Dodwell and Theodore F. Rixon. It deals first with topographical matters, agricultural lands, stand of timber, timber trees, forest fires, mining, roads, &c. The principal part of the report gives a detailed description of the various townships contained in the forest reserve. There is much useful information regarding the accessibility of the forests and the facilities of timber transport, which are matters of considerable importance.

The forest conditions in the northern part of Sierra Nevada, by John B. Leiberg, form the fifth paper of the series. This report deals with the topographical features of the region examined, along with the extent and composition of the forest and woodland. The distribution of the various coniferous trees and forest type presented by each receive adequate attention from a sylvicultural point of view. The topographical, agricultural, and sylvicultural aspects of the various river basins are then taken up and described in detail.

In addition to the above, three volumes on forestry, each consisting of several papers, have already been published in former annual reports of the United States Geological Survey.

We have only been able to sketch in the briefest outline the scope and significance of the above works, which represent several years of painstaking and accurate investigation. The undertaking shows that the great importance of the forest is now duly recognised in America, although not so many years have elapsed since forestry was a comparatively unknown science in that country.

In the days of early settlement axe and fire were indiscriminately employed to the great destruction of the forest, and in later days, when timber was required for structural purposes, lumbering operations were so diligently and recklessly pursued in the most accessible forests that in a short time they were depleted of all but the most worthless material. He who wants a vivid description of this state of affairs need only refer to Prof. Heinrich Mayr's work, "Die Waldungen von Nord America," which contains a great amount of information and good advice as regards the conservation of the North American forests. We are glad to see such advice has now been accepted. The good work already done by the Geological Survey will form a basis upon which future schemes of management for the conservation of the forests of North America may be built.

THE VIENNA ACADEMY OF SCIENCES.

WE have lately received the *Proceedings* (vol. cxi.) of the Imperial Academy of Sciences at Vienna (*Sitzungsberichte der kaiserlichen Akademie der Wissenschaften*) for part of 1902. The volume is an important publication now, and is divided into four sections, dealing with different branches of the natural and physical sciences.

Section i. (April to July) includes mineralogy, crystallography, botany, physiology of plants, zoology, palæontology, geology, physical geography, and travels. We notice several important papers on systematic zoology and botany; by F. Siebenrock, on Podocnemis, Wagl., a genus of tortoises; by A. Zahlbruckner, on Brazilian Lichens; by E. Lampa, on liverworts; and by A. Attems, on the Myriopoda of Crete. There are also papers by O. Richter, on magnesium in its relation to plants; by F. Pischinger, on the structure and regeneration of the assimilative apparatus of Streptocarpus and Monophyllæa; by A. Abel, on asymmetry in the skulls of the toothed whales; by H. Hofer, on petroleum; and by F. Berwerth, on the structure of a meteorite from Mukerop, German West Africa; and several other papers, chiefly dealing with geology and palæontology.

In section ii*a*. (May to July), devoted to mathematics, astronomy, physics, meteorology, and mechanics, we have a large number of important papers, of which those relating to meteorology are perhaps of most general interest, such as those by J. Haan, on the meteorology of the equator, from observations taken at the Museum Goeldi at Para; by F. M. Exner, on the variations of the pressure of the air from day to day; and by J. Valentin, on the fall of dust between March 9–12, 1901. There are also several interesting papers on electricity, magnetism, photography, &c., as well as on mechanics and applied mathematics.

Section ii*b*. (April to July) includes chemistry, and comprises a large number of papers by various writers, among which we notice one, by R. von Hasslinger, on the formation of artificial diamonds by the fusion of silicates.

Section iii. (January to December) deals with the anatomy and physiology of men and animals, and also with theoretical medicine. There are only a few papers of importance in this section; by C. Storel, on caseine in asses' milk; by F. Winkler, on the infiltration of the vessels of the skin, when stimulated by heat; by F. Ballner, on the disinfective effect of saturated vapour of water at different boiling points; by O. Löw, on the chemiotaxis of spermatozoa in the female genital tract; by S. von Schuhmacher, on the cardiac nerves of men and Mammalia; by K. Toldt, jun., on the development and structure of the zygoma in man; and by J. Seegen, on the influence of alcohol on the diastatic energy of the ferments of saliva and of the secretion of the pancreas; and also on the formation of sugar in liver preserved in alcohol.

This imperfect sketch may serve to illustrate the activity of Austrians in various branches of science, and it will also be seen that, while the separation of the journal into sections is convenient, it can only be rough and imperfect, for the various sciences trench upon each other to such an extent that many papers might almost as well be referred to a different section to those in which they have been with equal propriety placed; thus a paper on organic chemistry would not be out of place in the section on physiology, or perhaps even zoology or botany, and so in other instances.

We may also direct attention to another point. All the papers in this volume (apart from their publication in it) are separately priced, and can be bought separately. In Britain, except where a paper fills the whole of a part, this is not the case, and separate papers are only furnished to authors to give away, on the tacit understanding that they are not to be sold. Perhaps this is sufficient for British needs, owing to the much smaller number of students who are engaged in special scientific work in Britain, as compared with German-speaking countries.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ON more than one occasion it has been pointed out in these columns that the study of economic botany is neglected by our universities and colleges. But though educational authorities have failed to make provision for students and research in economic botany, Kew has long been a training school from which men have been sent to all parts of the world, and a centre of expert advice on vegetable products. For thirty years or more a course of lectures on economic botany, intended to prepare men for service in India and the colonies, has been given in the museums of the Royal Botanic Gardens, Kew; and the course just finished, by Mr. J. M. Hillier, the keeper was attended by twenty gardeners in training. It is desirable that the study of vegetable economics should be encouraged in great commercial centres such as Glasgow, Liverpool and Belfast, as suggested by Prof. Bower in an address referred to in NATURE of December 18, 1902 (vol. lxvii. p. 165); but it must not be forgotten that, while universities and educational authorities have practically ignored the subject, Kew has been steadily training practical botanists and investigators for botanic gardens and other establishments at home and abroad. As a result there is now scarcely a botanic garden in India and the colonies which has not on its staff one or more men trained at Kew or recommended by the director of the Royal Gardens. Kew affords facilities for scientific and technical training in botany unequalled by any other institution, and it is satisfactory to know that so many members of the staffs of our botanic gardens have been trained there.

WE have received two publications from the United States concerning the education of deaf children. One pamphlet is the sixth report of the home in Philadelphia for the training in speech of deaf children before they are of school age, and the other is a special report, by the superintendent of schools, of the school for the deaf and the normal training department for teachers of the deaf in connection with the Board of Education of the City of Detroit. These booklets show clearly enough that it is quite possible so to educate deaf children that they can understand ordinary speech, and so work satisfactorily with normal persons.

WE have received a copy of the report of Prof. Starling, the Dean of the Faculty of Science of University College, London. The report was read at the assembly of the Faculties of Arts and Laws and of Science which took place in July last, and reference was made to it in our issue for July 9. Referring to the amount of scientific research done at University College, Prof. Starling says:—"I believe I may safely assert that in no university does the quality and the quantity of the original work turned out exceed that which we have to record at University College. Our success in this direction is attested by the continued increase in the number of research students, that is, of men of the highest ability who are seeking the best form of training for their subsequent careers. Whereas last year we had seventy-two research students, this year we have eighty-seven on our books. These men are drawn from all parts of the world, the British Isles, colonies of Canada, Australia and South Africa, and our Indian dependencies, Japan, Germany, Switzerland, and so on. Much of the work which they have turned out represents important advances in our knowledge, and will be of lasting value. It is satisfactory to know that, whereas a few years back all our best students and we ourselves regarded a visit to Germany as a necessary part of a science curriculum, the conditions are now beginning to be reversed." The list of original papers and other publications from the scientific departments of University College during the past year, with which the report concludes, contains more than a hundred entries.

A BLUE-BOOK showing the amount spent on technical education by local authorities in England and Wales, with the exception of five which have made no return, during the year 1901–2 has been issued by the Board of Education. The return shows that the total amount thus expended on technical education in England and Wales during the year 1901–2 was 1,057,399*l*. This amount is exclusive of the sums allocated to intermediate and technical education under the Welsh Intermediate Education Act, 1889. The amount raised by loan on the security of the local rate under the Technical Instruction Acts was 206,426*l*., the amount of loans, so raised, outstanding was 1,030,952*l*., and the balance in hand of moneys received and allocated to technical instruction was 658,319*l*. 16*s*.

SOCIETIES AND ACADEMIES.

EDINBURGH.

Royal Society, July 20.—The Rev. Prof. Flint in the chair.—An obituary notice of Prof. Cremona, by Prof. **Blaserna,** was communicated by Prof. Chrystal.—Mr. James **Russell** read a paper on the molecular condition of iron, demagnetised by various methods, in which a large number of experiments on the mutual effects of superposed magnetisations were described and discussed in the light of the molecular theory which had suggested them. According to the author's view, when iron has been demagnetised by a series of reversals diminishing by very small steps, the molecules in any small region, instead of being left in a condition in which as many point one way as another, are left with a preponderance pointing uniformly round the equatorial belt at right angles to the direction in which the magnetising forces had been applied. It is obvious that if a new magnetic force be applied codirectional with, or perpendicular to, the direction of the original set of forces, there will be no induction at right angles to the new force. But if the new force be applied in any other direction, there will be a component of induction perpendicular to this direction. The consideration of the theory in various combinations led to results which were tested by experiment. In all cases the theory stood the test of experiment satisfactorily.—Dr. D. Fraser **Harris** read a paper on affectability and functional inertia as the two fundamental properties of protoplasm. These were regarded as the two physiologically opposite functional capabilities, the degree of the relative intensities of which determined the particular manifestation at the moment. As examples of manifestation of functional inertia were mentioned insusceptibility, automatism, heredity, rhythmicality of action, the manner in which functional exhaustion was warded off and the state of fatigue substituted, &c. Functional inertia not only accounted for vestigial organs, but also for vestigial metabolism, as, *e.g.* the formation of uric acid in the mammal, an avian or reptilian metabolic relic.—Dr. Noel **Paton** communicated a paper on October salmon in the sea, in which some new points in the life-history of these fish were brought to light. In late runs of salmon male fish markedly preponderated. In the series studied, ovaries in all stages of development were found, so that ripeness of ovary was not the determining factor of migration from sea to river. One fish which had been obtained was of peculiar interest. In its strong mandible and large teeth it resembled a male, but when the viscera were exposed ovaries were found. The ovaries were flabby and soft, and had a yellowish opaque appearance, with pale opaque patches on many of the eggs.—In a note on resistance change accompanying transverse magnetisation in nickel wire, Prof. C. G. **Knott** and Mr. P. **Ross** described an experiment which seemed to show that in nickel wire in strong fields (in moderate fields in which the effect of longitudinal magnetisation is easily observed there is no measurable effect) there is very slight effect until a field of nearly 2000 units is reached, when the resistance begins rapidly to decrease, and goes on decreasing linearly with increase of current to fields of 5000. When the coil is wound with a pitch of 1 in 20, the component of the field along the wire gives rise to an increase of resistance which in the lower fields may counterbalance the slight decrease due to the transverse field. In the higher fields, however, this longitudinal effect is of comparatively small account. —Mr. J. H. Maclagan **Wedderburn** communicated a paper on the application of quaternions in the theory of differential equations.—In a note on a method of bringing together the two spectra produced by the ordinary spectrophotometer, Mr. J. R. **Milne** described a neat application of the well-known heliometric device of the divided lens. By using a divided lens in the eye-piece, he was able not only to bring the two spectra edge to edge without intervening dark space, but was able to shift the spectra sideways relatively to one another so as to compare directly the luminosities of strips belonging to different parts of the spectrum.—A paper by Dr. Thomas **Muir** on the theory of axisymmetric determinants in the historical order of development up to 1841 was also communicated.

PARIS.

Academy of Sciences, August 17.—M. Albert Gaudry in the chair.—Spectroscopic observations of the Borrelly comet (1903 *c*), by M. H. **Deslandres.** The spectrum obtained with an exposure of two hours is nearly identical with that of the comet 1893 *b* (Rordame). The bands due to hydrocarbons and cyanogen are clearly made out, and from the nature of the cyanogen bands it is concluded that the illumination of this gas on the comet is due to electrical phenomena.—On the aërodynamical phenomena produced by the cannon used in dispersing hailstorms, by M. J. **Violle.**—Examples of the mechanical analysis of soils, by M. Th. **Schlœsing,** sen. Examples are given of the mechanical analysis of soils by the method described in a previous paper. It is shown that the amount of clay does not interfere, and that analyses of the same earth, repeated under different conditions, give concordant results.—On the relation of the work of S. Lie to that of Liouville, by M. N. **Saltykow.**—On entire functions of zero order, by M. Edm. **Maillet.**—On the integrals of Fourier-Cauchy, by M. Carl **Störmer.**—A diagram giving the properties of nickel-steels, by M. Léon **Guillet.** The diagram is constructed with percentages of carbon as abscissæ, and percentages of nickel as ordinates. The diagram is divided into four areas, and allows of the deduction of the structure and mechanical properties of the steel from its composition.—On unsymmetrical tetramethyl-di-amino-diphenylene-phenyl-methane and related dye-stuffs, by MM. A. **Guyot** and M. **Granderye.**—A fixing liquid isotonic with sea-water, by M. M. C. **Dekhuyzen.** The solution is made up of a 2·5 per cent. solution of potassium bichromate in sea-water, 25c.c. of normal nitric acid, and 54c.c. of a 2 per cent. solution of osmic acid.—On the presence of lactic acid in the muscles of the invertebrates and the lower vertebrates, by M. Jean **Gautrelet.**—On the presence of microsporidia of the genus Thelohania in insects, by M. Edmond **Hesse.**—On the post-embryonic development of Ixodes, by M. A. **Bonnet.**

PSYCHOMETRIC OBSERVATIONS IN MURRAY ISLAND.

Reports of the Cambridge Anthropological Expedition to Torres Straits. Vol. ii., Physiology and Psychology. Part i., Vision. Pp. vi+140. By W. H. R. Rivers, with an appendix by C. G. Seligmann. Part ii., Hearing, Smell, Taste, Cutaneous Sensations, Muscular Sense, Reaction-Times. By C. S. Myers and W. McDougall. Pp. 141–223. (Cambridge: University Press, 1901, 1903.)

IN his short preface to this second volume of the Cambridge anthropological reports, Dr. Haddon remarks that no investigation of a race of people can be considered as complete unless it embraces observations on such psychological phenomena as admit of definite determination. In order to carry this into practice, he appears to have resolved that such branches of study should be efficiently dealt with in the second expedition to Torres Straits. Dr. Haddon is to be congratulated on having framed this comprehensive and truly scientific conception of ethnographical study, and he is further to be congratulated on having secured the services of such efficient psychological representatives as Dr. Rivers, Dr. Myers, and Dr. McDougall. The psychometric observations carried out by these gentlemen have, as was to be expected, been conducted on thoroughly sound lines, and the results described in the reports thus form not only an extremely valuable addition to anthropological knowledge, but an almost unique contribution to the physiology of the special senses. To Dr. Rivers in particular, special praise is due for the thoughtful care which he has bestowed upon the conduct of the inquiry, and for the way in which he has collated and presented the results.

The main part of the work was carried out in Murray Island, where the observers lived for four months. This island was originally selected by Dr. Haddon as being, in his judgment, particularly favourable for the study of a simple primitive people; it is out of the track of commerce, and its inhabitants still retain their simple natural characteristics; it is true that they have come into contact with missionaries and have acquired a certain knowledge of pidgin English, but this was found to be a distinct advantage from the point of view of the expedition, since it facilitated the establishment of a good understanding between the natives and the members of the expedition, besides enabling the observers to converse more freely with those selected for psychometric experiment. The limited population, 450 all told, was an obvious aid to the inquiry, and, judging from the reports, it appears doubtful if any other community, European or Polynesian, has been psychometrically investigated under more favourable conditions as regards both absence of disturbing factors and simplification of method.

The observations discussed in the reports are mainly those involving sensation, their scope being determined by the time at the disposal of the investigators, the available apparatus, and the nature of the individuals on whom the experiments were made. In the first part of the reports Dr. Rivers gives an account of various visual experiments chiefly made on the Murray islanders, but also carried out with the aid of Dr. Seligmann on some of the other small islands in Torres Straits. The chief points aimed at were the determination of visual acuity, of colour vision, and of visual spatial perception. As regards visual acuity, the most trustworthy test seemed to be the well-known E type method, which consists in determining at what distance a given size of this letter can be recognised; the letter was placed in various positions (sideways, upside down, &c.), and recognition was indicated by the observed person placing in a similar position a corresponding E on a card which he held in his hand. The conclusion arrived at by Dr. Rivers is that the visual acuity of the Torres Straits islanders is only slightly more pronounced than that of normal Europeans, and that probably this difference would disappear on taking into account the refractive errors, myopic and other, of the latter class. The unanimity with which travellers ascribe a high degree of visual acuity to savage races does not, therefore, mean that these races have organs which are abnormally sensitive to stimulation by light, but is related to the power of the primitive savage to make correct inferences from comparatively insignificant visual data. This power does not depend on a more perfect organ, but is associated with the close attention which the savage pays to the natural objects which surround him. Dr. Rivers appears to agree with Ranke in believing that this close attention to detail can be acquired by practice, but that in primitive races it is associated with lower mental development and with incapacity to feel any marked æsthetic interest or enjoyment even in scenes which the European regards as of great natural beauty.

A very large number of observations were made upon the extremely interesting phenomena of colour vision. It is well known that the references to colour in classical literature show a limited variety of colour nomenclature as compared with modern colour vocabularies. The view of Gladstone and others that this indicates a difference between the range of colour sensations of the ancients and those of their modern successors has, however, been generally rejected on the ground that sensations may have been undoubtedly experienced even when no special terminology has been framed in order to describe them. It appears, however, from the observations on the Murray islanders that it is precisely those colour sensations which are more or less defective for which there is no definite descriptive word, thus supporting Gladstone's views. In Murray Island 107 individuals were tested for colour, and it is remarkable that not a single case of red-green blindness could be detected, although in Europeans such defects amount to quite 4 per cent.

The colour vocabulary is largely framed from the names of such natural objects as force themselves on the attention; thus the word for "red" is derived from blood, that for "green" from the bile of the turtle, it being common knowledge that if the turtle's gall-bladder was accidentally opened in preparing the

animal for food, then the intensely green bile rendered all parts inedible; only one colour was named from the hue of a flower, in spite of the great variety which tropical flowers show. Points of equal interest are the indefinite character of the word used for "blue," this being applied indifferently to blue-green, dirty yellow, grey, &c., and the complete absence of any word for "brown," the language resembling in this respect Homeric Greek. The Murray islander recognised "red" far more distinctly than any other colour; yellow was the next most recognisable hue, "blue" could only be differentiated when in considerable strength, and brown was merely a dull-looking light.

In this connection the simple experiments made upon peripheral colour vision were extremely suggestive. It is well known that in the European the red-green visual field is the smallest, whilst the blue and yellow fields are far larger, but in the Murray islander the green field was distinctly the smallest, and the red field extended widely into the peripheral regions; the largest field of all was, however, the blue one, these colours being far better recognised with peripheral vision than in vision involving the central macula. Probably, as Dr. Rivers suggests, the defective stimulation of the macula by blue light may be related to the excess of yellow pigment present in the Papuan race, and would not be in itself a sign of defective retinal capacity for excitation by these rays.

Many other points of great interest are detailed in this part of the reports, colour contrast, after-images, visual perception of distance, binocular vision, capacity to bisect lines, capacity to compare the length of vertical with that of horizontal lines, susceptibility to such well-known visual illusions as those of Müller-Lyer, Zöllner's line displacements, &c. In regard to all these points there appears to be little, if any, difference between the Murray islander and the average European; the details of these experiments will well repay the reader, particularly as Dr. Rivers has presented the results and described the methods in such a manner that his account can interest those who have not especially devoted themselves to this kind of work.

The second part of the present volume of reports deals with other sensory phenomena. The investigation of hearing was undertaken by Dr. C. S. Myers; it was rendered difficult by the not infrequent presence of defects in the ears due to the now prohibited practice of deep diving for pearls. The experiments on the younger inhabitants were free from such hampering circumstances, and the results showed that, as compared with Europeans, both the acuity of hearing and the capacity to distinguish differences of tone were distinctly inferior in the case of the islanders; on the other hand, it is remarkable that the range, as estimated by modified Galton whistles, was at least as extensive in the islander as in the European. The investigation of the sensations of smell by Dr. Myers was also extremely difficult, owing to the great objections entertained by the islanders for this class of experiment, but it seems from such observations as could be made that there is no marked hyper-sensitiveness to olfactory stimulation in this primitive race as compared with Europeans.

Dr. Myers also made some limited experiments on tastes; a specially interesting feature brought out by these observations is the complete absence of any word to describe the extremely conspicuous gustatory sensation which we denote as "bitter," although it is certain that the sensation was experienced. In connection with this remarkable omission is the circumstance that, even in Europeans, there is considerable confusion as to the sensory significance of the qualities connoted by the word "bitter." Cutaneous sensations, muscular sense, &c., were undertaken by Dr. McDougall, and here there are some striking, but not unexpected, differences between the Murray islander and the European. In the former the sense of pure contact was twice as delicate as in the average Englishman, whilst the susceptibility to pain through pressure, &c., was far less pronounced. It is somewhat surprising, considering how unfamiliar the islanders were with the necessary procedure, to find that, as regards the estimation of different weights, the average least recognisable weight increment was actually smaller in their case than in the corresponding average of thirty Englishmen, being 3·2 per cent. as compared with 3·9 per cent.

Finally, the very important subject of reaction-time was undertaken by Dr. Myers, who gives most valuable details of the results of his observations. It appears that, as regards auditory reaction-time, the younger Murray islanders give results identical with the average young English townsmen, but that, as regards visual reaction-time, the Murray islanders give distinctly longer results. This lag becomes more perceptible when the attention is definitely fixed on the visual stimulus rather than the preconcerted movement, a procedure which always lengthens the reaction-time of Europeans, but which lengthened that of the islander comparatively more. Further, when the method of choice visual signal was used, involving a complexity of psychical conditions, then the increased lag became still more apparent. The reader is referred to the original for the very instructive and, from a psychological standpoint, most suggestive details of these observations.

In conclusion, the authors are to be heartily congratulated on the appearance of this work, which is a very important contribution to both physiology and psychology. The reports form a lasting memorial both of the activity of Cambridge anthropology and of the genuine character of the scientific spirit which now actuates those who study the various aspects of ethnography; the appearance of the remaining volumes promised by Dr. Haddon will be looked forward to with the greatest interest by a wide circle of biological students. F. G.

A REVISION OF PRINCIPLES.

The Principles of Mathematics. By Bertrand Russell, M.A. Vol. i. Pp. xxviii+534. (Cambridge: University Press, 1903.) Price 12s. 6d. net.

THE appearance of a book addressed equally to mathematicians and to philosophers, setting forth all the assistance which philosophy can afford in the shape of material for mathematics to work

with, is a remarkable event, and the fact that the criticism, pertinent and lucid as it is, of the work of the great Continental thinkers is adverse on many fundamental points should claim for it the patient consideration of both classes of students. We quote:—

"The distinction of philosophy and mathematics is broadly one of point of view: mathematics is constructive and deductive, philosophy is critical, and in a certain impersonal sense controversial. Wherever we have deductive reasoning, we have mathematics; but the principles of deduction, the recognition of indefinable entities, and the distinguishing between such entities, are the business of philosophy."

In answer to the question, "what is mathematics?" we are told that

"Pure Mathematics is the class of all propositions of the form 'p implies q' where p and q are propositions containing one or more variables, the same in the two propositions, and neither p nor q contains any constants except logical constants."

These logical constants are defined in terms of the fundamental concepts which mathematics accepts as indefinable; the philosophical discussion of the latter occupies part i. of this volume. The remaining six parts are devoted to the establishment of the main thesis, that what is ordinarily known as mathematics is deducible from these fundamental concepts by purely logical processes. This, of course, necessitates a philosophical account of the processes which are admissible; the carrying out of the deductions in their most abstract and rigorous form lies in the province of symbolic logic, and is reserved for the second volume.

The mathematical reader is recommended in the preface to pass over some of the more philosophical portions and begin at part iv., on "Order." We do not endorse this recommendation, for the exact establishment of the notion of order is one of the most tedious pieces of work that the mathematical philosopher has to do; besides, many of the preceding chapters are not only extremely interesting in themselves, but absolutely essential to a correct appreciation of the science of arithmetic subsequently developed. For example, a *number* will be found to be defined as a *class*.

Concerning the notion of class, some slight criticism may not be inappropriate. The distinction between class, class-concept, and concept of class, which is of fundamental importance to exact thinking, is made admirably clear, but the same cannot be said of what is necessary to constitute a class. A class may be defined either extensionally, by an enumeration of its terms, or intensionally, by the concept which denotes its terms. The former method seems applicable only to finite classes; we cannot agree with the author that it is logically, though not practically, applicable to infinite classes, unless some meaning is attached to the word "enumeration" different from what is ordinarily understood. On the other hand, the latter method implies that a class is defined by a predicate, and contains those terms of which the predicate is predicable; but this leads to an apparent contradiction which Mr. Russell has discovered; for consider the predicates which are not predicable of themselves, for example, humanity, which is not human; "not predicable of itself" seems to be a predicate defining a class of predicates, yet to suppose that this defining predicate either is, or is not, contained in that class, leads to a contradiction. A similar contradiction is reached when we consider the class whose terms are all the classes, each of which does not constitute as *one* a term of itself as *many*; for in attempting to form this class, at any stage the terms already obtained constitute a class which must be included as a new term, and so on. This may be compared with the attempt to sum a numerical series each of whose terms is the sum of all the preceding terms; the comparison does not completely explain the paradox, but suggests that a distinction should be made among infinite classes somewhat like that between convergence and divergence.

Leaving the logical side of the subject, we come to the first mathematical idea to be defined, that of number. It was formerly supposed that the notions of "1" and "+1" were fundamental, and that from them all other numbers could be defined. In the present work the number of terms in a class is defined, in a manner slightly differing from Peano's, as the class of all classes similar to the given class. Similarity depends on a one-one relation, which can be defined without reference to number, and indicates by Mr. Russell's "principle of abstraction" the possession of a common property which may be called the number. Various reasons are given for preferring this definition, one of the chief being the inclusion of the infinite numbers introduced by Cantor.

Part iii. deals with quantity and magnitude, between which a subtle distinction is drawn, and contains an introduction to the problems of infinity and continuity, which are to be more fully discussed in part v. Part iv. develops the difficult theory of order and Dedekind's theory of integers. The next part is necessarily based largely on the work of Cantor. To readers unacquainted with the "Mengenlehre," the introduction of transfinite numbers must appear rather startling, but this is perhaps partly due to an unusual weakness in the English language. It must be remembered that by a transfinite cardinal number is meant a certain kind of infiniteness of aggregate, the same number belonging to different aggregates which are similar in the preceding sense; and a transfinite ordinal number is another name for a type of infinite series, or of generating relation.

In the chapters on real numbers and irrationals, we approach controversial ground. The particular object which the arithmetisers of mathematics have here in view is to complete the series of rational numbers by the introduction, without any appeal to intuition, of other numbers, so as to satisfy the abstract definition of continuity. One consequence of this will be that it will then be possible to assign a real number to every point on a straight line. Three great thinkers —Dedekind, Weierstrass and Cantor—have done this, making their definitions of an irrational number depend upon the theory of *limits*. Their methods are explained and criticised, the chief objection being that

there is no adequate ground for assuming that a limit such as that of the series of rationals whose squares are less than 2 does really exist. Instead of this Mr. Russell defines a *segment* as a class of rationals less than a variable term of itself, and shows that segments possess all the usual properties of real numbers. This theory agrees very closely with Cantor's, the point of divergence being where Cantor appears to regard the rational number a as identical with the real number defined by the series $(a, a, a, \ldots)$ whereas Mr. Russell will not admit this. On the one hand it is obvious that the two concepts are as distinct as "man" and "featherless biped," and therefore cannot be identical; but, on the other hand, it seems unnecessary to insist too much on the distinction, because no confusion need arise from using the expression "a" in two different senses. Thus, if b is the irrational number defined as the series $(\ldots a_n, a_{n+1}, \ldots)$ we may write $b-a=(\ldots a_n-a, a_{n+1}-a, \ldots)$ and in this equation a is a series or so-called real number on the left and a rational number on the right. The conclusion is that the series of rational numbers cannot be completed exactly as it stands, but the rationals must first be replaced by series, or, if preferred, by segments, and then by means of other series the continuum of real numbers can be constructed.

Limitations of space forbid detailed comment on part vi., in which, incidentally, Euclid gets some rather hard knocks; and in the matter and motion of part vii. Newton's laws are condemned as confused, worthless, and wholly lacking in self-evidence, while we are told that force is a mathematical fiction, and velocity and acceleration must not be regarded as physical facts.

On the whole the book is very interesting, although somewhat too long. The presentation is admirably clear, and the seriousness of the style is relieved here and there by neatly turned bits of humour. It does not pretend to say the last word on any subject, and, indeed, bristles with unsolved difficulties, towards the correct solution of which a great step is undoubtedly made by its publication.

R. W. H. T. H.

ELECTROCHEMICAL ANALYSIS.

Quantitative Chemical Analysis by Electrolysis. By Prof. Classen. Translated by Bertram B. Boltwood. Pp. vii+315. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 12*s*. 6*d*. net.

ELECTROCHEMICAL methods of analysis are now coming into such general use on the Continent and in America, and to a smaller extent in this country, that chemists will be prepared to welcome the latest translation of Prof. Classen's "Quantitative Analyse durch Elektrolyse."

The translation is made from the fourth German edition published in 1897, but, as the translator has been allowed wide latitude by the author, he has brought the book well up to date, and we find several features in this book which are not in the German original.

In chapters xiii. and xiv., for example, which deal respectively with "measurements of current strength" and "sources of current," there are quite a number of new blocks, as, for example, Bredig's amperemanometer and the Weston ammeters and voltmeters. We also find several new diagrams in chapter xvi., which deals with the accessory apparatus employed in analysis. As a matter of fact, we think, considering that the book is devoted to electro-analysis, some of the apparatus described is rather superfluous. A quadrant electrometer is not usually to be found in a laboratory devoted to electro- or any other analysis, the description of such apparatus appertaining more to works on physics or perhaps on general electro-chemistry. In chapter xviii. the author gives details as to "arrangements for analysis." The details which are given refer mainly to the very thorough installations at Aachen, and two photo-plates of the laboratories, as they are at present, also one showing the former equipment of the private laboratory, are given. One cannot learn very much from these photographs, but they improve the appearance of the book, and incidentally give an idea of the large number of platinum basins which Prof. Classen possesses.

On p. 153 we come to the analytical portion of the book, the first metal dealt with being iron. For the analysis of iron there is no doubt that Classen's oxalate method is extremely satisfactory, and the analytical results obtained are generally very accurate. At the same time, as Kohn and others have shown, this is really due to a balancing of errors. The iron deposited always contains traces of carbon, but, on the other hand, there is usually a trace of iron left in the solution, and these two errors balance. Classen states that iron, when deposited from solutions containing citrates and tartrates, always contains carbon, but leaves it to be inferred that when oxalates are employed, the metal is deposited free from carbon. Prof. Classen employs the oxalate method not only for iron, but he uses it for almost every metal, very often, too, when other ways are vastly superior, and he seems very much afraid that someone else will take credit for the method, because in almost every case we find a bracket in which it is stated that this is the "method of the author." As a matter of fact, there are only a few cases in which the employment of oxalates has any real advantage, as *e.g.* with iron and zinc. There is certainly nothing to be gained by using it when depositing copper, nickel, or mercury, where there are many much more satisfactory methods. Cobalt, according to the author, when deposited, shows its characteristic metallic properties. Generally speaking, when electrically deposited, cobalt is brownish or smoky in appearance—are these its characteristic metallic properties?

Section ii. of the analytical portion deals with the analysis of nitrates, and section iii. with the determination of the halogens.

Section iv., on the separation of the metals, is perhaps one of the best parts of the book. It may be very easy, and generally is, provided one employs the correct conditions, to analyse from pure salts of the metals, but the electrolytic separation of metals is

not always so simple. Of course, the chief point is to know how and when to combine pure analytical with electro-analytical methods in such a way as to attain the greatest accuracy, and to save as much time as possible.

Section v. is devoted to a short account of a very neat method of determining the halogens in presence of each other. It depends upon the fact that iodine is precipitated from its solutions at a lower potential than bromine. A silver anode is employed, and when at the lower potential all the iodine has been deposited, a fresh anode is placed in the solution, and a higher E.M.F. employed. Part iii. of the book is divided into two sections, the first of which gives some examples of applied electrochemical analysis, as *e.g.* analysis of alloys, such as brass, solder, type metal, &c., and of certain ores, such as cinnabar and molybdenite. The second section gives details for the preparation of reagents.

The book in its present form is a very useful addition to laboratory text-books. The introduction is, perhaps, rather unnecessarily long, but it explains Faraday's and Ohm's laws clearly, and gives a good general account of the theories of electrolysis. At the heads of the chapters very full references to the literature of the subject are given; the references are mainly to German and American authors, the reason being that Germans and Americans have done most of the work.

The translator, Dr. Bertram Boltwood, has carried out his labour with care and discretion, and many of his additions are very valuable. The book is splendidly printed, and the diagrams are very clear and well produced.

F. Mollwo Perkin.

TECTONICS OF THE EASTERN ALPS.

The Geological Structure of Monzoni and Fassa. By Maria M. Ogilvie-Gordon, D.Sc., Ph.D. Pp. x + 180. (Edinburgh: For the Geological Society of Edinburgh, Turnbull and Spears; London: Simpkin, Marshall and Co., Ltd., 1902–3.)

It is indeed satisfactory that the Geological Society of Edinburgh has, with considerable enterprise, published the very detailed observations of Dr. Maria Ogilvie-Gordon. We can easily conceive that, when originally presented to the Royal Society of London, this paper seemed of somewhat local application (prefatory note, p. v.), and it is the privilege of societies with fewer claims upon their funds to do justice to the work of their own members. It rests with the author to see that the circulation of separate copies is judiciously carried out, in which case, from a cosmopolitan point of view, the place of publication has little influence on the judgment of scientific men.

One feels, however, that continuous energy and persistent attention to detail on the part of Dr. Ogilvie-Gordon have brought into an important controversy a feature that may be superficial, but which, none the less, jars upon the reader. One becomes inclined to believe that an observation claims our notice because it was made by the authoress, and not because it furnishes a link in the long chain of argument. The same impression, it is true, is often produced in the works of Ruskin or Carlyle, but does not form their most enduring attraction for posterity. The recognition of Dr. Ogilvie-Gordon's work is manifest from the frequent references to it by Continental writers, notably in the new "Führer für die Exkursionen," issued for the ninth Geological Congress in Vienna. Yet we cannot forget that the authoress attaches so much importance to the views adopted by her as to have introduced disparaging remarks upon a rival school in the "translation" of a work by Prof. von Zittel. The paper now before us the record of some years of devoted and faithful study in the field, describes how the Triassic masses have been broken up by a double series of planes of fracture, along which igneous rocks have crept during the period of earth-movement. Possibly, then, there is some appropriateness in a mode of treatment which causes us to see the lines of weakness in previous descriptions penetrated with an almost intrusive pertinacity.

Not that there is any note of battle in the present treatise. The authoress gives her reading of the very numerous observations made by her in a classic area, and the difficulties to be faced are well realised by Doelter in the "Führer" above referred to, when he says of Predazzo,

"Die Teilnehmer an dieser Exkursion betreten ein Gebiet, welches zu den allerinteressanten Europas gehört, aber auch zu denen, wo der Zwiespalt der Meinungen am grössten ist. Die verschiedensten und widersprechendsten Ansichten haben hier geherrscht und herrschen teilweise heute noch."

Similar caution is shown by Drs. Diener and Arthaber in treating of the "reef-facies" in the Schlern area. With regard to the causes that bring massive limestones into juxtaposition with normal sediments, along surfaces that occasionally interlock, all geologists are aware that Dr. Ogilvie-Gordon has adopted a theory of cross-fracture and faulting (p. 67), and has done so after detailed mapping on the ground. Her views of the Monzoni mass are admirably stated on p. 176 of the present paper.

"I therefore strongly insist upon my observation in the case of Monzoni that the particular band of limestone strata entered by the sill was at the time of inflow *in process of sinking* steeply inward at the inthrow faults . . . While the ascending magma involved and engulfed fragmentary portions of the insinking calcareous rock, it clearly found easiest access amidst the multiplicity of fracture and shear-slip planes in the body of Werfen strata to the south."

The succession of intrusions is then described, and the suggestive conclusion is arrived at (p. 177) that

"during the geological periods when the fault-vent continued intermittently active, the form of the sill-complex was capable of being re-moulded periodically in harmony with the localised crust-stresses."

The Cainozoic age often assigned to the whole eruptive series of Monzoni, which can only be proved to be later than the Lower Trias, is not a vital point in Dr. Ogilvie-Gordon's paper. Its interest lies in its tectonic details, and these are illustrated by a number

of coloured sections and two folding maps. Some of the photographic plates, such as that of the "block-structure" in porphyrite, facing p. 106, are of unusual beauty. G. A. J. C.

OUR BOOK SHELF.

A. Koelliker's Handbuch der Gewebelehre des Menschen. 6te Auflage. Drittes Band. Von Victor v. Ebner. Pp. 1020; 633 illustrations. (Leipzig: W. Engelmann, 1902.) Price 18s. net.

THE conclusion of the sixth edition of Koelliker's "Histology" merits more than a passing remark. The first appearance of this well-known handbook about the middle of the last century formed an epoch in the science of which it treats (which it may almost be said to have created), and ever since it has held the foremost rank in works dealing with the subject. But it is now more than thirty years ago that the fifth edition was published, and progress has been rapid in the interval.

The first two volumes of the present edition were edited by the original author, and no work that he has done has been better done than this. But the weight of years must eventually tell, even if one is Koelliker, and the task of editing the third volume was handed over by him to Prof. v. Ebner. A first part of this volume, dealing with the digestive, respiratory, and urinary organs has appeared, and has already been noticed in NATURE; the last part of the work, embracing the structure of the generative organs, the vascular system and the organs of special sense, and comprising also an index of subjects and authors for the whole book, is now in the hands of histologists. Prof. Koelliker's selection of an editor for his great work is amply justified; a better successor to himself could hardly have been found than the eminent Vienna histologist, who has, moreover, been ably assisted by Dr. Joseph Schaffer and Dr. Hans Rabl. It is to all intents and purposes a new book which has made its appearance. Hardly a page but has been rewritten, and of the 633 illustrations, 533 are entirely new—for the most part from original preparations. Nevertheless, the general style of the preceding volumes is singularly well carried out in this one, so that it is difficult at first to recognise that the work is by another hand. Too much praise cannot be given to the bibliographical notices, which are far more complete than are to be found in any other work on histology.

The whole book is a storehouse of information based on personal observations, and must long remain the standard work of reference on the subject.

The octogenarian master, whose own scientific activity is by no means exhausted, must be well content to know that his work has been brought to so brilliant a completion, and in presenting to him our respectful congratulations, we may be permitted to express the desire that he will still continue for many years to enjoy the satisfaction of witnessing the success of his life-long labours. E. A. S.

Building Superintendence. New edition, revised and rewritten. By T. M. Clark. Pp. 306. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 12s. 6d. net.

THIS is a book which appears to have had an extended circulation in the United States, and, although it contains a good deal of practical information, a large amount would only apply to construction methods on the North American Continent. It is primarily addressed to the young architect, and gives him hints as to the selection of good materials and as to the direction of building operations generally. A knowledge of building construction is therefore assumed, and the book is intended to supplement that knowledge by the practical application to existing buildings.

The subject is divided into three main heads, namely, stone buildings, wooden buildings, and steel-framed buildings, and in each case a typical building is described from the foundations upwards, showing the successive stages of construction and general direction for the judging of the quality of materials. The term "superintendent," which occurs so often, is presumably the American equivalent for the English clerk of works.

The English student should beware of information which may apply in the States, but is not correct as applied to England; for instance, on p. 5 we are told that five courses of bricks commonly equal one foot in height, whereas, as a matter of fact, four courses in England usually equal one foot. Many of the terms and names will also be quite unfamiliar to him.

Chapter i., dealing with stone buildings, takes up the construction of a stone church intended to be erected on elevated ground. This occupies more than 100 pages, and deals with the preliminary staking out of its various parts—foundations, damp in cellars, the making of concrete and mortar, defects common to various kinds of stone, walling, flooring, roofing beams, and plastering. The information is sometimes effected by means of question and answer between the architect and foreman in the manner made familiar in the treatises of Viollet le Duc.

Chapter ii. deals with wooden dwelling-houses, their location and aspect, drainage of site, employment of contractors, the framing of the timber (uprights and sills), chimneys, electric wiring and fitting, roof shingles, plastering, plumbing fittings, doors, windows, stairs and their arrangement and defects, drainage and water supply, and painting. Chapter iii., dealing with the writing of specifications, can be passed over, as essential differences exist between English and American practice. Chapter iv. deals with contracts, and the author rightly dwells on the importance of these, especially with regard to the necessity for protecting the building owner.

Chapter v. deals with the construction of a steel-frame office building, eleven storeys high, on a corner city site 25 feet by 100 feet, in which economy of space has to be carefully studied. This is probably one of the most interesting chapters in the book, and its construction is dealt with in a progressive way, in the same manner as in the stone and wood buildings.

The plan, question of fire escapes, foundation, steel framework, vaults, floors (fire-resisting), elevators, are dealt with in turn. As will be seen, the book is arranged on a sensible and convenient plan, and if it could be written to be suitable for English readers, it would be of greater benefit. As it is, however, it contains a great deal of excellent advice founded upon practical experience, and no architect could read it through without having his wits sharpened for discovering defects in workmanship at the periodical visits which he pays to buildings in course of erection from his designs.

A Key to the Time Allusions in the Divine Comedy of Dante Alighieri. By Gustave Pradeau. Pp. 32. (London: Methuen and Co., 1902.)

THE author, having found that different editions of the great poem of Dante assigned different durations of time for the action supposed to be occupied by it, set himself to investigate the matter by a comparison of all the time allusions until the poet ascends from over Jerusalem to the *primum mobile.* He ingeniously illustrates his argument by a diagram or "dial" in the circumference of which are the signs of the zodiac, whilst in the centre are four points representing respec-

tively Jerusalem, Purgatory, the Ganges, and Morocco. Dante imagined that, with respect to Jerusalem, the Ganges was the extreme east and Morocco the extreme west. The four important divisions of the day, *mezzodi* or midday, *sera* or evening, *mezzanotte* or midnight, and *mattino* or morning, are represented by lines towards the circumference. At the beginning of the poem Gerusalemme must be placed at the top of the circle, with Mattino over it. Now looking southwards, holding the dial straight before us, it will be found that the sun on the dial follows the same course as the real sun. The lines in the Inferno, Purgatorio, and Paradiso which contain the time allusions are given in Italian and in Longfellow's English translation, and the author finds that the whole duration from the beginning of the poem to the final morning in Purgatorio is seven and a half days, *i.e.* seven days from the entrance with Vergil into Hell.

The conceptions of great poets like Dante and Milton must ever be of interest, though we cannot, of course, expect them to be in agreement with modern astronomy. The latter, though constructing the universe according to Ptolemy, yet, living after Copernicus, and being personally acquainted with Galileo, evidently had misgivings with regard to the truth of that system. None such troubled the mind of Dante; to him the earth was the centre of the universe, both in appearance and in reality. But M. Pradeau presents a scheme concerning his views as bearing upon the progress of time in the "Divina Commedia" which is both ingenious and consistent with itself.

W. T. L.

A School Geometry. Part iii. By H. S. Hall, M.A., and F. H. Stevens, M.A. Pp. vii+137 to 210. (London: Macmillan and Co., Ltd., 1903.) Price 1s.

IN this volume we have a further instalment of the new text-book of elementary geometry which the authors have in preparation, a school geometry based on the recommendations of the Mathematical Association and the recently adopted report of the Cambridge Syndicate.

The present contribution deals with the geometry of the circle, and contains the substance of Euclid, book iii., 1–34, and a portion of book iv. The authors have omitted some of Euclid's propositions, and have not adhered strictly to Euclid's sequence, but the Euclidean form of proof has been retained.

The conception of a "limit" is appropriately introduced in explaining the nature of tangency, and in establishing some of the propositions.

The exercises, which follow the propositions at short intervals, are partly deductive and partly graphical, the latter requiring the use of compasses and scale, the numerical answers being collected at the end of the volume. The examples are simple and well graduated.

We consider that problem 23 would be better omitted, together with the exercises based thereon. It is of no practical value, and should be consigned to the Euclidean relics. Every draughtsman knows that a line can be drawn with greater accuracy to touch two given circles than to pass through two given points, and if the points of contact are wanted, they can be determined subsequently by drawing perpendiculars from the centres of the circles.

The circumference and area of a circle are briefly dealt with on p. 198. The experimental determination and verification of these quantities might with advantage have been more fully gone into. The book concludes with some propositions on circles and triangles, including a demonstration of the property of the nine-points circle.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

American Botanic Laboratory in Jamaica.

THE Director of Kew presents his compliments to the Editor of NATURE and requests the favour of his publishing the enclosed letter.

Kew, August 23.

Sir William Thiselton-Dyer,
Royal Botanic Gardens,
Kew,
Surrey, England.

My dear Sir,

The Government of Jamaica has decided to relinquish its use of the buildings at Cinchona. The experimental and botanical plantations are, however, to be maintained as before. The Surveyor-General of Jamaica offered under public advertisement on June 15 the group of buildings known as Bellevue and some land for rental. I have personally accepted this rental for the purpose of saving the station for scientific purposes, and with the plan of establishing there, if possible, the long desired botanical laboratory in the American tropics. At my request, Dr. MacDougal has recently visited Jamaica to arrange details of the lease, and reports that the buildings and their furnishings are already comfortable and well adapted for the use of investigators.

Dr. MacDougal and I decided to take these steps after consultation and correspondence with Prof. Underwood, who spent the early part of the year in Jamaica in the study of ferns, and who is now in Europe; with Dr. Duncan S. Johnson, who has recently returned from Jamaica, where he has been collecting material for embryological studies; with Mr. Wm. R. Maxon, who was with Prof. Underwood there during the spring; and with Prof. Earle, who spent last November in Jamaica in mycological investigations. Dr. MacDougal was already familiar with the locality from his visit there with Prof. Campbell in 1897, and we had discussed the topic with the Hon. Wm. Fawcett, director of the public gardens and plantations of Jamaica, while he was in New York last autumn during the meeting of the Plant Breeding Conference. The aid and cooperation of all who regard the securing of Cinchona as a proper and desirable act will be needed to maintain such a laboratory, and to this end I ask that you write me your opinions on this subject, and to indicate what aid you can render, and whether either you or your students would wish to make use of the station during the next year, and if so, for what length of time approximately.

I may say that the Jamaican Government is heartily in sympathy with the enterprise, and will cooperate to a very important extent, furnishing facilities for growing plants under the widely different climatic conditions offered by the gardens at Cinchona, Hope, and Castleton, the use of the large botanical laboratory and herbarium at Hope, and the use of visitors' tables in the laboratory at Hope.

As regards Cinchona, I quote the following from Prof. Underwood's account of his work in Jamaica from the July issue of the *Journal* of the New York Botanical Garden:—

"Not the least important of the results of the expedition was a possible solution of the problem of a suitable location for a tropical laboratory, which has long been under consideration by American botanists. At the time of the visit of the committee appointed some years ago to investigate the subject, the plant at Cinchona was occupied by the Government botanist, and was consequently out of the question. A one-story six-room house, three or four low buildings suitable for laboratory work, with two greenhouses of sufficient capacity to conduct experimental work under glass, could be had of the Jamaica Government at a nominal rent. Cinchona is nearly a mile above the sea, with a delightful climate (the extremes of temperature for the past twenty years being 45° F. and 79° F.), a delightful outlook, and as closely accessible to virgin forest as could be obtained. Within three miles, nearly on a level, is

Morce's Gap, whose tropical conditions I have described above; close to Morce's Gap you make the ascent to John Crow Peak (6000 feet), through a forest of tropical luxuriance. Below is Mabess River (3000 feet), with similar but lower-level vegetation. At about the same distance from Cinchona (three miles) is New Haven Gap (5500 feet), with a similar but higher-altitude flora. Still higher altitudes are accessible at Portland Gap and Blue Mountain Peak at a distance of eight to ten miles.

"There are no human habitations above Cinchona, so that the Clyde River, which supplies it with water, is pure and without sources of contamination; a more healthful location could not be found in all the American tropics."

Briefly expressed, the above scheme offers the investigator residence accommodations and laboratory facilities at Cinchona under the most pleasant and advantageous conditions, from which place he may quickly transfer his work to more pronounced tropical conditions at Hope in a dry climate; or to Castleton in an extremely humid locality. The marine flora is equally accessible.

The locality furnishes easy access to an immense number of species of plants different from those available at any other similar institution; travelling and living expenses are very reasonable, and Jamaica may be reached at intervals of only a few days by numerous steamers from England, Germany (Hamburg), and nearly all ports of eastern America.

Yours sincerely,
N. L. BRITTON.

New York Botanical Garden, Bronx Park,
New York City, August 13.

Training of Forest Officers.

IN a sympathetic notice in the *Indian Forester* of the late distinguished Inspector-General of Forests in India, Mr. H. C. Hill, Sir Dietrich Brandis stigmatises as "absurd" "the idea which, until a short time ago, was current in England, and which to this day is held by many English botanists, that a good botanist must necessarily be a good forester." I quite agree that the idea is absurd; but as I am probably better acquainted with the English botanical world than Sir Dietrich Brandis, I doubt very much whether the idea was ever current in this country, or is held at the moment by many English botanists. For my part I entirely dissociate myself from it, as I know many accomplished botanists who would probably make very indifferent forest officers.

I am more able to agree with Sir Dietrich Brandis when he says, "A forester, more than almost anybody else, must use his eyes and must be able on the spot to draw conclusions from what he has observed." But the power of observation is by no means possessed by everyone. A further requisite, in which I think Sir Dietrich Brandis also agrees, is sympathy with and pleasure in forest nature for its own sake. It appears to me that neither point is kept in view in the present mode of recruiting the Indian Forest Service.

Sir Dietrich Brandis lays great stress on sport, and unless it becomes too absorbing a pursuit, it undoubtedly fulfils the conditions I have stated. It would, however, be as undesirable to insist that every forest officer should be a sportsman as that he should be a botanist.

But I entertain a very strong opinion that a forest officer will never rise to the highest level of efficiency in his work unless he has a scientific grasp of the principles which underlie it. He should be able to identify the trees which compose the forest vegetation under his charge, and for this purpose he should have such an elementary acquaintance with botany as will enable him to use intelligently the book which Sir Dietrich Brandis has been for several years occupied at Kew in preparing for the purpose. He should further have some knowledge of the nature and conditions of vegetable life; he should grasp the idea that a tree is a living organism the growth and development of which are subject to adverse or favourable conditions. He should further have some idea of the enemies and diseases by which trees are liable to be attacked, and of how these attacks can be met. All this a man of ordinary intelligence can acquire if he possesses a real taste for nature without rising to the level of the professional botanist, which it would be absurd to demand of him.

There is the same fallacy underlying the view that mere administrative efficiency is sufficient for a good forest officer as in thinking that mere mechanical drill, without resource or initiative, will make a good soldier.

As I have felt it my duty to urge these views officially, I should be glad to state them more publicly.

I should like to take the opportunity of expressing my regret at the untimely death of Mr. H. C. Hill, the late Inspector-General. Largely as the result of my personal persuasion he accepted a mission in 1900 to initiate a scientific forest administration in the Straits Settlements. His reports were of the highest value, and will be a permanent basis for the future forest policy of that part of the Empire.

W. T. THISELTON-DYER.

Kew, August 28.

Peculiar Clouds.

CAN any of your correspondents explain the following phenomenon? At 5.20 p.m. to-day, the sky to the W. and S. being covered with a dense and unbroken mass of cloud, and the sun, therefore, entirely obscured, I saw a broad patch of iridescent colours like a piece of a rainbow on the clouds to N.N.E., many points more to N. than a rainbow would have been had the sun been shining. No part of the sky was clear, but the clouds were lighter in the N.W.

I saw a similar phenomenon at Colwyn Bay on December 17, 1898, the iridescent cloud being due E. at 2.45 p.m., the sun shining intermittently. I know true "iridescent clouds" well, but they are generally near the sun.

ALFRED O. WALKER.

Ulcombe, Maidstone, August 30.

THE EARTHQUAKE OBSERVATORY IN STRASSBURG.

NOW that the earthquake observatory in Strassburg has been offered as a centre for the proposed international association for seismological research, at which the work of the world so far as it bears upon earthquakes and kindred phenomena may be concentrated, a short description of this institution and its present output may not be devoid of interest.

The building stands in the back part of the University gardens, and lies between two streets, along which heavy traffic is forbidden. Externally it measures 19 x 15m., and essentially consists of four rooms, round the walls of which there is a passage or air space 1m. in width, walls, a second air space, and the outer walls. In short, it is a building with its floor 1·50m. below the surface, within two other buildings.

The object of the construction is to obtain rooms which are light tight, free from currents of air, and in which changes of temperature and moisture should be small. For certain classes of observations these conditions may be imperative, but when recording earthquakes, which is the chief work at Strassburg, gloom and a still atmosphere are distinctly undesirable. In the early days of seismometry the proper place for an earthquake recorder was considered to be a cellar, and when we find instruments with complicated parts which frequently require inspection, and which write their records on smoked paper, together with photographic apparatus designed to be used in broad daylight, relegated to darkness, we realise that traditions still survive.

Although it is well known that different results are obtained from similar instruments installed on different formations, the choice of site at Strassburg was apparently governed by the advantages offered by proximity to its University. In consequence of this, town traffic, which includes that of an electric service,

which might influence certain geophysical investigations, and the fact that alluvium might mask small tremors, are conditions that cannot be avoided.

In the *Beiträge zur Geophysik* (vi. Band, 3 Heft) issued "Zur Begrüssung der II. Internationalen Seismologischen Konferenz," Prof. Dr. Bruno Weigand gives an account of the instruments now in use at Strassburg Observatory, and an explanation of the monthly reports issued from the same.

The instruments longest in use are two Rebeur-Ehlert horizontal pendulums. In each instrument there are three pendulums arranged at angles of 120° with each other, the idea being that the three records would enable an observer to determine the direction in which an earthquake motion was propagated. Inasmuch as it has been well known for many years past that the movement of the ground as recorded at a given station may be in any azimuth, we are not surprised when Dr. Weigand tells us that no satisfactory result has been obtained.

The records are photographic, the source of light and the record receiving surface being at a distance of 5 metres from mirrors on the pendulums. This necessitates the use of powerful electric lamps. This condition, the high sensibility due to high multiplication of the instrument, which on certain foundations leads to wandering of the light spot, and the cost of photographic paper, which is run at the rate of 36cm. per hour, preclude the use of this instrument excepting at a few selected stations. Other instruments are Wiechert's astatic pendulum, Vicentini's microseismograph, and Omori's conical pendulum, all of which write on smoked paper, Milne's photographic horizontal pendulum, which is a type adopted by the British Association, and Schmidt's trifilar gravimeter.

Brief references to the records of these instruments are published in a *Monatsberichte*. All that this gives about the Strassburg records of an earthquake is a time for its commencement and its duration as recorded by a Von Rebeur pendulum. The times of maximum or other phases of motion, amplitudes, periods, and other information required by seismologists is omitted. A plus or minus sign indicates whether other instruments did or did not respond to the movement, and the latter signs predominate.

With the object of showing the superiority of the Strassburg type of instrument, particularly as compared with the type adopted by the British Association, which latter, according to his opinion, should cease to exist, Dr. Weigand emphasises the discrepancies between his various registers. As illustrative of the supposed want of sensibility in the British Association type, he points out that the Strassburg *Circular* for August, 1901, shows that the Rebeur pendulum recorded twenty-four earthquakes, whilst a British Association type, in the same building, only recorded seven. This latter number he now raises to ten. As a matter of fact, seventeen of the Strassburg records correspond with seventeen records obtained in Britain, whilst five entries in the Strassburg list refer to very small disturbances peculiar to that place, which therefore may well be regarded as being of doubtful origin. The earthquakes recorded in a given period by the Rebeur and British Association pendulums were therefore nineteen and seventeen. Dr. Weigand published these numbers as twenty-four and seven, and similar discrepancies between the records of the Rebeur pendulum and the records of all other instruments in use at Strassburg appear in each of the Strassburg registers.

That the Rebeur pendulums as installed at Strassburg have a higher sensibility than other seismographs is well known, but it must not be overlooked that this high sensibility is one factor which prevents their general adoption. That the British Association type of instrument is sufficient for the purposes for which it was intended is amply shown in the reports issued by the Association. Experiments are now in progress to increase the speed of the record receiving surface connected with this apparatus about four times, and to reduce the cost of photographic material to about 3*l.* per annum. It now costs 6*l.* 10*s.* per annum, whilst paper for the Rebeur apparatus costs 15*l.*

When Dr. Weigand complains of the want of sharpness in the trace yielded by the British Association instrument, he should evidently look to its adjustments, for it is its pronounced sharpness that compensates for its want of multiplication. In this respect the records it yields are far superior to those obtained from any other form of photographically recording seismograph.

That it should be affected like other instruments with so-called "Mikroseismische Unruhe" is what might be expected if located in a cellar.

Altogether, the institute at Strassburg as "der Kais. Hauptstation" might easily be improved, whilst if its publications took the form of the excellent registers issued in the *Bollettino della Societa Sismologica Italiana*, they would be of greater value to working seismologists.

THE INTERNATIONAL STUDY OF THE SEA.[1]

THE publications mentioned below are the first reports of the International Council for the Study of the Sea which was constituted by the meeting of representatives of the maritime Powers of northern Europe at Christiania in 1901, and now has its seat at Copenhagen. The bulletins deal with what has come to be known as hydrographic work carried out on the quarterly cruises, in which special ships of each of the participating States take part. The word hydrography is not, however, used in the sense made familiar by the hydrographic offices of the various Admiralties; it means, if we may borrow for a moment the terminology of chemistry, scarcely more than inorganic oceanography. We say scarcely more, for in these bulletins it does include the study of the distribution of plankton, but for this purpose plankton are treated rather as current-floats than as organisms.

It will be remembered that the International Council was formally constituted at a conference held at Copenhagen in July, 1902, and that no time was lost in getting to work is plain from the fact that the first number of the Bulletin deals with a series of cruises in August, 1902, the second with a similar series in November or December, 1902, and the third with February, 1903. These cruises have since been continued quarterly, and we understand that they are now more complete, and the results obtained more readily comparable than was possible when the collaboration was only beginning. Viewed from the standpoint of scientific efficiency, the work of the Council is hampered by the very short term for which the various Governments have granted the necessary funds and the stringent conditions as to endeavouring to obtain practical results directly beneficial to fisheries which have been insisted on in some cases. But there is reason to hope that these very difficulties will act as a spur.

The bulletins are mere records of observations, they contain a minimum of explanatory letterpress, and no discussion at all. It might be found desirable to print

[1] Conseil permanent international pour l'Exploration de la Mer. Bulletin des Résultats acquis pendant les courses périodiques. Publié par le Bureau du Conseil avec l'assistance de M. Knudsen, Chargé du Service Hydrographique Année 1902–1903. Nos. 1, 2 et 3. (Copenhague: A. F. Höst et Fils, 1903.)

a little more information, for instance, as to the constitution of the International Council and its administrative bureau, the address of the office and a brief statement of the objects for which the organisation has been brought into existence. The salient features of the maps of the physical conditions of the surface water might also be expressed in words, and the stations at which observations were made ought to be indicated on the map of each cruise by dots. We are inclined to lay stress on this point, as without some indication of the kind the maps are difficult to interpret, and the scale is not large enough to permit the figures of each observation to appear.

The August and November cruises were carried out in the Baltic by Finland, Sweden, Denmark, and Germany, in the North Sea by Germany and Scotland, and in the North Atlantic and Arctic Sea by Norway and Russia. To these there were added in February observations in the North Sea by Holland, and in the English Channel by England, England and Scotland being separately represented, mainly on account of the different nature of the fishery problems in their respective areas. It may be noted that these bulletins do not touch on the fishery observations, nor on the biological work (the determination of plankton excepted), which occupy the whole time of the various national staffs between the quarterly cruises. They do not refer either to the work of the Central Laboratory at Christiania.

The importance of the bulletin lies in the fact that it gives particulars of the temperature and salinity at a great number of points from latitude 45° to 75° N., observed nearly simultaneously and with comparable instruments of the highest precision, the temperature being determined by means of the Pettersson-Nansen insulating water-bottle and thermometers graduated to the fifth or even the tenth of a degree centigrade, the salinity by estimation of chlorine.

Both for August and November the central part of the North Sea appears to have been left without observations, but this gap was partly filled up in February when the system of quarterly cruises was more complete, and a number of supplementary observations by trading steamers had been added. The indications in the published maps are of a slight freshening along the British coast, a belt of maximum salinity running parallel to the coast towards the middle of the North Sea, increasing in salinity rapidly to the north-west between Scotland and Faeroe, and to the south-west towards the English Channel. The whole of the eastern half of the North Sea shows a rapid freshening towards a stream issuing from the Baltic close along the west coast of Jutland.

Where the temperature observations were sufficiently close and regular to permit of isotherms being drawn, they present a remarkable relation to the isohalines. In August the one isotherm shown is that of 12° C., which runs from Aberdeen to Lindesnaes, cutting the isohalines at right angles. In the November map, however, the isohalines and isotherms exhibit a most striking parallelism, so that the circulation of the water in that month could be studied with equal facility by considering either the temperature or the salinity. Thus at the southern end of the North Sea the isotherm of 13°.5 C. coincides with the isohaline of 35.25 per mille, and the isotherm of 13° C. with the isohaline of 35.00 per mille. At the mouth of the Baltic the two sets of lines though parallel do not correspond symmetrically, while on the north-west side of the Baltic stream 10° lies close to 34‰, on the east side it lies close to 32‰. Still the axis of the Baltic stream is the same whether it is drawn from the one set of lines or the other.

The February map shows the isotherms parallel with the isohalines in the south and east of the North Sea, but cutting them nearly at right angles in the more open waters of the north and west. The difference in the broad action of the Atlantic in the wide part of the sea and the river-like action of the Channel in the southern part is brought out in a most interesting manner.

It is very important to secure a great extension of surface observations, and this, we believe, is now being done by many shipmasters who make regular observations on the various trade routes across the North Sea. Even if these fall short of the high accuracy attained by the special scientific vessels, they will prove invaluable in fixing the general run of the isotherms during the quarterly cruises, and of following the changes which take place between them.

We consider that these bulletins are satisfactory and full of the promise of large results. The too scanty letterpress is printed in parallel columns in German and English; the title only is in French.

ARCTIC GEOLOGY.

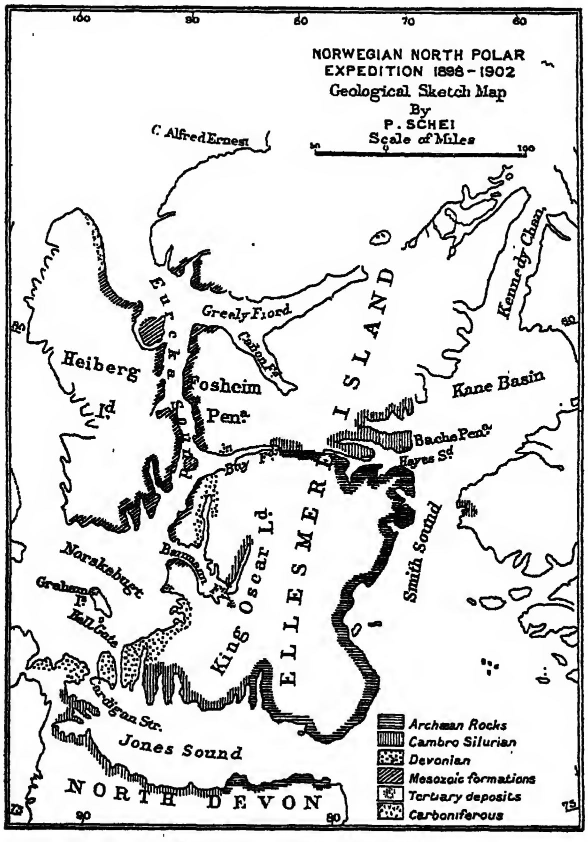
DR. P. SCHEI'S preliminary sketch of the geological work accomplished during Captain Sverdrup's four years' exploration of the region west of Smith Sound, an account of which is given in the *Geographical Journal* for July, makes important additions to our knowledge of Arctic geology.

About a quarter of a century ago Sir G. Nares's expedition examined the northern and eastern coasts of Grinnell Land down to the north-east corner of Ellesmere Island. The collections brought back by the *Fram* continue the geological information from this district round the southern part of that land mass, now named King Oscar Land, and all up its western shore to the north of Greely Fjord, including also the eastern coast of a newly-discovered island called Heiberg Land, and the coast of North Devon, south of Jones Sound, thus filling in the angle between Smith Sound and the group of the Parry Islands. Possibly they complete our general knowledge of this region, for Captain Sverdrup is disposed to think no more land exists to the north and north-west of Heiberg Land.

Previous explorations, summarised by Messrs. Feilden, De Rance and Etheridge in the *Quarterly Journal* of the Geological Society for 1878, proved the existence of crystalline Archæan rocks in the north-east of Ellesmere Island, of ancient sedimentaries, possibly Huronian, along the western coast of Kennedy Channel as far as the north-east angle of Grinnell Land, where they were succeeded by Carboniferous strata (with a little Devonian). West of these were Archæan schists, and those in the south were parted from the Huronians by a tract of Upper and Lower Silurian. Tertiary deposits, presumably of Miocene age, were discovered at more than one spot on both sides of Smith Sound and the channel north of it, and ample proofs obtained of a comparatively recent general elevation of the land, in some cases amounting to a thousand feet. Dr. Schei confirms the existence of the older Palæozoics near the middle of Ellesmere Island. Archæans follow them to the south, and continue along the coasts of Smith and Jones Sounds, appearing also on that of North Devon. On both sides they are succeeded by Cambro-Silurian deposits, and these, just at the western end of Jones Sound, by Devonian, which occur on both sides of the strait and extend some distance up the west coast of King Oscar Land. That formation had been already identified in the Parry Islands, and is now proved to extend over a considerable area. The strait parting Ellesmere Land from Heiberg Land is bordered by Mesozoic strata, which had already been detected in the Parry Islands, and these in the most northern part of

Heiberg Land are underlain by Carboniferous, with some interesting volcanic deposits. Tertiary strata were detected on Baumann Fjord, west of King Oscar Land, containing plant remains in an unusual state of preservation. Towards the western side glaciers are neither frequent nor large, owing probably to a deficient precipitation, and no signs were found of their having had a greater extension.

Thus Dr. Schei's researches corroborate and carry further the work of his predecessors. They show that a plateau-like region of Archæan rocks was submerged—perhaps before the beginning of the Palæozoic—and was buried beneath Cambrian, Ordovician, and Silurian deposits, it may be in orderly succession. These were followed by Devonian and Carboniferous, both marine, and possibly without interruption. After a break, with considerable physical disturbances, some beds of Triassic age were deposited, which are succeeded by Jurassic. Another great break is only



(From the *Geographical Journal.*)

interrupted by isolated Tertiary deposits, and, with the exception of a considerable late or post-Glacial submergence, terrestrial conditions may have been since then generally persistent.

T. G. BONNEY.

FISHERIES INVESTIGATION IN IRELAND.

IRELAND seems to be happier for the moment than either England or Scotland in the organisation and in the results of its official fisheries research. In England the official Fisheries Department has been for some years under the Board of Trade, and is soon, we believe, to be transferred to the Board of Agriculture. It has had no laboratories, no boats, and no scientific assistants, and it is no reflection upon H.M. Inspectors of Fisheries in such circumstances to say that they have carried on no biological, chemical, or other laboratory investigations.

In Scotland there is the well-known Fishery Board, provided with laboratories, vessels, and a sea-fish hatchery, and much good scientific work has been done in the past by Dr. Fulton and his able staff; but it is said that nearly all the available funds (without which practical work cannot be carried on), and the energies of the scientific men, of the Fishery Board for Scotland have now been diverted for several years into the service of the international North Sea investigation scheme.

In Ireland matters seem to be managed better. Competent scientific men are carrying on important investigations having for the most part a direct bearing on the local fisheries, and there seem to be sufficient funds not only to meet the necessary expenses of the work, but also to publish the results in suitable form—with coloured plates and other good illustrations. Across the Irish Sea there is a "fisheries branch" in the Department of Agriculture and Technical Instruction, and the two names that appear prominently in connection with the work—Wm. Spotswood Green and E. W. L. Holt—are ones that command respect from marine biologists and from fisheries experts alike. Mr. Green is Chief Inspector of Fisheries, and Mr. Holt is his scientific adviser, and from what we know of the work accomplished the combination seems a good one. The department in question has now issued the "Report on the Sea and Inland Fisheries of Ireland for 1901," in which, for the first time, as the report of the scientific adviser states, a part ii. on scientific investigations appears as a separate volume. It contains a couple of hundred pages and more than twenty plates, and Mr. Holt—for it is evidently very largely his work—and the department, and all others concerned, are to be congratulated on its appearance. The volume is entitled the report for 1901, but we notice occasional references to work done in 1902, and it contains the translation of a Norwegian paper said to be published in 1902. There is no harm in this, but we may be allowed to hope that the volumes for 1902 and 1903 will follow soon.

After a brief report from the scientific adviser to the chief inspector dealing with sea fisheries, inland fisheries, and the Cork Exhibition (1902), there follows an appendix, which is the main part of the book and contains a number of memoirs by Mr. Holt and his colleagues which are of both scientific and economic value. Amongst these we may note a brief account of a fishing survey of the Porcupine Bank, which is supplemented by a paper on the rock specimens trawled from the floor of the Atlantic and examined by Prof. Grenville Cole and Mr. T. Crook; a paper on Copepoda and one on Nudibranchiata by Mr. G. P. Farran; a useful paper on the British and Irish gobies, by Mr. Holt and Mr. Byrne, which is illustrated by two beautiful coloured plates and a number of figures in the text; an account of an investigation of the oyster beds of Wicklow and Wexford; and a translation of A. Wollebaek's three papers on oyster culture from "Norsk Fiskeritidende." The section on inland fisheries has papers and reports on salmon, pollen, and trout.

It is interesting to notice that Mr. Holt speaks of his oyster investigation as "part of the systematic examination of all our eastern fishing grounds, which is an item in the work of the scientific section of the fisheries branch." That is a programme such as we should expect from Mr. W. S. Green, and we have no doubt it will be ably carried out by Mr. Holt.

W. A. H.

THE SANITARY EXAMINATION OF WATER SUPPLIES.

AN extremely valuable and interesting report[1] has been issued by the sanitary authorities of the City of Chicago on the results of the chemical and bacteriological examinations of the waters between Lake Michigan at Chicago and the Mississippi River at St. Louis for the purpose of determining their condition and quality before and after the opening of the Sanitary Canal. For the diversion from Lake Michigan of the sewage of Chicago and its inoffensive disposal towards the Mexican Gulf, a canal was cut to carry the sewage, much diluted with lake water, into the Illinois River, a distance of 29 miles. From this point the Illinois River, after a course of 289 miles, discharges into the Mississippi at Grafton, which is about 38 miles above St. Louis. The investigations originated from the fact that the State of Missouri and the City of St. Louis had applied for a Federal injunction against the further operation and development of the Sanitary Canal of the Chicago Sanitary District on the ground that the purity of the water supply of St. Louis was endangered thereby. Chicago replied by instituting a commission to examine into the condition of the waters between Chicago and St. Louis, a distance of 356 miles.

The Chicago Municipal Laboratory (Dr. Gehrmann), the University of Chicago (Prof. Jordan), and the University of Illinois (Profs. Palmer and Burrill) collaborated in the work, a common plan of operation was devised, a uniform scheme for the bacteriological and chemical examinations agreed upon, and forty stations were fixed for taking the samples, of which forty were collected weekly and delivered to *each* of the three laboratories. The work extended over a period of about thirteen months, and during that time some 8600 samples were examined. The investigations show that considerable self-purification has taken place before the Sanitary Canal discharges its sewage into the Illinois (29 miles), and that this continues until, before Averyville (159 miles) is reached, all trace of sewage pollution has disappeared from the waters of the Illinois. Since there is still another 188 miles to be traversed before any pollution could reach St. Louis, the possibility of Chicago's sewage endangering the purity of St. Louis's water must be dismissed as impossible. In all probability such an exhaustive series of observations over so extended a stretch of water for so long a period has never before been attempted, and the results obtained are of considerable general interest. A valuable feature of the report is the detailed description of the methods employed for both the chemical and bacteriological portions of the examinations. The report illustrates the proper manner in which a great question, such as it deals with, should be approached and a solution be sought for, and we commend its perusal to hygienic authorities in this country.

R. T. HEWLETT.

NOTES.

THE British Rainfall Organisation, founded in 1860 by the late Mr. G. J. Symons, F.R.S., will henceforth be carried on under the sole charge of Dr. H. R. Mill, Mr. Sowerby Wallis having been compelled by ill-health to retire after more than thirty years' connection with the association.

THE summer meeting of the Iron and Steel Institute was opened on Tuesday last at Barrow-in-Furness under the chairmanship of Mr. Andrew Carnegie, the president of the institute.

THE whaler *Terra Nova*, which has been acquired by the Government and fitted out as a relief ship for the *Discovery*, left Portland on Wednesday of last week for Hobart, Tasmania, where, as has been mentioned in a former issue, she will be joined by the *Morning*. In order that she may reach her destination as rapidly as possible, she will be towed as far as Aden by one of His Majesty's ships; from Aden she will have to depend on her own resources of steam and sail. It is, however, anticipated that the two ships, the *Morning* and *Terra Nova*, will be able to leave Hobart in order to make their way south through the Antarctic ice in search of the *Discovery* by December 1.

ACCORDING to a Reuter telegram from Brest, the steamer *Français*, with the members of the Charcot expedition, which is proceeding towards the South Pole in search of Dr. Otto Nordenskjöld, left that place on Sunday afternoon last.

THE German South Polar Expedition has arrived safely at St. Helena.

A TELEGRAM from Naples on August 26 through Reuter's Agency stated that on that day a crater of Vesuvius which had been quiet since 1895 opened, and a great flood of lava poured forth.

A TELEGRAM from Wellington, New Zealand, states that an eruption of the Waimangu geyser took place on Saturday last, causing the loss of four lives.

ACCORDING to a telegram from New York a gold seeker has just arrived at Vancouver after an absence of four years, during which time he has been exploring the Mackenzie River district in the direction of the Arctic circle, and has brought with him what purports to be a piece of silk which formed part of the balloon of the ill-fated André.

WE regret to have to announce the death at Marstrand, Sweden, at the age of sixty years, of Prof. W. H. Corfield, sanitary adviser to H.M. Office of Works, and author of numerous works relating to hygiene.

A MONUMENT to the French chemist Laurent was recently unveiled by the French Minister of Agriculture at Langres (Haute-Marne).

THE *British Medical Journal* states that Dr. Stiles, who, it is said, has discovered a parasite which he believes to be effective in destroying mosquitoes, is about to put the efficacy of the destroyer to the test at Cape May or some other place in New Jersey where mosquitoes are prevalent. The investigation is undertaken at the request of Prof. Smith, State Entomologist of New Jersey, who has helped Dr. Stiles in his search for a parasite suitable for the purpose.

A REUTER telegram from Lagos states that the Legislative Council has passed a law making it a penal offence to introduce wireless telegraphy into the colony without the sanction of the Governor in Council.

ACCORDING to a telegram received through Laffan's Agency, Mr. Marconi, on his arrival at New York by the *Lucania*, stated that the vessel was never out of communication with either Great Britain or America on any day during the voyage. On Tuesday night of last week a message was received from Poldhu, when the *Lucania* was in mid-ocean, giving the result of that day's yacht race. The Nantucket station gave the result of Thursday's race. Mr.

[1] "Report of Streams Examination." Made under the Direction of Arthur R. Reynolds, M.D., Commissioner of Health, City of Chicago. December, 1902.

Marconi added that he was going to consult Mr. Edison on four inventions he has recently made for improving his system, one being a method of reducing by one-half the high power now necessary for transmitting messages.

THE inaugural address of the new session of the School of Pharmacy, in connection with the Pharmaceutical Society, will be delivered on October 1 by Dr. J. W. Swan, F.R.S., and the bust of the late Mr. W. Martindale will be unveiled on the same date, and the Hanbury gold medal presented to M. Eugène Collin for his researches in the natural history of drugs.

THE Swiss Alpenklub will, according to the *Athenaeum,* hold its *Klubfest* at Pontresina on September 12, 13, and 14. The Morteratsch glacier has been chosen for the excursions.

A GENERAL meeting of mining engineers is announced to take place in Vienna from September 21 to 26, at which many papers of interest will be read and discussed. Simultaneously, there will be held a meeting of the Boring and Mining and Metallurgical Engineers for Styria and district.

THE British Mycological Society will hold its seventh annual week's fungus foray at Marlborough from October 5 to 10. On the evening of Wednesday, October 7, Miss A. Lorrain Smith will read a note on *Gloeosporium Tiliae,* a disease of lime leaves, and Mr. Carleton Rea, the hon. sec. of the Society, will read a note on the occurrence of a Phalloid new to Britain. On the following evening the Rev. W. L. W. Eyre will deliver his presidential address, entitled "Mycology as an Instrument of Recreation."

THE fine chemical laboratory of the University of Modena, Italy, was recently completely destroyed by fire, and the library of scientific works in connection with it, comprising 60,000 volumes, also perished.

AN exhibition of electric automobile chairs is to take place in connection with the World's Fair at St. Louis next year. The chairs, according to the *Electrical World,* of New York, will have a uniform speed of three miles per hour, the operator having no control over the speed, and the same rate is maintained uphill, downhill, or on the level. The chair takes the form of a low phaeton without a cover. There are two large rear wheels and two small ones under the foot-rest. All are pneumatic-tyred; the seat is upholstered in cane. Behind the seat is a box which contains the batteries to operate the machine. If two persons desire to occupy the chair, and the service of a guide is wanted, the latter can sit on an adjustable seat at the rear. On the inside of the chair, attached to the arm, is a lever which puts the chair in motion or stops it at the will of the rider. A long lever attached to the front truck has its handle directly in the centre of the chair within easy reach of the driver. A gentle pressure guides the machine in the desired direction. A feature of the machine is a "sensitive rail" which surrounds the chair on all sides save at the rear. This prevents any accidents, for when the rail comes in contact with any object, even though it weighs but 1 lb., it presses against a device that locks the wheels and brings the chair to a dead stop.

WE learn from the *Scientific American* that Prof. Langley's 12-foot aërodrome was tested on August 8. The model flew a distance of 600 yards and then sank in 22 feet of water. When it was finally recovered, all that was left was a tangled wreck of twisted wires. The time consumed in flight was not more than 45 seconds. The course described was a semicircle. According to accounts which have been published, the motor of the machine and the rudders failed to work properly. The altitude of the machine at the time of the fall was not greater than 50 feet. The airship is stated to have been driven by an 8 horse-power hydrocarbon engine connected up with two two-bladed propellers located one on each side of the machine at about its middle point. One four-bladed wind vane rudder was mounted behind the engine; then came the rudder proper. On each side the airship was supported by a pair of white silk wings, 4½ feet long by 2 feet in width. The propellers were located on the side between the wings and turned toward each other. The wings, rudders, engine and other running gear were fastened to a central cylindrical tube of aluminium 18 inches in length and about 4 inches in diameter, and tapering at both ends. The test of the small model will, it is said, be followed at an early date by a trial by the 60-foot aërodrome which is owned by the Government, the cost of which was 70,000 dollars.

WITH reference to the letter which appeared in our issue of August 6 from Prof. C. V. Boys concerning "The American Tariff and the St. Louis Exhibition," Mr. George C. Comstock, director of the Washburn Observatory, Madison, Wis., U.S.A., writes to say that the following letter received by him from the office of the secretary of the Treasury Department, Washington, illustrates the manner in which, in one class of cases, the American customs authorities have apparently overruled the plain intent of the statute cited by our correspondent. "The Department is in receipt of your letter of the 12th inst. in which you inquire whether photographic lenses imported for colleges and universities can be admitted to entry free of duty as scientific apparatus. Paragraph 638 of the Act of July 24, 1897, provides for the free entry of scientific apparatus, &c., when imported for educational institutions and the Department, and the Board of U.S. General Appraisers, have held that photographic apparatus, dry plates, lantern slides and lenses are not scientific apparatus within the meaning of said paragraph of law, and such articles, therefore, when imported for the use of educational institutions would be liable to duty." Whether the above represents a policy of the Treasury Department in cases other than those named it is impossible to say, but it may serve to illustrate the danger of relying upon a lay interpretation of the Tariff Act, and the need for determining in each particular case the policy pursued in the custom house. The possibilities of interpretation presented by a Board of Appraisers that holds photographic lenses not to be scientific apparatus seem unlimited.

A FEATURE of the mosquito as the agent of malaria that has in the past been difficult to understand is that occasionally a locality is found where the physical conditions appear to be such as to favour the development of malaria, susceptible species of anopheles abound, and yet malaria is absent. Not only do such areas exist in some cases in immediate proximity to active foci of the disease, but the introduction of persons whose blood contains the malarial parasite is unattended by the development of malaria in others. The mosquitoes of such immune areas appear, in fact, to be insusceptible, but the cause has been hitherto unknown. The researches of Dr. Schoo, however, to which Lieut.-Colonel Giles directs attention in the April number of the *Indian Medical Gazette*, offer an explanation. Dr. Schoo observed that, so long as they were fed on acid fruits, it was extremely difficult to infect mosquitoes with the malarial parasite, while they were easily infected when the acid food was withheld. This observation accords with a

point noticed by Prof. Celli, who has stated that one of the Italian immune areas is remarkable for an enormous development of the cultivation of the tomato, a fruit rich in vegetable acid, and an attractive food for mosquitoes. The necessity of further investigation of this matter is clear, for if confirmation is obtained, such knowledge may be of much importance in its practical application for the prevention of malaria.

THE micro-balance exhibited by Prof. Nernst at the Berlin congress is described in a recent number of the *Berichte*, and a number of results are given which illustrate its remarkable sensitiveness and accuracy. The control is a stretched quartz fibre, and the pointer moves over forty small divisions, each of which represents 0·03763mg., and can be read to a twentieth part. The scale pan is a tiny platinum tray weighing only 20mg., and in this the analyses are carried out. Three analyses of calcite, in each of which less than 3mg. was taken, gave $CO_2=43{\cdot}80$, 43·66, and 43·81 per cent., theory 43·96, and the ignition of a single milligram of yttrium sulphate gave the atomic weight as 88·0 and 87·8, theory 89. The balance is specially suited for the analysis of traces of rare earths, and an attempt was made to carry out a fractional distillation of the chlorides of yttrium, erbium, and ytterbium in a platinum tube, but analysis showed that the sublimate had the same composition as the residue. Even where considerable quantities of material are available, as in the analysis of the salts of organic acids, the use of the micro-balance would lead to a great reduction of time and trouble, as it would only be necessary to read the deflection before and after igniting a trace of the salt. The balance, in a portable form, is manufactured by Messrs. Spindler and Hoyer, at Göttingen, and is sold at 70 marks.

OWING to the growing use of fused quartz in physical and chemical experiments, considerable interest attaches to determinations of the coefficient of thermal expansion of this substance. Several papers on this subject are before us. Messrs. L. Holborn and F. Hemming, in the *Annalen der Physik* (4) x., find an average value for the coefficient of expansion between 0° and 1000° of $5{\cdot}4\times10^{-7}$, but consider that the relation between length and temperature cannot be adequately expressed even by a quadratic formula within these limits. Mr. Karl Sheel, using optical interference-methods, and working with the temperatures 15°, 56° and 100°, obtains between these temperatures the formula

$$l_t=l_0(1+0{\cdot}322.10^{-6}t+0{\cdot}00147.10^{-6}t^2),$$

while for expansion of crystalline quartz parallel to its principal axis he finds

$$l_t=l_0(1+7{\cdot}144.10^{-6}t+0{\cdot}00815.10^{-6}t^2).$$

In the *Bulletin des Séances* of the French Physical Society, M. A. Dufour, in treating generally of the uses and properties of fused quartz, refers to the work of Holborn and Hemming, Le Chatelier and Callendar, and points out the difficulty of forming junctions between the quartz and metal or glass, consequent on the low coefficient of dilatation of the former. Mr. Sheel finds confirmation of his results in a recent paper by Chappuis, who also used optical methods in his determinations.

IN the July issue of the *Quarterly Journal of Microscopical Science*, Dr. R. Evans, of the Georgetown Museum, describes a new species of Peripatus from British Guinea, illustrated with a coloured plate. The species is said to be markedly different from the other members of the group from the same district. The author remarks that measurements and descriptions of colours and markings from preserved specimens are of little value in specific discrimination, and are, indeed, liable rather to cause confusion. In the same journal Dr. G. C. Bourne describes and figures a new ascidian (*Oligotrema psammites*), belonging to the family Molgulidæ, dredged off New Britain. The peculiarities of the new form are twofold. Firstly, it differs in general appearance and structure from the other members of the group, presenting a superficial resemblance to a sea-anemone. Secondly, as indicated by the occurrence of small crustaceans in its interior, it has a different class of nutriment. It is, in fact, "an ascidian which captures and feeds on active crustacea of large size relatively to itself, and is no longer dependent on minute organisms and organic débris swept into its branchial chamber by ciliary currents."

"THE BUILDING OF THE GRAMPIANS" is perhaps about as difficult a geological subject as could be found, but thanks to the labours of James Nicol, Sir A. Geikie, Prof. Lapworth, and others, much has been done, while the memoirs and maps of the Geological Survey form a good basis for further work and criticism. Mr. Peter Macnair has dealt boldly and confidently with the subject (Royal Phil. Soc., Glasgow), his object being to bring out the striking similarity which exists between the structure of the Grampians on the one hand and the Alps on the other, the Grampians being regarded as simply the basal wreck of such a mountain chain as the Alps. He is more confident than others are of the succession of the rock-groups met with in the Highland schists, but when he comes to criticise the belt of supposed Arenig rocks along the southern Highland frontier, he finds that there no reliance can be placed upon the apparent order of succession. He may be right in maintaining that there is nothing to justify the separation of this supposed Arenig belt from the crystalline schists. He may be right also in his criticisms on the structure of the Cowal region, with especial reference to the development of the foliation planes. This much may be said, that while hammering earnestly at the rocks, he has also made a careful study of the work of others, and he attacks the Highland problems with evident enthusiasm for his subject. We must leave to those concerned the defence of the positions which he assails, although in some instances Mr. Macnair has advanced, perhaps, where others fear to tread.

PROF. JOLY has done well to undertake the petrological examination of paving sets. In the first part of his work (*Sci. Proc.* Royal Dublin Soc., vol. x., No. 5) he deals more particularly with certain granites, diorites, and dolerites. In his general remarks he observes that the resistance to wear varies directly, as do the amounts of quartz and felspar, the holocrystalline igneous rocks being as a rule the toughest. Markedly porphyritic, vesicular, and glassy rocks are to be avoided. He deals with the durability and with the character of the surface produced by various paving sets, remarking that mechanical forces are applied on the roads in the most destructive form, the attrition and crushing being combined with the solvent action of impure waters. Fine-grained rocks, such as the diorite of Penmaenmawr, may become too slippery for use on inclined surfaces; a certain coarseness of grain is usually desirable.

WE have received the annual report (vol. xii.) of the Geological Survey of Canada for 1899 (dated 1902), by Dr. Robert Bell, acting director. This is a bulky work made up of various independent reports lettered A to S, and

separately paged. Reference has already been made in NATURE to the more important matters dealt with. A general index is appended, which gives the paging under the reference letter of each report. The volume is accompanied by maps of the Klondike Gold-fields, and of parts of British Columbia, Ontario, Quebec, and New Brunswick.

AN orographic sketch of Korea, with photographic illustrations and an excellent map, has been published by Dr. B. Kotô (*Journ.* Coll. Science, Tokyo, Japan, vol. xix.). He discusses the various faults and folds which have influenced the scenery of the peninsula—a region which, as he remarks, in reference to Suess and Richthofen, "seems to have interested our two masters almost as deeply as it has the political leaders of our times." The Cretaceous Cephalopoda from the Hokkaidō are under description by Mr. H. Yabe. Part i., dealing with Lytoceras, Gaudryoceras, and Tetragonites, is accompanied by seven plates (*Journ.* Coll. Science, Tokyo, vol. xviii.).

MR. F. CHAPMAN AND MR. H. J. GRAYSON contribute an article on "Red Rain" to the *Victorian Naturalist* (vol. xx., June). After discussing the subject generally, they direct attention to falls of red mud in Victoria in February and March of this year. In one case the amount was estimated to equal fifty tons per square mile. The material comprised much limonite, and many mineral fragments and diatoms. The material was probably derived from areas from 30 to 300 miles north and west of Melbourne, being swept up from the borders of swamps and salt lakes during an abnormal season of drought.

IN a monograph supplement to the *Psychological Review* (vol. v. No. 4), Mr. J. B. Miner reports a study of "Motor, Visual, and Applied Rhythms." It has been frequently asserted that rhythmical grouping of sensory impressions is peculiar to auditory and tactual perception, but Mr. Miner shows that a series of similar visual impressions regularly repeated may fall into spontaneous rhythm, and that, in fact, visual impressions obey laws of rhythm very similar to those established for auditory perception. Since rhythm is, as Mr. Miner rightly maintains, a feature of the motor expression evoked by sensory impressions to which the attention is directed, there is no reason to suppose that it should be limited to perception by any one or two of the senses, and it may be hoped that the erroneous statement to that effect will now disappear from the text-books. Mr. Miner shows that subjects seem to fall naturally into two classes, according as their power of concentrated mental work is favoured or hindered by a concurrent rhythmical stimulus to the senses; that those who naturally work most rapidly and concentratedly are most apt to be hindered; while those who work slowly, with less tense concentration, in many cases produce better results under the influence of such stimulus. This unexpected result suggests to the author certain pedagogical reflections.

THE *Barbados Agricultural Reporter* of August 1 contains the text of a petition to the Governor praying that the destruction of mongooses may be authorised in the island. A quarter of a century ago the sugar industry of the island suffered much from the depredations of rats, and about 1878 mongooses were introduced for the purpose of thinning their numbers. These carnivores discharged their task with conspicuous success, but at the same time they cleared off much of the indigenous fauna. The destruction of the lizards has led to a large increase in the number of moth-borer caterpillars, which perforate the sugar-canes and thus give entrance to the spores of noxious funguses. These cause a serious loss, which it is hoped may be in some degree mitigated by the destruction of the mongooses. All this shows the danger of attempting to interfere with the equilibrium of nature.

IN the annual report of the Indian Museum, Calcutta, for 1901–2, Major Alcock, the director, states that a bronze medallion portrait and inscribed brass tablet have been placed in one of the verandahs of the old museum building in memory of the late Dr. J. Anderson, the first superintendent of that institution. During the period under review the museum has acquired by purchase the valuable de Nicéville collection of Oriental butterflies, which includes a large number of type specimens.

THE *Journal* of the Straits branch of the Royal Asiatic Society contains two important communications on the language of the Sakais and Semangs of the Malay Peninsula. Mr. H. N. Ridley describes some new Malay orchids, while Mr. P. Cameron continues his account of the Hymenoptera collected by Mr. R. Shelford in Sarawak. To the *Zoologist* for August, Mr. Shelford himself contributes some highly interesting notes on the habits of Bornean species of mantises, with illustrations reproduced from photographs of these insects.

IN the journal last mentioned, the Rev. F. C. R. Jourdain records the occurrence of an example of the harp-seal (*Phoca groenlandica*) at Teignmouth on March 10, on what appears to be sufficient evidence. The carcase was seen on a fishmonger's barrow, but it is not known how it was disposed of. The species is a very rare straggler to the British shores.

THE recent additions to the Municipal Museum of Hull are made known to the public by means of illustrated notes and short articles in the *Eastern Morning News*. These are subsequently reprinted as penny pamphlets under the title of "Hull Museum Publications." By this means the local public are kept in touch with the growth of the museum, and it certainly must benefit the museum, as well as interest and instruct the public. This system might with advantage be copied by other local museums. The fifteenth publication, entitled "Quarterly Record of Additions, No. 5," has just been published.

THE report of the Trivandrum Museum for the year 1901–2 contains a reprint, with two coloured plates, of a paper from the *Journal* of the Bombay Natural History Society, on a couple of cetaceans recently stranded on the beach near that city. One of these has been identified by Mr. Lydekker with the widely spread *Pseudorca crassidens*, while the second is made the type of a new species, *Tursiops fergusoni*, named in honour of the director of the museum.

IN a third museum report just to hand, that of Manchester for the year 1902–3, special attention is directed to the acquisition of the interesting series of mammalian remains from a cave of Pliocene age at Doveholes, Derbyshire. These remains, which it will be remembered were exhibited at the soirée of the Royal Society in the spring, have recently been described by Prof. W. B. Dawkins in the Geological Society's *Quarterly Journal*.

THE *Zoological Society Bulletin*, published by the New York Zoological Society, is a brightly written, well illustrated periodical, and the July issue, which has just reached us, contains quite a number of interesting contributions, notably one on "Training Orangs and Chimpanzees," in which particulars are given of the acquired accomplishments of past and present members of the New York Zoological Park collection. The training of the orang-utan

and the chimpanzee, remarks the writer of the article, closely approaches the management of an untaught child. These creatures do not seem as much like lower animals as do the majority of the so-called "dumb brutes." Coaxing and perseverance have been responsible for the exhibitions which from time to time have taken place.

IN the *Journal of Botany* (August) Dr. G. Murray publishes a short note on Atlantic diatomaceæ. Some few species were obtained in all the captures, even far out at sea, but an increase in the quantity of the take was generally found to indicate the proximity to land. Miss A. L. Smith describes some interesting microfungi, and Dr. W. G. Smith refers *Nidularia dentata* to the genus Sphærobolus. Biographical notices of the botanists L. A. Deschamps and F. Noronha are contributed by the editor.

THE number of the *Minnesota Botanical Studies* published in July is mainly given up to articles dealing with flowerless plants. Mr. Bruce Fink presents a list of lichens collected on the northern boundary, and Mr. H. L. Lyon catalogues the pteridophyta which grow in the State. Contributions to the algal flora are furnished by Dr. H. F. Schrader, who describes a new species of Alaria, and by Mr. Skinner, who discusses the tide pool vegetation at Port Renfrew. The distribution differs considerably from that found on our coasts, seeing that a Corallina extends throughout the whole tidal range, while a Codium is associated with it in the higher pools.

THE *Agricultural News* of Barbados for August 15 reprints from the *India Rubber World* an interesting article on the subject of the preparation of Para rubber in Ceylon, in which full and detailed instructions are given for collecting and coagulating the rubber. The text is elucidated by illustrations.

A PAMPHLET on "The Boiling Lake of Dominica," by Mr. F. Sterns-Fadelle, has lately been published (office of the *Dominican*, price 1s.). It gives an historical and general account of this well-known geyser, which will be useful to travellers in the West Indies.

THE annual report of the Yorkshire Philosophical Society for 1902 contains part ix. of a catalogue of British plants in the herbarium of the Society, and a popular article on "Sea Sand," by Mr. Hugh Richardson, in which the characters and origin of the grains of sand are discussed.

IN the *Proceedings* of the Nova Scotian Institute of Science (vol. x. part iv.) Dr. H. M. Ami shows that the slates yielding *Dictyonema Websteri*, and which were regarded by Sir J. W. Dawson as Upper Silurian, belong to the Upper Cambrian.

A PAMPHLET entitled "A Historical Sketch of the Experimental Determination of the Resistance of the Air to the Motion of Projectiles," by the Rev. Francis Bashforth, has recently been published by the Cambridge University Press.

MESSRS. CHARLES GRIFFIN AND CO., LTD., have published a second edition of "Animal and Vegetable Fixed Oils, Fats, Butters, and Waxes," by the late Dr. C. R. Alder Wright. The new edition has been revised and partly rewritten by Mr. C. Ainsworth Mitchell, who, though he has retained the general arrangement of the original work, has, especially in the chapters dealing with the manufacturing processes, modified the text and brought it up to date.

A NINTH edition of Bloxam's "Chemistry" has been published by Messrs. J. and A. Churchill. The book has been rewritten and revised by Prof. J. M. Thomson, F.R.S., and Mr. A. G. Bloxam. A change has been made in the present edition in the order of treatment of the non-metallic elements, and carbon is now considered after hydrogen, oxygen, and nitrogen. The plan of making no division, in the portion of the book dealing with organic chemistry, between the treatment of the fatty and aromatic compounds has again been followed.

A NEW edition—the twelfth—of "The Art of Retouching," by Mr. J. Hubert, has just been issued by Messrs. Hazell, Watson and Viney, Ltd.

MESSRS. GEORGE ROUTLEDGE AND SONS, LTD., announce for early appearance a series of "Nature-Study Readers" for general school use, under the editorship of Mr. John C. Medd. The aim of the books is to present varied aspects under which nature may be most conveniently studied alike in urban and in rural districts. Each subject is to be treated by a different writer, who has devoted special attention to it, and knows from personal experience what is within the capacity of, and calculated to interest, children of from nine to thirteen years of age.

MR. R. LYDEKKER, F.R.S., will shortly issue, through Messrs. Hutchinson and Co., a volume of zoological essays entitled "Mostly Mammals."

THE additions to the Zoological Society's Gardens during the past week include a Himalayan Bear (*Ursus tibetanus*) from East Asia, presented by Lady Constance Mackenzie; a Common Otter (*Lutra vulgaris*) from Scotland, presented by Mr. J. B. A'Deane; a Rock Thrush (*Monticola saxatilis*), European, presented by Mr. W. H. St. Quintin; a Delalande's Gecko (*Tarentola delalandii*) from West Africa, presented by Mr. P. C. Challice; a Black Lemur (*Lemur macaco*), a Black-headed Lemur (*Lemur brunneus*) from Madagascar, a Black Sternothere (*Sternothoerus niger*) from West Africa, seven Dalmatian Lizards (*Lacerta mosorensis*) from Dalmatia, twelve Sharp-headed Lizards (*Lacerta dugesi*) from Madeira, an Indian Eryx (*Eryx johni*) from India, a Black-tailed Snake (*Ungalia melanura*), a Black-spotted Snake (*Ungalia pardalis*), a Cuban Snake (*Liophis andreae*) from Cuba, deposited.

OUR ASTRONOMICAL COLUMN.

SPECTRUM OF COMET 1903 *c*.—Observations of the visual and photographic spectra of this comet were obtained at the Meudon Observatory, and were communicated to the Académie by M. Deslandres, whose communication appears in the *Comptes rendus* for August 17.

A spectrograph containing a 60° heavy flint glass prism was especially constructed for these observations, and was used in conjunction with the large double telescope. The faint light of the comet was concentrated from a wide slit by having the collimator of the spectroscope 55cm. long, whilst the focal length of the observing telescope or camera was only 12cm.

The spectrum generally is of the characteristic hydrocarbon type, but near to the nucleus of the comet it contains several extra faint lines; the brightest bands are those at λλ 3881, 4681, 4314 and 4052, their relative intensities being 10, 8, 7 and 7 respectively. The blue bands at λ 473 are separated into their several groups, thus affirming the presence of the hydrocarbon spectrum; this separation was also noticed in the spectrum of Rordame's comet (1893 *b*) obtained by Campbell at Lick in 1893, with which Deslandres's spectrum is practically identical.

M. Deslandres proceeds to note the similarities and differences of the cometary spectrum and the cyanogen spectrum as obtained in laboratory experiments, and suggests, as an explanation of the differences, that, although

the temperature of the comet is of the same order as the laboratory temperature, and high enough to produce incandescence, yet it is not sufficiently high to dissociate the compounds and thus produce the hydrogen and nitrogen spectra as obtained in the laboratory.

In the concluding portion of his communication M. Deslandres describes some experiments, similar to those by which he has obtained such excellent results in determining planetary rotations, whereby the differential movements of a comet's various parts may be determined from the inclination of its spectral lines to the lines of two comparison spectra photographed alongside the spectrum of the comet.

THE SPECTRUM OF NOVA GEMINORUM.—A telegram from Prof. Pickering, published in No. 3895 of the *Astronomische Nachrichten*, announces that the spectrum of Nova Geminorum was observed by Dr. H. D. Curtis at the Lick Observatory on August 17, and was seen to be of the nebular type which is characteristic of the spectra of declining temporary stars.

UNITED STATES NAVAL OBSERVATORY.—Vol. iii. (second series) of the United States Naval Observatory *Publications* has been received, and contains some 550 pages of useful observational details and results.

Part i. is devoted to observations of Eros made with the twenty-six inch equatorial and the Clark micrometer "No. ii," during 1900–1901, by Messrs. T. J. J. See and G. K. Lawton. After a description of the instrument, which has recently been supplied with an entirely new mounting by Messrs. Warner and Swasey, Dr. See proceeds to give details of the instrumental constants and their determination, and then gives the results of the individual observations for each night.

Assistant-astronomer King has used the nine-inch transit circle for observations of Eros and the reference stars suggested by the Conférence Astrographique Internationale of July, 1900, and, in part ii. of the report, gives the individual results of his observations.

Part iii. is a detailed description of the observations of 495 zodiacal stars made with the nine-inch transit circle by Prof. Eichelberger in accordance with Sir David Gill's catalogue of 2798 zodiacal stars which it was intended to observe, but in November, 1900, it was found that the pivots of the instrument were badly worn, and therefore the work is suspended until the necessary repairs have been effected.

In part iv. Mr. Updegraff gives a description, a photograph, and a diagrammatic sketch of the six-inch steel transit circle, and in a lengthy introduction gives minute details of the determination and reduction of the instrumental constants, followed by the separate observations of 130 comparison stars for the planets, including a large number of observations of reference stars for Eros. This section is concluded by two catalogues of stars and their positions, the first containing 139 zodiacal stars, and the second the Eros reference stars.

Part v. concludes this publication, and contains the individual observations made with the prime-vertical transit instrument from 1882 to 1884 by Lieutenants Ingersoll and Bowman and Ensign Taylor, all of the U.S.A. Navy.

THE WHITE SPOTS ON SATURN.—In the *Astronomische Nachrichten*, No. 3894, Senor J. Comas Solá, of Barcelona, publishes his observations of Barnard's white spot and the smaller white spots which have been recently observed on Saturn.

Using a six-inch equatorial, he easily observed Barnard's spot and several smaller ones. On June 26 the former crossed the central meridian at 13h. 19m. (G.M.T.), and was seen to be double, whilst in contact with it, and on the left side (reversed image) a small spot was observed. On July 1d. 13h. 55m.± a feebler spot, which also appeared double, was observed to cross the central meridian in the same zone as the larger one. By July 20, when it crossed the meridian at 11h. 32m., the large spot was seen to be much feebler and apparently elongated, and on July 28 (time of transit =11h. 15m.) it was yet feebler, and a rather difficult object for the six-inch.

Several other spots were observed, and their times of transit recorded, by Senor Solá, and, as a first approximation, he finds the rotation period of the planet to be 10h. 38·4m.

THE TEACHING OF PSYCHOLOGY IN UNIVERSITIES OF THE UNITED STATES.[1]

A TRUE estimate of the position of psychology in the curriculum of American universities can hardly be formed without a brief survey of the general system of education which prevails there. In earlier years, one need hardly say, the training was far narrower and less liberal than it is now. The candidate for the B.A. degree had his educational career as carefully prescribed for him as if he were still at school, and he had little or no opportunity to deviate from it. At the present day, the various universities of the United States offer every gradation between relatively elective and relatively non-elective systems of study. In most universities the undergraduate will find his course of work strictly defined during at least his first or freshman year. Little by little, however, the elective is gradually replacing the non-elective system. Quite recently, Harvard, for example, determined to allow a very considerable measure of optional subjects, from which the student has to make his choice from the moment he is admitted to the university.

The danger of such a system is increased by the absence of any special *ad hoc* examination for the B.A. degree. As a rule, this degree is conferred solely on the results of the terminal examinations held biannually, so that, unless proper precautions were taken, it would be possible for a student, after having passed his three or four years at college, to graduate on the basis of a superficial and very elementary knowledge of many subjects, and a detailed knowledge of none. This drawback American universities have largely succeeded in overcoming by a series of appropriate regulations concerning the relative number of elementary and advanced lectures at which attendance is required, and concerning the conditions of admission to advanced lectures. At Yale, for example, undergraduate studies are ranged under three heads:—(1) Languages and literature; (2) mathematics, physical and natural science; (3) philosophy, history and the social sciences. Every student is required to have attended advanced courses in at least one of these departments, and to show at least an elementary knowledge of subjects in the two other departments.

It will now be evident why subjects which in English universities are studied by the few are in America taken up by the many. Take Yale, for instance, with her department of philosophy, history and the social sciences. Every undergraduate has to show at least an elementary knowledge of some subject in this department, *i.e.* of philosophy, psychology, ethics, pedagogics, logic, ancient, mediæval and modern history, economics, politics or sociology. Large numbers of American students take a course of economics. At one university I was told that, on an average, every student takes two courses of economics during his undergraduate career. This fact may be ranged beside another, viz. that there are twenty-four professors, lecturers and instructors of political economy at Harvard.

So also it comes about that a great number of students take up psychology, either by itself or with allied subjects. 250 students, chiefly in their second or sophomore year, attend the year's course at Harvard, which is equally divided between the study of logic and the study of elementary psychology. At Yale a similar year's course on ethics and psychology was attended this year by 225 students. At Cornell the year's course on psychology, logic and ethics is attended by 200 students. Princeton goes so far as to make psychology a compulsory subject, without which the B.A. degree cannot be obtained. The popularity of psychology is also shown in that it is taught in the upper forms of some of the better schools.

Experimental work in the laboratory is only performed by students who intend to proceed further in psychology. Their number is a very small fraction—from one-tenth to one-fifteenth—of those who attend the preliminary course. At Columbia they are expected to have attended either a general course on experimental psychology or a special course, in which no less than eight lecturers take part, each being responsible for a few lectures in his own department of psychology, be it physiological, genetic, comparative,

[1] Paper read before the Psychological Society at Cambridge, July 25, by Dr. C. S. Myers

pathological, experimental, historical or philosophical. By this means the student comes into relation with most of the teaching staff of the department in which he is interested. Later, more advanced courses are open to him in analytical psychology, educational psychology, the philosophy of mind, genetic psychology, and so on. At Pennsylvania the student spends two years at psychology, devoting the first half-year to analytical psychology, the second half-year to physiological psychology, the third half-year to synthetic psychology, and the fourth half-year to experimental psychology. Each of these half-courses comprises lectures and practical work, of an hour and two hours' duration respectively per week.

It would be wearisome to follow out at further length the various lines of undergraduate study pursued in psychology at the several universities visited by me. You will, however, hear with interest that men are offered at Yale a course of recent German psychology in their fourth or senior year, the class reading extracts from the works of Brentano, Wundt, Stumpf, Külpe, and others, while the different attitudes of these psychologists are explained by the instructor. At Harvard a half-year's course on the mental life of animals is offered, accompanied by lectures and demonstrations. At Cornell a course on the history of the psychophysical work of Weber, Fechner, and others is given.

This brings me to the more detailed consideration of experimental work in the United States. The laboratory in Harvard University has eleven rooms, in Yale it has seven, in Columbia nineteen, in Princeton five, in Cornell ten, and in Clark ten; these numbers generally include all public and private rooms of the department. Cornell has undoubtedly the best equipped laboratory, so far as human psychology is concerned. Two rooms here are devoted to vision, one to acoustics, one to touch, one to taste and smell, one to chronometric apparatus, one is a special research room, and there is a lecture room and a workshop. Both Clark and Harvard have rooms devoted to experiments on animals. Partly for this reason the Harvard laboratory suffers from lack of space; a new one will be built in the near future. Most laboratories have a departmental library, or at least a seminary, in which the students can read or meet for discussion. Practically all the laboratories have a workshop, and employ a trained mechanician, who is able to turn out even complicated and expensive apparatus.

The methods of conducting the experimental work naturally differ in the various laboratories. At Harvard and Columbia lectures are given in connection with the experiments, but at many other universities lectures and practical work are wholly independent. At Yale, Harvard, Princeton and Cornell, students work together in pairs, each member of a pair serving alternately as subject and as experimenter. At Pennsylvania students work together in groups of three, the third recording the results obtained by the two others. Stress is laid in most laboratories on the careful keeping of note-books. Many of those in Cornell are models of neatness and diligence; there they are inspected, marked and initialled monthly by the assistants. At Princeton, the times are so arranged that only a single pair of students is working in the laboratory at any one hour; they thus secure the undivided attention of the instructor. At Harvard and Pennsylvania the entire class is engaged upon the same kind of experiment simultaneously; the Pennsylvania students are each provided with lockers containing the simpler apparatus they are likely to use. At Yale and Cornell, on the other hand, students are simultaneously engaged at different experiments; one pair, for instance, is working on colour-vision, another on reaction-times, another on tactile sensibility, and so on. Save at Cornell, the students are each taken through all the laboratory experiments commonly described in the text-books. But at Cornell it is held sufficient for the student to devote himself to the investigation of a single sense, working over perhaps fifteen experiments therein, and then to proceed to one or two experiments on the expression of the affective states, thence to some of the experiments in attention and reaction, and so on, whereby he acquires a practical experience, less extensive, but probably more thorough than that usually obtained. He works four and a half months in qualitative, and four and a half months in quantitative, experimental work during his third year. His fourth year is devoted to some special problem, and he writes an essay on his results.

If, having taken his B.A. degree, the graduate determines to pursue his studies further, he enters the post-graduate school in order to proceed to his doctor's degree. After two or three years' post-graduate study, he may present himself for examination in a chosen division, *e.g.* philosophy, and within the division he must name some special field of study, *e.g.* psychology, in which he is liable to minute examination and must offer a thesis, showing evidence of independent research. In psychology, as in all subjects, advanced lectures are delivered to suit his requirements. At Cornell during his first year of post-graduate study, the student does not start any special research work; he reads and roams about the laboratory, observing what his senior fellow-students are doing. A very large proportion of post-graduate students at Yale and Harvard consists of graduates from smaller universities. At Harvard I found no less than sixteen students engaged in the psychological laboratory at original work for their Ph.D. degree. They attended there at fixed times in the mornings only, working in pairs alternately as subject and as experimenter. Weekly seminary meetings are held at Harvard, Yale, and Clark for post-graduate students. At Harvard three papers are read at each evening meeting by the students, and are discussed by themselves and their professors. At the Yale seminaries, a post-graduate student presents a paper weekly, dealing with the system of some well-known mental philosopher. At Clark, the students meet each week at the professor's house to narrate and criticise their progress in research work.

A very large proportion of theses, written for the Ph.D. degree in psychology, sees light in the pages of American psychological journals. In many instances this must turn out to be the one piece of original work such men have performed in their life. They drift away in various directions. The best are chosen by their professors to be laboratory instructors for a year or more. Thence they go to become assistant professors in other universities, or depart earlier to teach educational psychology in the State normal schools or in other teachers' training colleges. Mainly through lack of leisure, the majority put forth little in the way of further and mature research. There is a strong tendency, too, for psychologists in America to turn to editorial or literary work, to become busy with the organisation of science, or to deal with purely philosophical, ethical, or religious problems.

But apart from such drawbacks, which are the result rather of American ways of life and character than of deficient interest or training, I have said enough, I hope, to show what a living subject of education psychology is in the United States. It is becoming recognised there that a man of culture should know something, not only of the works, but also of the working, of the human mind. Psychology in the United States is not a subject of the philosophical few, as it is in our country. If it pays the penalty for, it also reaps the advantage of, its position. Numbers of undergraduate students acquire a notion, however dim and imperfect, of the range and importance of psychology, so that, if ever they become successful business men, as many of them do, they are prepared to lend it financial assistance in later life. Future medical students take up psychology during their academic career, and turn their knowledge of it to account when they come to deal with the problems of insanity. Zoologists pass from their museums to study it, and return to work out the psychology of animal life. Teachers obtain a useful smattering of it, sufficient to interest and improve them in their arduous career. At Pennsylvania, for example, they have the opportunity of attending a "pedagogical clinic," at which children with various mental disorders are brought before their notice, so that they may recognise them hereafter.

From these facts it will be seen that America provides us with a lesson in the organised teaching of a subject the success of which we have so much at heart, and with an example which we should do well to follow.

AMERICAN ETHNOLOGY.

It is with melancholy interest that we receive the nineteenth annual report of the Bureau of American Ethnology, as this was the last report that was edited by the late director; Major Powell's name for so many years has been associated with the publications of the bureau which he initiated that the two have come to be irresistibly associated in our minds. We can only say that his last report fully maintains that high standard to which he has accustomed us.

Sociologists as well as ethnologists will be interested in Mr. James Mooney's historical study of the Cherokee, forming part i. of the nineteenth report. The title "Myths of the Cherokee" is misleading, as the memoir includes oral and documentary history, legendary history, legends and myths, with a valuable appendix of notes and parallels to the myths. The true history of Sequoya, the inventor of the Cherokee alphabet, is given, and the remarkable effect of this innovation on the Cherokee nation is admirably sketched, but the promise of progress was ruthlessly destroyed by the action of the Georgia Legislature. In the temperate language of a scientific historian, Mr. Mooney narrates the invariable fate of a native population when the white man wants his country, and now the five civilised tribes are meditating wholesale removal from the Indian territory where they are still being harassed. There seems a determined purpose on the part of many full-bloods to emigrate either to Mexico or South America, and there purchase new homes for themselves and families.

The second part of the report contains one or two studies of the Hopi, or Moqui, Indians of Arizona. These pueblo Indians are among the few surviving tribes of American aborigines which still retain an ancient ritual that is apparently unmodified by the Christian religion. The importance of a careful investigation of these people is fully realised by American anthropologists, and the bureau has in Dr. J. Walter Fewkes a trained observer of the first rank. It is impossible to interpret the Hopi ritual without a clear idea of the present relationship between the existing clans and of their connection with the religious societies. The growth of the ritual has increased with the successive addition of new clans to the pueblo, and its evolution cannot be comprehended without an understanding of the social development and clan organisation of the pueblo. Appreciating this, Dr. Fewkes deals with Tusayan migration traditions, and unravels the history of the accretion of the clans into a community. The localisation of these clans in various pueblos is described by Cosmos Mindeleff, and mapped in several plans; the localisation of clans was rigidly enforced in ancient times, but it is now breaking down. May we suggest to American workers in the field that valuable sociological results would be obtained if they adopted genealogical methods devised by Dr. Rivers (*Journ. Anthrop. Inst.*, xxx., 1900, p. 74). Dr. Fewkes also gives some details of the famous Snake dance; this dance was primarily a part of the ritual of the Snake clan, and ancestor worship is very prominent in it, indeed, Dr. Fewkes suggests it is "totemistic ancestor worship." There still remain to be investigated various episodes and the sacred songs. The Flute ceremony, which lasts for nine days, is one of the most complicated in the Hopi ritual. Three elements appear to be prominent in the Flute observance—sun, rain, and corn worship, symbols of which are the most prominent on the altars and their accessories. The same is true of the Snake dance; but in both rites the cultus heroes and clan mothers are special deities to which the supplications for rain and corn are addressed. This is interpreted as a form of totemism in which the ancestors of the clan take precedence. The Sun as the father of all cultus heroes, and the Earth as the mother of all gods, ancestral and otherwise, necessarily form an important part of the worship. The relation between religion and sociology is brought out by the author.

"The Wild Rice Gatherers of the Upper Lakes," by Dr. A. E. Jenks, is a sociological study of great interest and value, and should form a model for other researches on sociological economics. The Indians in the wild-rice district exhibited some social aspects that were quite unique. Their superior physique and peaceful disposition were frequently spoken of. The wild rice led to the peaceful massing together of various tribes and to love for a common country, but being a precarious food-supply, much progress in culture was impossible to these barbarians.

Other papers in the report are "Mounds in Northern Honduras," by Thomas Gann; "Mayan Calendar Systems" and "Numeral Systems of Mexico and Central America," by Cyrus Thomas. The number 20 is the base of the numeral system of the Mexican and Central American tribes, but it does not appear to have been used as a mystic number in rites. There are other peoples who use the vigesimal system, but no others are known who adopt the twenty-day month or eighteen-month year. We cannot conceive how a twenty-day period could have grown out of a lunar count; probably two time systems, a secular and a sacred one, were in use at the same time, and the latter finally obscured the former. The author's conclusion is that the priests adopted a method of counting time for their ceremonial and divinatory purposes which would fit most easily into their numeral system, and this system, in consequence of the overwhelming influence of the priesthood, caused the lunar count to drop into disuse. Prof. W. J. McGee publishes a characteristic essay on "Primitive Numbers." The memoirs in these two volumes are copiously illustrated with numerous excellent plates, some of which are coloured. A. C. H.

AGRICULTURAL NOTES.

From a recent number of a Scotch agricultural newspaper it appears that the Earl of Rosebery has a private station for agricultural research on his home farm near Edinburgh, but the gratification which this information might otherwise have afforded is tempered by a perusal of an account, given by the newspaper, of a visit paid by a party of agriculturists to the place. The experiments, we gather, have been in existence for several years, but no reports on the station's work have been published, and we are left to glean something of its character from the statements made by the estate agent and the district analyst, who respectively represent practice and science in the control of the work. In speeches which are reported at some length, first the agent and then the analyst proceeded to ridicule the work done at other experiment stations. Rothamsted, Woburn, the East of Scotland Agricultural College, and the Highland and Agricultural Society were singled out for condemnation, and one is dismayed to find that "great laughter" was evoked by a quotation of what purported to be the words of the late Sir Henry Gilbert, whose fifty years' devoted service has earned the respect of all right-minded agriculturists. The claims made for Dalmeny—the experiment station—were as amusing as the references to others were offensive. We hear, for example, that "the Dalmeny station was the only agricultural experiment station in the world where the research work was carried out on biological lines," and that "if imitation was the sincerest form of flattery, Dalmeny had been very sincerely flattered of late years, for so-called new lines of investigation were being taken up and books were being written which were simply plagiarisms of Dalmeny work and its results." Until some change is made in the management of Dalmeny experiment station it is clear that no serious consideration need be given to the work being done there.

For the past three years Mr. S. H. Collins, agricultural chemist at the Durham College of Science, has been investigating the composition of the Swedish turnip, the chief root crop of the north of England. A large number of varieties have been grown under identical conditions and also under different conditions of soil, climate, and manuring. The work is still in progress, but certain conclusions which have been come to are stated in the eleventh report of the college agricultural department. They are (1) the higher the percentage of dry matter in swedes the greater the feeding value; (2) swedes are very variable in composition, and not less than fifty roots should be sampled for the purpose of analysis; (3) the average composition of some varieties is much better than that of others; (4) the varieties which are best at one farm will also be best at

other farms; (5) next to variety, season, and then soil, most affect the composition of swedes; the influence of manuring is not marked. The fourth conclusion is warranted by the facts which Mr. Collins brings forward, but this point is one on which further information is wanted, for it seems probable that the relative position of different varieties might change if the varieties were exposed to markedly different conditions.

A *Bulletin* recently issued by the U.S. Department of Agriculture, entitled "The Mango in Porto Rico," discusses the prospects of mango cultivation on the island. Porto Rico grows mangoes in abundance; the climate is very favourable, and the trees are free from disease, but hitherto seedling trees only have been grown, and one is not surprised to read that the mangoes have met with but little favour in the American markets. The fame of the Bombay mango is due to the fruit of grafted trees, and it is rarely that trees raised from seed produce fruit worth eating. Seedling trees abound in every village, but first-rate trees are very uncommon. The short list given in Woodrow's "Gardening for India" shows how rare really good seedlings are. When the Americans import fine strains and take to growing grafted mango trees the industry is certain to make rapid progress. We gather from the *Bulletin* that this subject is likely to engage the attention of the local experiment station. We hope it may, for if the matter is taken up with the energy characteristic of the American stations, there is every prospect of a great increase in the supply of the finest of tropical fruits.

REPORT OF THE MALARIA EXPEDITION TO THE GAMBIA.

THE Liverpool School of Tropical Medicine has just issued a most important and practical report upon the prevention of malaria in the tropics.[1] Dr. Dutton, who conducted the expedition with conspicuous success, shows with striking clearness how a great deal of disease is due to the want of knowledge of the nature of malaria, and that during the dry season the residents are largely to blame for the appearance of the disease. It is one of the most hopeful reports ever issued by the school, and it shows that the governors and others in authority upon the coast are fully alive to the importance of stamping out malarial diseases. The report is an immense step forward in preventive medicine.

The object of the expedition was to investigate the conditions under which mosquitoes were propagated in the town of Bathurst and at the principal stations of the colony, and to suggest methods of destroying these insects. Malaria was found to be prevalent in the colony; 80 per cent. of the native children examined harboured malaria parasites in their blood. The liability to infection of the Europeans commences soon after the rains are established, lasting up to the end of November. The various breeding places of mosquitoes are described in detail in chapter iv. of the report, particular mention being made of the wells, canoes, boats, lighters, cutters on the foreshore, and of the grass-clogged trenches in many of the streets, which together supply Bathurst with the majority of its mosquitoes during the wet season and for part of the dry season. The number of mosquito breeding places present in compounds was found to vary with the social position of the occupier. They increased in extent and number in proportion to the wealth and position of the occupier.

An account of the examination of one of the large compounds illustrates to what extent mosquitoes are bred by the white man in the tropics on his own premises.

In one factory yard were found six barrels, and in the garden there were seventeen tubs and eight small wells, all breeding quantities of Culex, Stegomyia, and Anopheles mosquitoes. Besides these dry season breeding places, discarded domestic utensils were scattered about the yard and garden which, in the wet season, would have acted as breeding places. It is pointed out that during the dry season, from November to May, natural breeding places for mosquitoes in Bathurst cease to exist, and from this period the people breed mosquitoes solely in their own compounds.

In chapter v., which deals with the prevention of malaria in Bathurst, a campaign against the mosquito is advocated; the town is judged especially suitable for its success. Thus Bathurst is situated on a practically isolated piece of land surrounded on nearly all sides by a broad expanse of sea water. The amount of land to be dealt with is comparatively small, viz. about a square mile. The surface is fairly level, sandy, absorbing water readily. In this area the breeding places of mosquitoes are a known quantity, the artificial, or those made by man, being in excess of the natural. The rainfall is very small, and rain occurs only during four out of the twelve months of the year.

The probability of the introduction into Bathurst of yellow fever from Senegal is pointed out as another reason for attacking the mosquito. The expedition was informed by His Excellency the acting Governor, H. M. Brandford Griffith, of the intention on the part of the Colonial Government to enter upon a crusade against the mosquito, and on November 18 the preliminary removal of rubbish from houses and compounds began; a sanitary inspector was appointed, and received special instruction in the work. Under him worked a gang of labourers, and at the time of the departure of the expedition (January 10) 363 houses and compounds had been inspected. From these 131 cartloads of old tin pots and other rubbish were removed. On the return of His Excellency the Governor, Sir George C. Denton, the inspector and a sufficient staff of labourers were appointed permanently, and a grant of 200*l.* per annum was given for the special anti-mosquito work. Anti-mosquito regulations have been drawn up by the Colonial Government. These are given at the end of the report.

An appendix, by Mr. F. V. Theobald, is attached to the report; in it are described the various species of mosquitoes collected by the expedition, many of which were new to science.

ZONES IN THE CHALK.

IN NATURE for August 8, 1901, attention was directed to the second part of Dr. A. W. Rowe's researches on the zones of the White Chalk. We have now had the satisfaction of receiving the third part of this most interesting and important work, which deals with the Chalk of Devon (*Proc.* Geol. Assoc., vol. xviii. part i., 1903).

Working the palæontology with such aids as can be gathered from the local stratigraphy and lithology, the author, assisted as before by Mr. C. D. Sherborn, has added extensively to our knowledge of the successive forms of life that are met with in the Chalk between Sidmouth and Lyme Regis. Whether or not the limits of the zones happen to coincide with definite stratigraphical limits, these latter afford useful data, and one marl band to which the author directs special attention, forms the plane of division between the zones of *Terebratulina gracilis* and *Holaster planus*. Such definite and continuous bands of rock (so far as they can be traced) must afford even more precise evidence of contemporaneity than the presence of this or that fossil. Even a tabular flint-band has proved "an almost constant feature throughout the coast"—an interesting fact, and one that was not to be expected. It is admitted that the name-fossils are not always confined to their zones. *Holaster planus* is found by Dr. Rowe throughout the zone of *Terebratulina gracilis*. But the guide-fossils, the general assemblages associated with the name-fossils, while they exhibit here, as elsewhere, local variations, tell the same story of the successive zones or stages of life, and indicate their approximate limits. Perhaps too much importance is given to the effort to fix a precise divisional plane between zones. When such divisions depend on the forms of life, and the succession of life is continuous though gradually varying, there can be no absolute planes of division, except through the absence or erosion of strata belonging to a particular period of time.

The work before us is rich in its stores of interesting facts. The zone of *Rhynchonella Cuvieri* presents noteworthy features in the presence of *Micraster cor-bovis* and *M. leskei*, the zone of *Terebratulina gracilis* is "singularly rich in fossils," while in the zones of *Holaster planus* and

Micraster cor-testudinarium the group-form of Micraster is almost wholly absent. Nor are the lithological deviations less noteworthy, for the particular characters of the Chalk vary at different stages, and the same division may be nodular or smooth, and have many or no belts of flints. The value of a detailed palæontological study of our strata is abundantly manifested in this essay, and not the least interesting part of it is in the light it throws on the geographical as well as geological distribution of the fossils.

A most excellent series of plates of cliff-sections, from photographs taken by Prof. H. E. Armstrong, accompany this work. H. B. W.

THE PHYSIOLOGY OF BREEDING.[1]

IT is a remarkable fact that the system of organs in the animal body to which they are themselves indebted for their existence is very largely neglected by physiologists; that a number of secretory, vascular and nervous phenomena intimately concerned with fertility, with the power of conception and the ability to bear young are neither understood nor investigated; and that a wide field of research as to the influences of various kinds of food supplied to the mother both on her capacity for breeding and on the growth, constitution, and variation of the embryo is as yet untouched. As a contribution to the subject of "breeding," therefore, this paper is specially welcome, and the author is to be congratulated both upon the careful work he has done and the treatment he has accorded the subject.

The wide variations in the power of breeding which different breeds of sheep and different individuals of the same breed are subject to is shown, and the effect of altitude, climate and food referred to.

The histological changes which take place in the uterus of the sheep during the œstrous cycle are carefully described and figured, and the homology of these changes with those elsewhere described for the bitch and monkey clearly established. A brief *résumé* of the author's work on the same phenomena in the ferret is given, and their essential similarity with that of the bitch shown.

Suggestive information follows on the question of ovulation in sheep and other mammals, on the stimulus necessary to bring about that process under various conditions, on the artificial methods adopted by some flock masters to stimulate breeding in their ewes, and on the effect of these methods on fertility. Here a subject is touched upon which is of vital importance to breeders, and one which requires and deserves careful study. Atresia among the follicles of the sheep's ovary is then studied, and its relation to the proportion of twins and to barrenness examined.

The remainder of the paper is occupied with a description of the formation of the corpus luteum of the sheep and an examination of the views of the most recent writers on that subject. The lutein cells are stated to be the much hypertrophied epithelial cells of the undischarged follicle, while the connective tissue element is supplied by ingrowth from both theca interna and externa.

Finally, the relation between the development of the corpus luteum and the changes which take place in the uterus during pregnancy is touched upon, and the view expressed that, while the functions of ovulation and œstrus do not represent cause and effect, they are primarily connected, inasmuch as each is dependent largely upon the same cause.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE new prospectus of the department of dyeing and tinctorial chemistry of the Yorkshire College, Leeds, shows that special facilities are provided for the study of the chemistry of the colouring matters and for research work upon coal tar products. An effort is being made to combine the standard of scientific teaching of a university with the practical training of a technical school, and to encourage the prosecution of original investigation in what is certainly the most scientific, yet unfortunately, in this country, the least studied branch of applied chemistry. The dyeing department was built, equipped, and endowed by the Clothworkers' Company, and is provided with lecture-rooms, pattern and diagram rooms, museums, experimental and practical dye-houses, as well as with adequate provision for research work.

THE Great Western Railway Company now offer facilities, in conjunction with the Swindon Education Committee, to their apprentices to enable them to gain technical scientific knowledge. A limited number of selected students may attend day classes at the Technical School. They must have spent at least one year in the factory, and must have regularly attended for at least one session in the preparatory group of evening classes at the Technical School. The number of studentships will be limited to thirty at any one time. For each year's course there will be a competitive examination, successful students passing on from one year's course to the next. The course of study for each year will consist of practical mathematics, practical mechanics, geometrical and machine drawing, heat, electricity, and chemistry. Those attending the classes will have their wages paid as if at work in the factory, and the Great Western Railway Company will pay their school fees. The students attending the day classes will be expected to give some time each evening to private study. Students who distinguish themselves will be allowed to spend part of their last year in the drawing office and chemical laboratory. The whole of the arrangements will at all times be under the direction of the chief mechanical engineer.

THE report on the secondary and higher education of the City of Sheffield, prepared by Prof. Michael E. Sadler, has been published in pamphlet form by the Education Committee of Sheffield. The schools and colleges now in existence in Sheffield are described and their work passed in review. A series of recommendations is then made with a view to equip the city with a complete educational system. Prof. Sadler says that the weakest spot in the educational arrangements of Sheffield is in the secondary education provided for boys. A promising boy ought to have the best educational opportunities within his reach, but at present the equipment of such higher education in Sheffield is very much behind the standard in the progressive cities of Germany and the United States. Dr. Sadler also recommends a development of the work of the Technical College. He remarks, "the work of the Technical College, admirable as it is, would greatly gain in force and depth if it were supported by a strong department of pure science." As the report rightly insists, what is wanted is that a workman should be able to deal with new problems, and in order to do this he must have, as a foundation for his technological skill, a thorough knowledge of the pure science which it is his task to apply to practical problems. The probable additional net annual cost to Sheffield of carrying out Prof. Sadler's chief recommendations is estimated at about 8500*l*., which would mean a rate of less than three halfpence. It now remains for the Education Committee of Sheffield to put into practice some of the excellent suggestions in the report.

THE volume of "General Reports on Higher Education for 1902," just published by the Board of Education, contains with other information of importance an account of the secondary schools, science classes, art classes, and evening schools of the southern and eastern divisions of England, the former by Mr. Buckmaster and the latter by Dr. Hoffert. Speaking of the evening schools in London, Mr. Buckmaster says "the impression formed in early visits has not been removed on more complete acquaintance, and the School Board, in its laudable anxiety to throw the educational net as wide as possible, has secured quantity at the expense of quality. As missionary agencies the schools abundantly justify their existence, they bring the opportunities for improvement near to all in all parts of the metropolis, but as centres for real solid work they are not so successful, in spite of the best efforts of the teachers, the majority of whom are most enthusiastic and devoted to their work." Several methods for the improvement of these schools are suggested, such as the alteration of the rule that, where the average attendance falls below 25 per teacher, a reduction in the number of teachers should be made; that

means should be taken to improve the attendance; and to encourage homework. The polytechnics are to some extent fed by students from these evening classes, and it is of importance that their work should be as serious as possible. Dr. Hoffert is able to report considerable progress in the organisation of higher education in the eastern division of England, especially the increased attention now being paid to the improvement of secondary education. In another place Dr. Hoffert refers to the question of higher elementary schools, and expresses the opinion that schools of this type might very profitably be distributed at suitable intervals over London. "They appear destined to fill an important place in any future organised scheme of elementary and secondary education, and to form the natural completion of the elementary system."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 18.—"Radiation in the Solar System: its Effect on Temperature and its Pressure on Small Bodies." By J. H. **Poynting**, Sc.D., F.R.S., Professor of Physics in the University of Birmingham.

PART I.—*Temperature.*

We can calculate an upper limit to the temperatures of fully absorbing or "black" surfaces receiving their heat from the sun, and on certain assumptions we can find the temperatures of planetary surfaces, if we accept the fourth power law of radiation, since we know approximately the solar constant, that is, the rate of reception of heat from the sun, and the radiation constant, that is, the energy radiated at 1° abs. by a fully radiating surface.[1]

The effective temperature of space calculated from the very uncertain data at our command is of the order 10° abs. Bodies in interplanetary space and at a much higher temperature may, therefore, be regarded as being practically in a zero temperature enclosure except in so far as they receive heat from the sun.

The first case considered is that of an ideal earth, more or less resembling the real earth, and it is shown that the temperature of its surface is, on the average, 325°, 302°, or 290° abs. according as we take for the solar constant Ångström's value 4 cal./min., Langley's value 3 cal./min., or a value deduced from Rosetti's work 2·5 cal./min. The lowest value found, 290° abs., is very near the average temperature of the earth's surface, which may be taken as 289° abs. As the earth's effective temperature must, if anything, be below this, and cannot differ much from that of the ideal planet, Rosetti's value for the solar constant, 2·5 cal./min. or $0 \cdot 175 \times 10^7$ ergs./sec. is probably nearest to the true value, and is therefore used in the following calculations.

The preceding calculations may be turned the other way. It is shown that, on certain assumptions, the effective temperature of the sun is 21·5 times that of the ideal earth. If we consider that the real earth with a temperature 289° abs. sufficiently resembles the ideal, we get a solar temperature $21 \cdot 5 \times 289 = 6200°$ abs.

The upper limit to the temperature of the surface of the moon is determined and is shown to be 412° abs. when no heat is conducted inwards. But Langley finds that the actual temperature is not much above the freezing point on the average. This leads us to the conclusion that it is not higher than four-fifths the highest possible value, the reduction being due to inward conduction.

The temperature of a small body, dimensions of the order of 1 cm. or less, but still so large that it absorbs radiation, is shown to be nearly uniform, and at the distance of the earth from the sun about 300° abs.

Under otherwise similar conditions temperatures must vary inversely as the square root of the distance from the sun. Thus Mars, if an earth-like planet, has a temperature nowhere above 253° abs., and if a moon-like planet, the upper limit to the temperature of the hottest part is about 270°.

PART II.—*Radiation Pressure.*

The ratio of radiation pressure due to sunlight to solar gravitation increases, as is well known, as the receiving body diminishes in size. But if the radiating body also diminishes in size, this ratio increases. It is shown that if two equal and fully radiating spheres of the temperature and density of the sun are radiating to each other in a zero enclosure, at a distance large compared with their radii, then the radiation push balances the gravitation pull when the radius of each is 335 metres. If the temperature of two equal bodies is 300° abs. and their density 1, the radius for a balance between the two forces is 19·62 cm. If the density is that of the earth, 5·5, the balance occurs with a radius 3·4 cm. If the temperatures of the two are different, the radiation pressures are different, and it is possible to imagine two bodies, which will both tend to move in the same direction, one chasing the other, under the combined action of radiation and gravitation.

The effect of Döppler's principle will be to limit the velocity attained in such a chase. The Döppler effect on a moving radiator is then examined, and an expression is found for the increase in pressure on the front, and the decrease in pressure on the back of a radiating sphere of uniform temperature moving through a medium at rest. It is proportional to the velocity at a given temperature. The equation to the orbit of such a body moving round the sun is found, and it is shown that meteoric dust within the orbit of the earth will be swept into the sun in a time comparable with historical times, while bodies of the order of 1 cm. radius will be drawn in in a time comparable with geological periods.

"The Phenomena of Luminosity and their possible Correlation with Radio-Activity." By Henry E. **Armstrong**, F.R.S., and T. Martin **Lowry**, D.Sc.

The possibility of regarding *luminous manifestations* generally—including radio-activity—as the outcome of oscillatory changes in molecular structure was pointed out by one of the authors more than a year ago in a communication to the Society in which the kind of change contemplated was exemplified by reference to the case of nitrocamphor. As the phenomena of radio-activity are exciting so much interest, it is thought desirable to enter somewhat more fully into an explanation of the argument underlying this conception of the origin of luminous appearances.

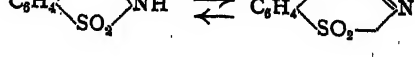
In the note referred to, it was suggested that *triboluminescent* substances, *i.e.* substances which become luminous at the moment of crushing, might conceivably, at the same time, manifest radio-activity. Sir William Crookes, at Dr. Armstrong's request, has recently examined saccharin from this point of view.

His remarks are described; they seem to show that saccharin is slightly radio-active towards barium platinocyanide when crushed. The authors have been unable hitherto to detect any effect on the electrometer.

Triboluminescence.—The authors consider the nature of the change involved in the production of the luminous flash, in order that it may be clear why, in their opinion, if radio-activity were observed in such a case, it would have been as the concomitant to chemical change.

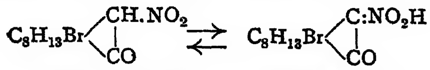
There is distinct evidence, they think, that the phenomena of triboluminescence may be correlated with the occurrence of the form of isomeric change which attends the passage of a compound into the isodynamic form of lower potential. Tschugaeff, who has examined more than 500 inorganic and organic compounds, found that about 25 per cent. of the latter gave a more or less intense flash when crushed; of these a considerable proportion appear to be such as could exist in isodynamic forms. Only about 5 per cent. of the inorganic substances flashed.

To take the case of saccharin, the two conceivable forms are:—



[1] W. Wien ("Cong. Int. de Physique," vol. ii. p. 30) has pointed out that Stefan's law enables us to calculate the temperatures of celestial bodies which receive their light from the sun, by equating the energy which they radiate to the energy which they receive from the sun, and remarks that the temperature of Neptune should be below −200° C.

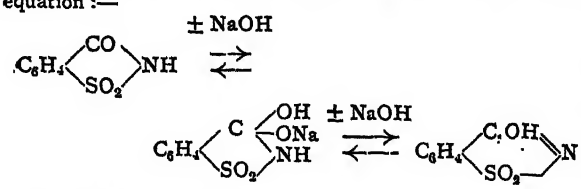
Comparable with these are the two isodynamic forms of π and β-bromonitrocamphor, for example:—



Normal neutral form. Pseudo-acid form.

In the solid state, both forms of π-bromonitrocamphor are stable; when either form is dissolved in a liquid, isomeric change sets in; sooner or later, it may be only in the course of a few hours or even days, a state of equilibrium is established, about 6 per cent. of the material being present in the pseudo form, and 94 per cent. in the normal form. The change, however, does not occur spontaneously, but is undoubtedly dependent on the presence of a catalyst, as equilibrium is established with great rapidity if a trace of alkali be added; acids have only a slight, although definite, accelerating effect. In the case of β-bromonitrocamphor, solutions in benzene of the neutral as well as of the acid form which have been kept during several days without undergoing change, when transferred to another vessel, have rapidly passed to a condition of equilibrium—doubtless because this vessel had been less successfully cleansed than that first used. It can, therefore, scarcely be doubted that the change occurs within a complex system—one which, it is only reasonable to suppose, constitutes an electrolytic circuit. The process is reversed when crystallisation sets in; if the evaporation of the solvent take place sufficiently slowly, the whole of the material is converted into and crystallises out in the less soluble form; if, however, evaporation take place rapidly, the isomeric change may lag behind the crystallisation and both forms may separate. In the case of nitrocamphor, the normal form is the one that separates from the solution; but in the case of π- and β-bromonitrocamphor, although the pseudo form is the minor constituent in the solution, being much less soluble than the isomeride, it is one to separate on crystallisation.

The passage of the one form into the other in the case of saccharin, for example, may be pictured as involving the occurrence of changes such as are represented in the equation:—



Supposing the stable form of lower potential to crystallise out, the crystals, in almost every case, would contain a minute and variable amount of the isodynamic form entangled, as it were, in the mass. In the solid, reversion to the stable form would take place very slowly. Presumably, however, sudden crushing of the crystals would afford opportunity for the change to take place and for the sudden *liberation of energy*—hence the momentary flash.

It is not, at present, necessary to assume that the phenomena are limited to cases of isomeric change; obviously, changes such as those considered may be regarded broadly as dissociative or reversible changes; and from this point of view, it is sufficient to regard the phenomena as the outcome of a loss of potential consequent on the passage from an unstable to a stable system.

From the point of view here advocated, it would be impossible to construct a condenser from a *pure* dielectric; and if the dielectric of a charged condenser were suddenly smashed under suitable conditions, it might exhibit the phenomenon of triboluminosity and perhaps radio-activity.

Fluorescence.—It was originally suggested by one of the authors, in discussing the origin of visible colour, that fluorescence is the "beginning of colour." Subsequently, Dr. J. T. Hewitt, in a paper on the relation between constitution and fluorescence, published early in 1900, took the important step of associating the appearance of fluorescence not with the mere occurrence of the quinonoid type of structure, but with the continued *development* of such a structure—in other words, he has regarded it as the outcome of oscillatory changes in the course of which a non-quinonoid compound undergoes conversion into the isodynamic quinonoid compound.

According to Hewitt, "all the molecules will be undergoing tautomeric change continuously and frequently, and energy absorbed when the molecules have one configuration will be, to an appreciable extent, emitted when they correspond to the other configuration. It is practically certain that the vibration frequency of fluorescein is different in the two states, and hence every opportunity is offered for energy of a rapid vibration frequency to be largely transformed into energy of greater wave-length."

Hewitt obviously does not regard fluorescence as a "flash phenomenon," but as a form of colour, as it were.

While agreeing with Hewitt that the origin of the effect is to be sought in the occurrence of reversible changes involving the production of dynamic isomerides, the authors think that fluorescence is to be regarded as something apart from colour, which, more often than not, is superposed upon colour. The character of the colour effect in fluorescence is quite distinctive; it is not only remarkable on account of its intensity, but there is in it an indefinable qualitative difference which seems to separate it from ordinary colour. If regarded as a "flash phenomenon" this difficulty disappears.

Hewitt appears to regard fluorescence as the outcome of mere intramolecular wobble. To the authors it seems likely that the change is conditioned by a catalyst, and that it occurs within a complex electrolytic circuit.

Phosphorescence.—The phenomena of phosphorescence need to be considered with reference both to cases in which the manifestation attends oxidative or other kinds of chemical change (the glow of phosphorus, the glow-worm, phosphorescent bacteria) and to those in which it is induced by exposure to light (luminous sulphides). The former might well almost be regarded as cases of fluorescence, as a continual supply of energy is derived from the continued occurrence of a chemical change involving loss of energy. With regard to the latter, it would seem that it is not a property of pure substances.

The phosphorescent medium may be pictured as a complex system capable of undergoing "electrolytic" deformation under the influence of light of high refrangibility; as the changes thus induced are reversed, the energy stored up during insolation becomes liberated, and the persistence of the effect is but a consequence of the fact that the change takes place under restraint in a viscous medium.

Dewar's remarkable observations on phosphorescence at low temperatures clearly foreshadow the conclusion that the property is to be correlated with structure.

Radio-Activity.—Pursuing the argument a stage further, it appears to the authors justifiable to regard the activity of radium tentatively as but an exaggerated form of fluorescence in which radiations unnoticed by substances generally—capable of penetrating substances generally—become absorbed and rendered obvious. Such an explanation, from the chemist's point of view, is at least as rational as one which assumes that nature has endowed radium alone of all the elements with incurable suicidal monomania.

There seems to be no good reason for assuming that in fluorescent and other ordinary substances we possess screens capable of arresting rays of every conceivable kind; it may well be that our knowledge of solar radiations is not yet complete.

With regard to "thorium and thorium X," the facts, as stated by Rutherford and Soddy, do not seem to be incompatible with the view that these are but isodynamic forms of thorium or their equivalent, their behaviour being very similar to that of the isodynamic forms of nitrocamphor. In any case, it appears desirable to approach the problem from this point of view, and to investigate the phenomena far more thoroughly on the chemical side.

Whatever the ultimate value of the considerations advanced in the note, they at least serve to show that much may be learnt by further study of the extent to which luminous phenomena generally are to be correlated with structure and structural changes.

July 21.—"On the Oxidising Action of the Rays from Radium Bromide as shown by the Decomposition of Iodoform." By W. B. **Hardy**, F.R.S., Caius College, Cam-

bridge, and Miss E. G. **Willcock**, Newnham College, Cambridge.

A solution of iodoform dissolved in chloroform rapidly becomes purple owing to the liberation of free iodine. This reaction, which seems not to have been previously described, takes place in all the solvents tried, namely, chloroform, benzene, carbon bisulphide, carbon tetrachloride, pyridine, amyl alcohol, and ethylic alcohol, but oxygen is always necessary to the change.

The decomposition of iodoform in solution is not, as it at first sight appears to be, a spontaneous change. It is due ordinarily to the action of light. The solvent has a great effect on the rate of decomposition—the solution in chloroform is very sensitive, that in benzene relatively stable. The solution in chloroform furnishes a delicate test for oxygen and for obscure radiations. It suffers change in gas light, faint daylight, and in X-rays or radium rays. The intensity of the action can easily be measured in time units by choosing some standard colour and matching the fluids under examination with it.

The action of light is due to the ordinary light waves, that is to say, any opaque screen completely arrests the action even of sunlight. Solutions in chloroform enclosed in opaque cardboard boxes have remained unchanged near a window for four days.

The action of radium is due to the more penetrating rays. By screening off the various rays, it can be shown that the α rays have no influence—the oxidation appears to be due solely to the β and γ rays, that is, to the negative electrons (β rays) and to the very penetrating ethereal waves (γ rays), which are said to be identical with X-rays. The action of the radium rays, therefore, will take place through as much as 8mm. of lead, though, of course, relatively very slowly, owing to the stopping of the β rays.

Some idea of the intensity of the action of radium may be obtained from the fact that a solution in chloroform in an ordinary test tube is changed to deep purple in twelve minutes by resting the point of the tube upon a mica plate covering 5 milligrammes of radium bromide. Radium rays, however, are much less active than daylight, as is shown by the fact that the more stable solution of iodoform in benzene resists their action for forty-eight hours, though it becomes purple in about fifteen minutes in the least lighted part of an ordinary room. Seeing that the thinnest opaque screen seems completely to stop the active rays of sunlight, it is obvious that sunlight, as it reaches the surface of the earth, can contain at the most exceedingly few β and γ rays.

M. Blondlot has described recently the presence in sunlight of certain rays which traverse metals but are arrested by water (N rays). These rays have no detectable action upon iodoform; the action of sunlight is not delayed appreciably by interposing a water screen many inches in thickness, and the action is completely arrested by even an opaque deposit of lampblack or by aluminium foil.

The fact that light waves[1] exert a chemical activity more intense than that of radium rays compels us for the present to refer the profound, and often lethal, physiological action of the latter to their power of penetration rather than to any novel or peculiarly intense action upon the tissues. They reach parts which ordinarily are shielded by a cuticle impervious to light waves.

One of us has already shown that the α rays profoundly modify the *physical* state of colloidal solutions (*Journal of Physiology*, vol. xxix. p. 29). If the colloid particles be electrically negative, the α rays act as coagulants; if the colloid particles be electrically positive they act as solvents, that is to say, the rays decrease the average size of the particles.

As a provisional basis for the investigation of the physiological action of radium rays, we may therefore regard the α rays as altering the physical state of the living matter, the β and γ rays as altering the chemical processes, especially, perhaps, the oxidation processes of the tissues.

[1] Including, of course, the ultra-violet waves. Hardy and D'Arcy have shown that the production of "active" oxygen by light falling upon a moist surface is limited in the spectrum to rays from the ultra-violet to the blue end of the green (*Journal of Physiology*, xvii. 1894, p. 390).

PARIS.

Academy of Sciences, August 24.—M. Albert Gaudry in the chair.—Batteries with several different liquids, but identical metallic electrodes, by M. **Berthelot**.—Observations of the sun made at the Observatory of Lyons with the Brünner 16cm. equatorial during the second quarter of 1903, by M. J. **Guillaume**. Observations were possible on sixty-seven days during the quarter; the results are given in three tables showing the number of sun-spots, their distribution in latitude, and the distribution of the faculæ in latitude.—On the problem of S. Lie, by M. N. **Saltykow**.—On the Fourier-Cauchy integrals, by M. Carl **Störmer**.—On the function of the metallic core in induction coils, by M. B. **Eginitis**. The effect of the core varies with its shape, material, the temperature of the sparking poles, their nature and explosive distance, and also on the self-induction of the coil.—On the constitution of the phospho-organic acid in the reserve material of green plants, and on the first reduction product of carbonic acid in the act of chlorophyll assimilation, by M. S. **Posternak**. The acid, heated with dilute mineral acids, is quantitatively hydrolysed into inosite and phosphoric acid. From this, and its cryoscopic behaviour in aqueous solution, the formula $O[CH_2.O.PO(OH)_2]_2$, the anhydride of oxymethylene-diphosphoric acid, is given to the substance, and conclusions are drawn from this as to the nature of chlorophyll assimilation.—On the general equation of curves of fatigue, by M. Charles **Henry** and Mlle. J. **Joteyko**.

RECENT MINERALOGY.

Mineralogy: an Introduction to the Scientific Study of Minerals. By Henry A. Miers, D.Sc., M.A., F.R.S. Pp. xviii + 584; with two coloured plates and 716 illustrations in the text. (London: Macmillan and Co., Ltd., 1902.) Price 25*s*. net.

THE author of this work has various qualifications for the difficult task undertaken by him, a task which has occupied the leisure hours of many years of an otherwise busy life. For thirteen years he was closely associated with the most beautiful and extensive of mineral collections; during that time he became thoroughly familiar with such objects as are described in his book, and attained scientific distinction by reason of the thoroughness and delicacy of his varied scientific researches; further, he visited not only all the best collections in the world, but also many noted mineral localities, and viewed the specimens in their own homes. He introduced, and for several years taught, the subject of crystallography to the students of the City and Guilds Technical Institute, invited thereto, and encouraged therein, by that far-seeing and enthusiastic chemist Prof. Henry Armstrong; he thus prepared the way for the brilliant discoveries since made by his crystallographic pupil Dr. Pope, and at the same time not only became familiar with the difficulties met with by students, but was compelled to discover the best ways of surmounting them. During the last eight years he has been at Oxford as occupant of the Waynflete chair of mineralogy, in succession to the veteran mineralogist and crystallographer Prof. Maskelyne, and by his development of mineralogical study in that university has more than justified his appointment.

The volume, though announced to be merely "an introduction to the scientific study of minerals," immediately impresses even a superficial observer with the magnitude of the subject, for its pages are at once large and numerous (584). But the reader, on opening it, instead of being immediately repelled by the obvious details and technicalities of a difficult subject, is at once attracted by the artistic character of the workmanship, for both paper and type are excellent, and the pages are adorned with no fewer than 716 illustrations, most of them of a style to which we are quite unaccustomed. Every artist knows the difficulty of making even a fair representation of the aspect of minerals, and both authors and students have thus had to remain content with mere diagrammatic figures in illustration of mineral "habit." In this case the author has been able to make many experiments by presuming on his relationship and exercising the artistic patience of a sister; as a result, they have evolved a series of figures most of which leave little to be desired; these are process reproductions of shaded drawings of actual, not imaginary, specimens, and, through the emphasis given by the artist to the leading lines of the figures, are as good substitutes, in two dimensions, for the actual specimens as can be wished. Among the most striking are Figs. 402, flos ferri; 407, calcite showing conchoidal fracture and cleavage; 422, diamond; 437, cryolite; 447, blende; 478, corundum; 486, rutile; 506, quartz twinned; 519, chrysoberyl; 554, witherite; 587, chiastolite; 627, harmotome. For the diagrammatic figures of crystals, the author is indebted partly to the same artist, Miss J. Miers, and partly to the assistant, Mr. R. Graham, whom he has trained in crystallography and perhaps represented, on p. 263, in the very act of crystal measurement. Further, there are two coloured plates which have been executed at the Oxford University Press by the three-colour collotype method, and are the outcome of much experiment; unfortunately, the method is as yet found to be too costly for general use. One of these plates represents the simple biaxial figure shown by a section of an orthoclase crystal when viewed in the polariscope by blue, green, and red monochromatic lights respectively; the other represents the complex figure yielded by the same section when viewed by white light. The actual chromatic effect of the "inclined dispersion" so characteristic of the mineral is thus beautifully reproduced by photography instead of being diagrammatically represented, as is usually the case, by a more or less plausible arrangement of colours. The trouble taken, and the expense incurred, to obtain this result are characteristic of the book in general.

The author himself points out that the treatise is no exhaustive introduction to the study of mineralogy, and that he has deliberately abstained from giving a systematic account of the modes of occurrence of minerals, their geological distribution, their origin, their alterations, and their artificial production. Indeed, the account and discussion of the essential characters of only the more prominent of the minerals which are so common as to be found in all museums occupies a volume which, to put it mildly, is quite as large as a student of average strength can conveniently carry about and handle; the other subjects are of necessity left for treatment in one or more later volumes.

The present volume is divided into two nearly equal parts; the first deals with the properties of minerals in general (286 pages); the second gives a description of the more important species (244 pages); these are followed by 28 pages of tables and a most elaborate and useful index (22 pages). One of the tables gives in a compact form a classified arrangement of the mineral species and a simple chemical formula for each, thus enabling the mind to grasp more readily some of the chemical relationships of the species. Of the tables useful in the practical determination of minerals, the most noteworthy are those giving the arrangement of the species according to the increasing magnitude of the mean refractive index, the birefringence, the optic axial angle, and the specific gravity respectively.

Part i. is subdivided into four books, treating of (1) crystalline properties (179 pages); (2) general properties (23 pages); (3) relations between the properties (30 pages); (4) description and determination of minerals (44 pages). Of the three latter and shorter

books, the second contains a chapter on the chemical properties, more especially with regard to the problem of the classification of species; the third contains several articles which have not previously found their way into text-books of mineralogy (pp. 228–41); they relate to the crystalline form and physical properties of "solid solutions," and are especially useful in the discussion of the felspars; the fourth contains a chapter on the determination of minerals, and affords many useful and practical hints suggested by a long experience.

The first book is by far the longest, and is itself divided into two nearly equal sections; the first (98 pages) deals with the geometrical properties of crystals, the second (81 pages) with their physical properties. It may be objected that it is impossible to give to the student, within the compass of 98 pages, an adequate idea of the theory of crystallography, but it must be remembered that, in a work on mineralogy, minute crystallographic detail would be out of place; such detail is already given to the student in the special treatises of Prof. Maskelyne ("The Morphology of Crystals"), of Prof. Lewis ("A Treatise on Crystallography"), and of Mr. Hilton ("Mathematical Crystallography and the Theory of Groups of Movements"). What the mineralogical student requires is a brief sketch of the whole subject to enable him to grasp the general bearings; this the author has given, and it is all that should be expected from him. It may be mentioned that the author has sought to bring about uniformity of nomenclature of the thirty-two classes of symmetry by coming to an understanding with Prof. E. S. Dana, the editor of the well-known "System of Mineralogy"; but notwithstanding their agreement we find it difficult to reconcile ourselves to a nomenclature which compels one to say that a crystal of cinnabar (HgS) belongs to the quartz class; the systematic nomenclature suggested on p. 280 seems more full of promise. Attention may be directed to the form of student's goniometer, as improved by the author, which is figured on p. 101, and also to the convenient goniometer designed by him for fixing on the stage of a microscope (p. 178).

The chapters treating of the optical properties (70 pages) will probably be the most generally appreciated by students, owing to the great use made of these properties in the determination of the mineral constituents of rock-sections by means of the polarising microscope. It gives to the student a sufficiently precise sketch of the subject without entering into mathematical discussions, and proves once more that it is possible to give to the student an idea of the optical characters of biaxial crystals without any unsatisfactory hypothesis as to optical elasticity and its variability with crystallographic direction.

Part ii., which gives a description of the more important mineral species, is subdivided merely into sections dealing with the various mineral groups. It differs from other works of a similar kind in that it is in great part readable, instead of being a mineralogical dictionary. The readable part and the dictionary part are kept quite distinct from each other, both in position and in the size of type. Further, there is no attempt to give long lists of localities; these are left to be sought for in the books of mere reference; the author is satisfied, and doubtless the student will be satisfied, with descriptions of specimens from the more noteworthy localities, and with accounts of the more important modes of occurrence, and of these we think the author has made a judicious selection. As for the readable portion, it is full of interesting and valuable information.

The author has a simple and pleasant style which attracts the reader, occasionally relieving the technicality with a touch of the driest humour, as, for instance, when he finds it convenient (p. 350) to treat dihydric oxide as a member of an anhydrous series.

The English student of crystallography and mineralogy is to-day in a happy position as compared with his forerunners; his path is continually made more and more easy by the publication of excellent text-books; but there will long remain sufficient inherent difficulty to prevent these subjects of study from losing their educational value, and, as regards research, the recent discovery of radium in the long-known mineral pitchblende shows that the statement made by the alchemist several centuries ago is still true—"a man may consume his whole life in the study of a single mineral without arriving at the knowledge of all its qualities."

SCHOOL MATHEMATICS.

A Junior Geometry. By Noel S. Lydon. Pp. vi+171. (London: Methuen and Co., 1903.) Price 2s.

Technical Arithmetic and Geometry. By C. T. Millis, M.I.M.E. Pp. xiv+254. (London: Methuen and Co., 1903.) Price 3s. 6d.

The Modern Arithmetic for Advanced Grades. Woodward Series. By Archibald Murray (Harvard). Pp. 464. (St. Louis: Woodward and Tiernan Printing Co., n.d.)

The Junior Arithmetic, being an Adaptation of the Tutorial Arithmetic, suitable for Junior Classes. By R. H. Chope, B.A. Pp. viii+363. (London: W. B. Clive, 1903.) Price 2s. 6d.

MR. LYDON'S book, which is meant for young pupils, has many good points and a few bad ones. Like many other very recent books on geometry, it ignores Euclid's order, method, and language. In this way it appeals more readily to the understanding of the pupil than the orthodox Euclidean works do; but the definition "a straight line is one which lies 'evenly' between its extreme points," and the words "notice that the line you have ruled lies evenly between its extreme points A and B," show a strong conservatism. The pupil will indeed be clever if he can give a clear indication of the thing which he notices. The use of the terms *vertical* and *horizontal* in the following manner must be very strongly condemned:—

"When a straight line is drawn upright on the paper it is called a *vertical* line, when drawn in a slanting direction it is called an *oblique* line, and when drawn level on the paper it is called a *horizontal* line."

Early teaching of this kind is responsible for the flagrant misuse of the terms *vertical* and *horizontal*

which is so frequently exhibited by draughtsmen and students of engineering.

Again, the definition of an angle—"an angle is the difference in direction of two lines drawn from a point"—has nothing really quantitative about it, and should be used rather as a familiar *description* than as a quantitative definition.

After the definition of parallel lines—"parallel lines are such as are the same distance apart throughout their whole length"—we have the warning "be careful to distinguish between parallel and horizontal," which unintelligibility is, doubtless, in some way connected with the strange conception of *horizontal* above noticed.

We are now done with the blemishes; for the rest we have nothing but commendation. The book is divided into a series of lessons, each of which is followed by several exercises in the copying of various figures and patterns on squared paper, accompanied by arithmetical calculation. The little pupil is led easily into the subject, and he meets with nothing like severe reasoning until lesson vii. is reached. The grouping of propositions and constructions is throughout very good, and the chapters on areas particularly excellent. The most useful propositions of Euclid's books ii. and iii. are included, and the concluding lessons deal with loci, ratio and proportion, similar figures, &c., and include a large number of important problems, theorems, and constructions. This portion of the book (the most important) can scarcely be improved upon, and, indeed, for this part of the subject, we do not know of any work for beginners which deserves higher commendation.

The book by Mr. Millis can be very strongly recommended as one the study of which should go hand in hand with that of books on purely deductive geometry. It begins with the definitions and figures of geometry, and the use of instruments for the solutions of the problems which are usually treated of in geometrical drawing. Then follows the treatment of fractions, vulgar and decimal, their nature being explained and illustrated by geometrical construction. Contracted methods of multiplication and division are explained. The nature of ratio and proportion follows, and then the enlargement and reduction of figures, square root, propositions relating to areas—in the whole of which work arithmetic goes hand in hand with geometry. After the usual figures of elementary plane geometry are dealt with, conic sections and irregular curvilinear figures are taken, and their properties illustrated by arithmetical examples, with the use of squared paper. Simpson's rule and Henrici's method are explained. The last third of the book deals very fully with the mensuration of solids.

The pupil who uses this work will receive a thorough drilling in neat and accurate drawing—a thing which was very much needed when Euclid held sole sway in the schools.

Mr. Murray's book is a sequel to the work which we noticed some months ago. It is meant for teachers, inasmuch as no answers are given to the various questions. Comparing the work with either of the two books on arithmetic now noticed, it would appear that in the American schools the subject is taught in a very leisurely manner, since there is nothing of a very advanced nature in this work, and a great deal of the mere elements is included. This, of course, may in the end make for thoroughness. It seems somewhat strange that addition and subtraction of decimals are employed in the beginning (p. 31, &c.), while the subject of decimals is subsequently taken (p. 127, &c.) and treated *ab initio*.

Arithmetic and a certain amount of elementary algebra go hand in hand in the book—an arrangement which makes things simple for the beginner; but the purpose of several pages on very elementary algebra at the end of the chapter on percentage is not clear.

The metric system is, of course, explained and illustrated, but the large amount of space devoted to English weights and measures, with their antediluvian lawlessness and complexity, induces sad reflections on the utter waste of time which we impose upon our youth.

The chapter on "Computations and Approximations" contains a useful exposition of the use of squared paper for the plotting of curves and the determination of missing values by graphic interpolation. As compared with our English works, the most striking characteristic of this book is, perhaps, the absence of complexity and useless difficulty in the various examples. It is a merit of the author that he is very particular about the accurate use of language—a great desideratum in these days of slipshod writing, when English grammar and a logical arrangement of thought are steadily vanishing from our scientific treatises.

Teachers everywhere will find the work very helpful and suggestive for a natural and logical way of teaching the subject to young pupils, inasmuch as the methods employed are the result of many years' practical experience in the work of instruction.

Mr. Chope has prepared a treatise of the usual kind on arithmetic. It contains a very large collection of examples illustrating the various rules, and is just as good a handbook of the subject as the student can desire.

THE NEURONE THEORY.

Die Neuronenlehre und ihre Anhanger. By Dr. Franz Nissl. Pp. vi+478. (Jena: Gustav Fischer.) Price 12 marks.

ONE approaches this work with rather mixed feelings. While there is no doubt that an exhaustive survey of our present knowledge in any branch of science is certain to well repay the investigator, yet a book of the magnitude of the one now under consideration, which contains only a controversial view of already known facts, without introducing anything beyond what is familiar to us, leaves on the mind of the reader something of a feeling of weariness, and a suspicion that the same amount of labour would have been better expended in quarrying fresh knowledge rather than reshaping the blocks that have been already brought out. The author himself has realised this, and in the preface gives the reasons which induced him to give the present form to the

book. That even scientific men are too prone to take a plausible hypothesis as proved, and to fill in the little gaps in the observed facts with more or less probable assumptions, is unfortunately true in many branches of research besides the one in question, and the work even of an *advocatus Diaboli* may be of value if only to point out the places in the theory where these assumptions occur. Particularly has this been the case in the domain of nerve physiology, and the present volume is a useful corrective.

The earlier part of the book is occupied with a historical review. Commencing with Waldeyer, His and Forel, Dr. Nissl gives an account of the origin and development of the neurone theory, with the various additions, alterations, and subtractions made by Hoche, Münger, Verworn, and the other investigators who have treated the subject. Allowing for a little very pardonable controversial bias, the summary is a just and able one, and Dr. Nissl's comments are well conceived; so that, although there are a few points on which different opinions may be held—for example, as to the weight to be attached to the work of Forel—yet, as a whole, we may take the history of the neurone theory here presented to us as the most complete and trustworthy one yet published.

The latter part of the book contains the author's reasons for dissenting from the generally received opinion of the structural unity of the elements known as "neurones." He points out that the idea of contact of nerve elements as opposed to that of continuity is not necessarily dependent on the neurone theory, and that the present methods of microscopic technique are not sufficient to give a final answer in the matter. The conclusion is therefore not so much that Dr. Nissl's own views are necessarily correct as that the rival opinions of the authors already mentioned have not sufficient basis in observed facts, and should be received with very much more reserve than has commonly been the case. It is not, however, possible to give a fair abstract of Dr. Nissl's contentions within the compass of a review, and the book itselt must be consulted for further details. It will be found to well repay careful reading, though the unwieldy size, the absence of an alphabetical index—partly made up for by very full chapter-headings—and the fact that, following the German custom, the author has given no summarised conclusion, render it difficult without considerable labour to disentangle the essential from the non-essential portions of the treatise.

OUR BOOK SHELF.

The Cloud World, its Features and Significance. By Samuel Barber. Pp. xii+139. (London: E. Stock, 1903.) Price 7s. 6d.

In this volume Mr. Barber's object has not been to write a scientific treatise on cloud formation, but rather to put before us his own carefully made observations, and "to commend to the tourist, the cyclist, and the city man a delightful and refreshing field of study which may add a charm to a summer holiday." With this object the book has been illustrated with a large number of excellent photographs and sketches, and contains many hints on the prognostic value of different appearances of the sky. We cannot help thinking that it would have gained in value if Mr. Barber had added, or, better still, prefaced, a short chapter on the classification of clouds adopted by the International Committee. This would have familiarised his readers with the generally accepted terminology of the subject; the glossary partly answers this purpose, but it enumerates so many different cloud forms that it might become confusing to one entirely unfamiliar with the subject.

When dealing with the physics of the atmosphere Mr. Barber is distinctly less happy. Though the book is not a scientific treatise, it ought not to contain statements such as the following.

In discussing the question of the suspension of water particles in the atmosphere we read, "The mechanical problem is exactly analogous to that of a bird's flight. If the bird is shot it drops for want of a propelling force: just so with the water vapour. It is not sufficient to assume the vesicular form of water in cloud molecules; we should need to assume a higher temperature in the air enclosed by the vesicles than in the surrounding atmosphere. How can this be maintained, especially at great elevations?" The hypothesis that clouds consist of hollow water vesicles received its death blow about the middle of last century when Stokes calculated the limiting velocity of a falling drop; since that date the suspension of water globules in the atmosphere has ceased to be a stumbling block to physicists. A few pages later we find the statement, "Various forces affect water and ice particles; *e.g.* heat, electricity, gravity between particles, gravity towards mountains and other prominences, gravity to the earth, and last, but not least, the force of crystallisation. . . . Let anyone watch the formation of ice crystals on still water, and he will have an idea of the extent of this force." Are we to understand from this that "gravity towards mountains" affords an explanation of the tendency of clouds to form near the summit of a mountain?

The reader who is inclined to make the study of the appearance of the sky his hobby will find much to interest him in the descriptive part of the book, but he must be prepared to take many of the physical explanations it contains *cum grano salis*.

Graphical Statics Problems, with Diagrams. By W. M. Baker, M.A. Pp. 60. (London: Edward Arnold, n.d.) Price 2s. 6d.

This is a compilation of sixty problems in graphical statics, many of them taken, by permission, from the army entrance examination papers. Each problem is accompanied by a diagram, and has a separate page allotted to it. This leaves plenty of room for the problem to be worked graphically on the page itself, without requiring the diagram to be transferred to drawing paper. The pages are perforated, and are easily removed if desired.

There is, perhaps, some unnecessary repetition and not enough diversity in the problems. We would suggest for a future edition that problems be included involving a direct appeal to experiment in verification of the principles of the polygon and the lever; and the scope of the subject might well be extended by the introduction of position, displacement, velocity, and momentum vectors, including vector differences, thus helping very materially to an adequate understanding of Newton's great law. Students should always measure their graphical results, and an appendix containing numerical answers would have been found very useful in this connection.

But the design of the book and the arrangement of the problems greatly facilitates the work of the teacher, and the volume can be strongly recommended to all who wish to include this very important branch of geometry in their curriculum.

LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Mite whose Eggs survive the Boiling Point.

IN several preparations of boiled flax seeds for fungus-culture it was observed that numbers of mites (*Tyroglyphus histiostoma*) made their appearance. A petri dish containing mites was boiled, and in about three weeks there were again large numbers of them present, though the cover had never been removed since boiling.

On June 6 a decoction of flax seeds containing mites in a test tube was boiled for five minutes, and the neck plugged with cotton wool. On June 15 a similar preparation was made, but the test tube was covered with an indiarubber cap in addition to the plug of cotton wool. On August 24 both test tubes contained living mites. So the inference seems justified that the eggs, though saturated with water, must have survived the boiling point.

The mite is about 2/5mm. in length. The bean-shaped eggs ($108{\cdot}5\mu \times 66{\cdot}5\mu$) are enclosed in two transparent valves like watch glasses.

I am much indebted to Mr. G. H. Carpenter for identifying the species. J. ADAMS.

Royal College of Science, Dublin, September 2.

THE BERLIN CONFERENCE ON WIRELESS TELEGRAPHY.

WE have on two or three occasions referred in these columns to the International Conference on Wireless Telegraphy which was held last month at Berlin. The conclusions at which the conference arrived have now been published in the *Cologne Gazette*, and were summarised in the *Times* last week. In considering these conclusions it is as well to bear in mind that the conference was only preliminary; though representatives of nearly all the important States were present, it was not intended that the recommendations should be final, but rather that they should serve as a basis for discussion at a future conference with more definite powers. Still, the decisions are of interest as they indicate more or less clearly the general state of opinion on the present position of wireless telegraphy.

We have frequently pointed out in NATURE that for the present at any rate it should be the aim of those directly interested in the development of wireless telegraphy to perfect it as far as possible as a means of communication between ships at sea and between ship and shore. This is really an infinitely more important object than the more ambitious and more striking attainment of Transatlantic communication, and such seems to have been the opinion of the conference. Within the last few days it has been announced that Mr. Marconi is now practically in a position to reopen Transatlantic communication on a commercial basis, but even if the attempt proves successful on this occasion less will have been gained than seems to be the case at first sight. We have already means of communicating telegraphically across the Atlantic, and though wireless telegraphy may add another, and possibly a cheaper, method, the gain will be trifling compared with the advantage of perfecting it in a direction in which we have no other resources, whereas should the working of the high power long-distance stations in any way interfere with or hinder the development of the less pretentious short-distance signalling, the loss to the community generally will be very great. Unfortunately, the actual condition of affairs at the present time is difficult to determine; important facts are kept quiet for what are doubtless sound commercial reasons, and assertions and counter assertions are rife. On the one hand we are assured that the big stations do not interfere with the small ones, and on the other we have undeniable evidence that these monstrous etheric disturbances may affect all apparatus in their neighbourhood. It may be possible to avoid this interference by suitable adjustment, but it ought not to be permissible to make this necessary any more than it should be permissible for a factory to belch forth smoke from its chimneys on the ground that those who wish for cleanliness and health can move their firesides to the country.

Wireless telegraphy, indeed, presents a somewhat peculiar and difficult problem; in the first place its medium of communication is one to which all people have an equal right, and which, therefore, one person or set of persons must not be allowed to use to the detriment of others; secondly, its utility depends directly on its availability under all conditions, and at all places, so that to be most useful there must be either a world monopoly or else a perfectly free interchange between competing systems. The second consideration is a strong argument in favour of State monopoly of any means of communication, whilst the first is an additional reason for international control of wireless communication. At the same time it is naturally unjust that those who have spent time and money and energy in pioneering development should be deprived of the legitimate reward of their labours. It is obvious that a solution to the difficulties is only to be found by a fair compromise between conflicting interests, that of the public at large on the one hand and those of the various wireless telegraphy companies on the other. The resolutions of the Berlin conference indicate the only way we can see in which such a compromise can be arranged. Two of these, which are concerned with rates and the method of charging, are not of particular importance; the others propose that coast stations shall be obliged to receive and forward all telegrams from vessels at sea by whatever system transmitted, that telegrams referring to wrecks or calling for assistance shall have precedence, that stations shall be arranged to give the minimum of interference, and that any necessary technical details of the working of apparatus shall be published. The first of these is naturally the most important, and at the same time is the one which it will be most difficult to ratify. It is, of course, well known that the Marconi Company has refused to acquiesce in such an arrangement, by which, as far the largest and most powerful wireless telegraphy company, they have least to gain and most to lose; their position as undeniably the pioneers of practical wireless telegraphy entitles them to special consideration. For this reason the delegates of Italy and Great Britain did not sign this recommendation. The Italian Government is bound by a fourteen years' agreement with the Marconi Co., so that all the delegates could do was to undertake to suggest to the company the amendment of the agreement in the desired direction. The British Government is in an almost equally difficult position, for the Marconi Co. is a British company, and holds already a practical monopoly in this country. Still, it is to be hoped that these difficulties will not stand in the way of an ultimate settlement. There is not unnaturally a suspicion that so far as other countries are concerned there is a desire to benefit, if possible, by

the organisation which the Marconi Co. has built up, and to enable home-bred systems to reap some of the reward of the enterprise of others. To a certain extent this is unavoidable, but it should be possible to arrange matters so that little or no injustice is done to the Marconi Co. whilst securing to the public the very fullest benefit that wireless telegraphy can confer, and it must not be forgotten that the interests of the British public, especially where shipping is concerned, extend all over the world.

MAURICE SOLOMON.

THE SOUTHPORT MEETING OF THE BRITISH ASSOCIATION.

THE seventy-third meeting of the British Association was opened yesterday, when the President, Sir Norman Lockyer, K.C.B., F.R.S., delivered his address in the Opera House.

Everything points to a highly successful meeting, though the number attending will probably fall short of that of the previous Southport meeting twenty years ago. In other respects, however, this year's meeting will probably surpass in interest that of 1883. The second edition of the local programme shows some additional arrangements made since our last article.

The list of excursions is given in greater detail, and a dredging excursion has been added on Thursday, September 17. A good deal of interest is being manifested in the motor car excursion on Saturday afternoon to Hoole and Rufford. A number of Southport gentlemen have placed their cars at the disposal of the local committee, and the show of automobiles will in itself attract attention. The excursion has a further interest, as Hoole is being visited, so that an opportunity may be given of seeing the place where Jeremiah Horrocks, the astronomer, lived at the time of his observation of the transit of Venus. A proposal has recently been mooted in Liverpool and Southport to erect a memorial to Horrocks, and a good deal of attention has been given to the Lancashire astronomer in the local Press. The Liverpool Corporation has kindly lent Mr. Eyre Crowe's picture of Horrocks at Hoole to the Southport committee, and it will be exhibited in one of the reception rooms during the meeting. The accuracy of Mr. Crowe's delineation of Horrocks's astronomical apparatus having been disputed, a Southport gentleman who has made a special study of Horrocks and his works has had painted by a local artist a picture representing the same subject depicted by Mr. Eyre Crowe, and the two pictures will hang in the same room.

The dredging excursion arranged for Thursday, September 17, is being organised by Prof. Herdman, and has been made possible through the courtesy of Mr. R. Dawson, the superintendent of the Lancashire and Western Sea Fisheries, who has kindly put the Sea Fisheries steamer, *John Fell*, at the disposal of the local committee for that purpose.

It is yet uncertain whether the kite-flying experiments for investigating the upper atmosphere can be successfully carried out at Southport. As mentioned in our issue of August 13, the Admiralty vessel put at the disposal of the kite-flying committee is no longer available, and it has been found impossible to bring the *Renown* (the boat from which the experiments are being conducted by Mr. W. H. Dines at Crinan) to Southport. The local committee has been offered the use of the *John Fell* by the Lancashire and Western Sea Fisheries Board for three days (Monday, Tuesday, and Wednesday, September 14, 15, and 16), but it is feared that the deck space will be insufficient for the proper conducting of the experiments. It is, therefore, possible that Mr. Dines will merely exhibit the apparatus at Southport, though every endeavour will be made to make use of the boat.

Prof. Pernter, of Vienna, has had forwarded to Southport one of the cannons used on the Continent for firing on clouds so as to arrest hailstorms. Test experiments in horizontal firing of vortex rings will be carried out on the Southport shore by permission of the Corporation.

A lecture has been arranged for Wednesday night, September 16, on "Garden Cities," by Mr. Ebenezer Howard, the founder of the Garden Cities Association, following an excursion on the same day to Port Sunlight, Cheshire, the model village erected by Messrs. Lever Brothers.

The local loan exhibition which is situated in the corridor near the reception room is in the hands of a small committee drawn from the Southport Literary and Philosophical Society, Society of Natural Science, and Photographic Society, and comprises local botanical and geological exhibits, photographs and drawings illustrating the antiquities of the district, and various exhibits of general scientific interest. The canoe which was dug out of the bed of Martin Mere in 1899 is being exhibited during the time of the meeting in the lecture room of Section H (Anthropology) in the Town Hall. The canoe is seventeen feet long and four feet wide.

The reception and writing rooms in the Art Gallery are rendered specially attractive by the presence on the walls of a portion of the Southport Corporation permanent collection of pictures.

The Mayor of Southport (Mr. T. T. L. Scarisbrick) is extending an almost lavish hospitality at his residence, Greaves Hall, Banks, and the local committee and the Southport Corporation are doing their utmost to make the meeting a memorable one so far as social entertainment is concerned. The Mayor has invited members of the Association to attend Emmanuel Church on Sunday morning, when the preacher will be the Bishop of Ripon. Other special preachers in Southport the same day include the Bishop of Liverpool, the Dean of Peterborough, the Rev. J. D. Bevan, the Rev. A. L. Cortie, S.J., the Rev. T. J. Walshe, the Rev. J. H. Moulton and the Rev. Frank Ballard (Wesleyan), the Rev. Dr. John Hunter (Congregational), the Rev. Dr. S. R. Macphail, Moderator of the Presbyterian Church of England, and the Rev. R. A. Armstrong (Unitarian).

In connection with the Mayor's and the committee's receptions to-night and on Tuesday next, a portion of the municipal gardens in front of the Cambridge Hall will be enclosed. These gardens are illuminated by electricity at night, more than 4000 glow-lamps being installed among the foliage of the trees. The installation is quite unique in this country. Special fittings had to be designed, as, being an outdoor installation, the electrical conditions are very severe. More than sixteen miles of underground and overhead cable are used.

The Mayor's dinner at Greaves Hall on Wednesday, September 16, promises to be a very brilliant function, and the lecture by Prof. Forsyth before the Literary and Philosophical Society on the following night on "Universities" will be largely attended by members of the British Association, a large number of whom have accepted the invitation to be present.

INAUGURAL ADDRESS BY SIR NORMAN LOCKYER, K.C.B., LL.D., F.R.S., CORRESPONDANT DE L'INSTITUT DE FRANCE, PRESIDENT OF THE ASSOCIATION.

The Influence of Brain-power on History.

MY first duty to-night is a sad one. I have to refer to a great loss which this Nation and this Association have sustained. By the death of the great Englishman and great statesman who has just passed away, we members of the British Association are deprived of one of the most illustrious of our confrères. We have to mourn the loss of an enthusiastic student of science who conferred honour on our body by becoming its President. We recognise that as Prime Minister he was mindful of the interests of science, and that to him we owe a more general recognition on the part of the State of the value to the nation of the work of scientific men. On all these grounds you will join in the expression of respectful sympathy with Lord Salisbury's family in their great personal loss which your council has embodied this morning in a resolution of condolence.

Last year, when this friend of science ceased to be Prime Minister, he was succeeded by another statesman who also has given many proofs of his devotion to philosophical studies, and has shown in many utterances that he has a clear understanding of the real place of science in modern civilisation. We then have good grounds for hoping that the improvement in the position of science in this country which we owe to the one will also be the care of his successor, who has honoured the Association by accepting the unanimous nomination of your council to be your President next year, an acceptance which adds a new lustre to this chair.

On this we may congratulate ourselves all the more because I think, although it is not generally recognised, that the century into which we have now well entered may be more momentous than any which has preceded it, and that the present history of the world is being so largely moulded by the influence of brain-power, which in these modern days has to do with natural as well as human forces and laws, that statesmen and politicians will have in the future to pay more regard to education and science, as empire-builders and empire-guarders, than they have paid in the past.

The nineteenth century will ever be known as the one in which the influences of science were first fully realised in civilised communities; the scientific progress was so gigantic that it seems rash to predict that any of its successors can be more important in the life of any nation.

Disraeli, in 1873, referring to the progress up to that year, spoke as follows:—"How much has happened in these fifty years—a period more remarkable than any, I will venture to say, in the annals of mankind. I am not thinking of the rise and fall of Empires, the change of dynasties, the establishment of Governments. I am thinking of those revolutions of science which have had much more effect than any political causes, which have changed the position and prospects of mankind more than all the conquests and all the codes and all the legislators that ever lived."[1]

The progress of science, indeed, brings in many considerations which are momentous in relation to the life of any limited community—any one nation. One of these considerations to which attention is now being greatly drawn is that a relative decline in national wealth derived from industries must follow a relative neglect of scientific education.

It was the late Prince Consort who first emphasised this when he came here fresh from the University of Bonn. Hence the "Prince Consort's Committee," which led to the foundation of the College of Chemistry and afterwards of the Science and Art Department. From that time to this the warnings of our men of science have become louder and more urgent in each succeeding year. But this is not all; the commercial output of one country in one century as compared with another is not alone in question; the acquirement of the scientific spirit and a knowledge and utilisation of the forces of Nature are very much further reaching in their effects on the progress and decline of nations than is generally imagined.

Britain in the middle of the last century was certainly the country which gained most by the advent of science, for she was then in full possession of those material gifts of Nature, coal and iron, the combined winning and utilisation of which, in the production of machinery and in other ways, soon made her the richest country in the world, the seat and throne of invention and manufacture, as Mr. Carnegie has called her. Being the great producers and exporters of all kinds of manufactured goods, we became eventually, with our iron ships, the great carriers, and hence the supremacy of our mercantile marine and our present command of the sea.

[1] NATURE, November 27, 1873, vol. ix. p. 71.

The most fundamental change wrought by the early applications of science was in relation to producing and carrying power. With the winning of mineral wealth and the production of machinery in other countries, and cheap and rapid transit between nations, our superiority as depending upon our first use of vast material resources was reduced. Science, which is above all things cosmopolitan—planetary, not national—internationalises such resources at once. In every market of the world

> "things of beauty, things of use,
> Which one fair planet can produce,
> Brought from under every star,"

were soon to be found.

Hence the first great effect of the general progress of science was relatively to diminish the initial supremacy of Britain due to the first use of *material* resources, which indeed was the real source of our national wealth and place among the nations.

The unfortunate thing was that, while the foundations of our superiority depending upon our *material resources* were being thus sapped by a cause *which was beyond our control*, our statesmen and our universities were blind leaders of the blind, and our other asset, our mental resources, which was within our control, was culpably neglected.

So little did the bulk of our statesmen know of the part science was playing in the modern world and of the real basis of the nation's activities, that they imagined political and fiscal problems to be the only matters of importance. Nor, indeed, are we very much better off to-day. In the important discussions recently raised by Mr. Chamberlain, next to nothing has been said of the effect of the progress of science on prices. The whole course of the modern world is attributed to the presence or absence of taxes on certain commodities in certain countries. The fact that the great fall in the price of food-stuffs in England did not come till some thirty or forty years after the removal of the corn duty between 1847 and 1849 gives them no pause; for them new inventions, railways and steamships are negligible quantities; the vast increase in the world's wealth in free trade and protected countries alike comes merely according to them in response to some *political* shibboleth.

We now know, from what has occurred in other States, that if our Ministers had been more wise and our universities more numerous and efficient, our *mental resources* would have been developed by improvements in educational method, by the introduction of science into schools, and, more important than all the rest, by the teaching of science by experiment, observation and research, and not from books. It is because this was not done that we have fallen behind other nations in properly applying science to industry, so that our applications of science to industry are relatively less important than they were. But this is by no means all; we have lacked the strengthening of the national life produced by fostering the scientific spirit among all classes, and along all lines of the nation's activity; many of the responsible authorities know little and care less about science; we have not learned that it is the duty of a State to organise its forces as carefully for peace as for war; that universities and other teaching centres are as important as battleships or big battalions; are, in fact, essential parts of a modern State's machinery, and as such to be equally aided and as efficiently organised to secure its future well being.

Now the objects of the British Association as laid down by its founders seventy-two years ago are "To give a stronger impulse and a more systematic direction to scientific inquiry—to promote the intercourse of those who cultivate science in different parts of the British Empire with one another and with foreign philosophers—to obtain a more general attention to the objects of science and a removal of any disadvantages of a public kind which impede its progress."

In the main, my predecessors in this chair, to which you have done me the honour to call me, have dealt, and with great benefit to science, with the objects first named.

But at a critical time like the present I find it imperative to depart from the course so generally followed by my predecessors and to deal with the last object named, for unless by some means or other we "obtain a more general attention to the objects of science and a removal of any disadvantages of a

public kind which impede its progress," we shall suffer in competition with other communities in which science is more generally utilised for the purposes of the national life.

The Struggle for Existence in Modern Communities.

Some years ago, in discussing the relations of scientific instruction to our industries, Huxley pointed out that we were in presence of a new "struggle for existence," a struggle which, once commenced, must go on until only the fittest survives.

It is a struggle between organised species—nations—not between individuals or any class of individuals. It is, moreover, a struggle in which science and brains take the place of swords and sinews, on which depended the result of those conflicts which, up to the present, have determined the history and fate of nations. The school, the university, the laboratory and the workshop are the battlefields of this new warfare.

But it is evident that if this, or anything like it, be true, our industries cannot be involved alone; the scientific spirit, brain-power, must not be limited to the workshop if other nations utilise it in all branches of their administration and executive.

It is a question of an important change of front. It is a question of finding a new basis of stability for the Empire in face of new conditions. I am certain that those familiar with the present state of things will acknowledge that the Prince of Wales's call, "Wake up," applies quite as much to the members of the Government as it does to the leaders of industry.

What is wanted is a complete organisation of the resources of the nation, so as to enable it best to face all the new problems which the progress of science, combined with the ebb and flow of population and other factors in international competition, are ever bringing before us. Every Minister, every public department, is involved, and this being so, it is the duty of the whole nation—King, Lords, and Commons—to do what is necessary to place our scientific institutions on a proper footing in order to enable us to "face the music" whatever the future may bring. The idea that science is useful only to our industries comes from want of thought. If anyone is under the impression that Britain is only suffering at present from the want of the scientific spirit among our industrial classes, and that those employed in the State service possess adequate brain-power and grip of the conditions of the modern world into which science so largely enters, let him read the report of the Royal Commission on the War in South Africa. There he will see how the whole "system" employed was, in Sir Henry Brackenbury's words applied to a part of it, "*unsuited to the requirements of an Army which is maintained to enable us to make war.*" Let him read also, in the address of the president of the Society of Chemical Industry what drastic steps had to be taken by Chambers of Commerce and "a quarter of a million of working men" to get the Patent Law Amendment Act into proper shape, in spite of all the advisers and officials of the Board of Trade. Very few people realise the immense number of scientific problems the solution of which is required for the State service. The nation itself is a gigantic workshop, and the more our rulers and legislators, administrators and executive officers possess the scientific spirit, the more the rule of thumb is replaced in the State service by scientific methods, the more able shall we be, thus armed at all points, to compete successfully with other countries along all lines of national as well as of commercial activity.

It is obvious that the power of a nation for war, in men and arms and ships, is one thing; its power in the peace struggles to which I have referred is another; in the latter, the source and standard of national efficiency are entirely changed. To meet war conditions, there must be equality or superiority in battle-ships and army corps. To meet the new peace conditions, there must be equality or superiority in universities, scientific organisation and everything which conduces to greater brain power.

Our Industries are suffering in the Present International Competition.

The present condition of the nation, so far as its industries are concerned, is as well known, not only to the Prime Minister, but to other political leaders in and out of the Cabinet, as it is to you and to me. Let me refer to two speeches delivered by Lord Rosebery and Mr. Chamberlain on two successive days in January, 1901.

Lord Rosebery spoke as follows:—

"... The war I regard with apprehension is the war of trade which is unmistakably upon us. ... When I look round me I cannot blind my eyes to the fact that so far as we can predict anything of the twentieth century on which we have now entered, it is that it will be one of acutest international conflict in point of trade. We were the first nation of the modern world to discover that trade was an absolute necessity. For that we were nicknamed a nation of shopkeepers; but now every nation wishes to be a nation of shopkeepers too, and I am bound to say that when we look at the character of some of these nations, and when we look at the intelligence of their preparations, we may well feel that it behoves us not to fear, but to gird up our loins in preparation for what is before us."

Mr. Chamberlain's views were stated in the following words:—

"I do not think it is necessary for me to say anything as to the urgency and necessity of scientific training. ... It is not too much to say that the existence of this country, as the great commercial nation, depends upon it. ... It depends very much upon what we are doing now, at the beginning of the twentieth century, whether at its end we shall continue to maintain our supremacy or even equality with our great commercial and manufacturing rivals."

All this refers to our industries. We are suffering because trade no longer follows the flag as in the old days, but because trade follows the brains, and our manufacturers are too apt to be careless in securing them. In one chemical establishment in Germany, 400 doctors of science, the best the universities there can turn out, have been employed at different times in late years. In the United States the most successful students in the higher teaching centres are snapped up the moment they have finished their course of training, and put into charge of large concerns, so that the idea has got abroad that youth is the password of success in American industry. It has been forgotten that the latest product of the highest scientific education must necessarily be young, and that it is the training and not the age which determines his employment. In Britain, on the other hand, apprentices who can pay high premiums are too often preferred to those who are well educated, and the old rule-of-thumb processes are preferred to new developments—a conservatism too often depending upon the master's own want of knowledge.

I should not be doing my duty if I did not point out that the defeat of our industries one after another, concerning which both Lord Rosebery and Mr. Chamberlain express their anxiety, is by no means the only thing we have to consider. The matter is not one which concerns our industrial classes only, for knowledge must be pursued for its own sake, and since the full life of a nation with a constantly increasing complexity, not only of industrial, but of high national aims, depends upon the universal presence of the scientific spirit—in other words, brain-power—our whole national life is involved.

The Necessity for a Body dealing with the Organisation of Science.

The present awakening in relation to the nation's real needs is largely due to the warnings of men of science. But Mr. Balfour's terrible Manchester picture of our present educational condition[1] shows that the warning which has been going on now for more than fifty years has not been forcible enough; but if my contention that other reorganisations besides that of our education are needed is well founded, and if men of science are to act the part of good citizens in taking their share in endeavouring to bring about a better state of things, the question arises, has the neglect of their warnings so far been due to the way in which these have been given?

Lord Rosebery, in the address to a Chamber of Commerce from which I have already quoted, expressed his opinion that such bodies do not exercise so much influence as might be expected of them. But if commercial men do not use all the power their organisation provides, do they not by having built up such an organisation put us students of science to shame, who are still the most disorganised members of the community?

Here, in my opinion, we have the real reason why the scientific needs of the nation fail to command the attention either of the public or of successive Governments. At present, appeals on

[1] "The existing educational system of this country is chaotic, is ineffectual, is utterly behind the age, makes us the laughing-stock of every advanced nation in Europe and America, puts us behind, not only our American cousins, but the German and the Frenchman and the Italian."—*Times*, October 15, 1902.

this or on that behalf are the appeals of individuals; science has no collective voice on the larger national questions; there is no organised body which formulates her demands.

During many years it has been part of my duty to consider such matters, and I have been driven to the conclusion that our great crying need is to bring about an organisation of men of science and all interested in science, similar to those which prove so effective in other branches of human activity. For the last few years I have dreamt of a Chamber, Guild, League, call it what you will, with a wide and large membership, which should give us what, in my opinion, is so urgently needed. Quite recently I sketched out such an organisation, but what was my astonishment to find that I had been forestalled, and by the founders of the British Association!

The British Association such a Body.

At the commencement of this address I pointed out that one of the objects of the Association, as stated by its founders, was "to obtain a more general attention to the objects of science and a removal of any disadvantages of a public kind which impede its progress."

Everyone connected with the British Association from its beginning may be congratulated upon the magnificent way in which the other objects of the Association have been carried out, but as one familiar with the Association for the last forty years, I cannot but think that the object to which I have specially referred has been too much overshadowed by the work done in connection with the others.

A careful study of the early history of the Association leads me to the belief that the function I am now dwelling on was strongly in the minds of the founders; but be this as it may, let me point out how admirably the organisation is framed to enable men of science to influence public opinion and so to bring pressure to bear upon Governments which follow public opinion. (1) Unlike all the other chief metropolitan societies, its outlook is not limited to any branch or branches of science. (2) We have a wide and numerous fellowship, including both the leaders and the lovers of science, in which all branches of science are and always have been included with the utmost catholicity—a condition which renders strong committees possible on any subject. (3) An annual meeting at a time when people can pay attention to the deliberations, and when the newspapers can print reports. (4) The possibility of beating up recruits and establishing local committees in different localities, even in the King's dominions beyond the seas, since the place of meeting changes from year to year, and is not limited to these islands.

We not only, then, have a scientific parliament competent to deal with all matters, including those of national importance, relating to science, but machinery for influencing all new councils and committees dealing with local matters, the functions of which are daily becoming more important.

The machinery might consist of our corresponding societies. We already have affiliated to us seventy societies with a membership of 25,000; were this number increased so as to include every scientific society in the Empire, metropolitan and provincial, we might eventually hope for a membership of half a million.

I am glad to know that the Council is fully alive to the importance of giving a greater impetus to the work of the corresponding societies. During this year a committee was appointed to deal with the question; and later still, after this committee had reported, a conference was held between this committee and the corresponding societies committee to consider the suggestions made, some of which will be gathered from the following extract:—

"In view of the increasing importance of science to the nation at large, your committee desire to call the attention of the Council to the fact that in the corresponding societies the British Association has gathered in the various centres represented by these societies practically all the scientific activity of the provinces. The number of members and associates at present on the list of the corresponding societies approaches 25,000, and no organisation is in existence anywhere in the country better adapted than the British Association for stimulating, encouraging and coordinating all the work being carried on by the seventy societies at present enrolled. Your committee are of opinion that further encouragement should be given to these societies and their individual working members by every means within the power of the association; and with the object of keeping the corresponding societies in more permanent touch with the Association they suggest that an official invitation on behalf of the Council be addressed to the societies through the corresponding societies committee asking them to appoint standing British Association sub-committees, to be elected by themselves with the object of dealing with all those subjects of investigation common to their societies and to the British Association committees, and to look after the general interests of science and scientific education throughout the provinces and provincial centres. . . .

"Your committee desire to lay special emphasis on the necessity for the extension of the scientific activity of the corresponding societies and the expert knowledge of many of their members in the direction of scientific education. They are of opinion that immense benefit would accrue to the country if the corresponding societies would keep this requirement especially in view with the object of securing adequate representation for scientific education on the Education Committees now being appointed under the new Act. The educational section of the Association having been but recently added, the corresponding societies have as yet not had much opportunity for taking part in this branch of the Association's work; and in view of the reorganisation in education now going on all over the country your committee are of opinion that no more opportune time is likely to occur for the influence of scientific organisations to make itself felt as a real factor in national education. . . ."

I believe that if these suggestions or anything like them—for some better way may be found on inquiry—are accepted, great good to science throughout the Empire will come. Rest assured that sooner or later such a guild will be formed because it is needed. It is for you to say whether it shall be, or form part of, the British Association. We in this Empire certainly need to organise science as much as in Germany they find the need to organise a navy. The German Navy League, which has branches even in our Colonies, already has a membership of 630,000, and its income is nearly 20,000*l*. a year. A British Science League of 500,000 with a sixpenny subscription would give us 12,000*l*. a year, quite enough to begin with.

I for one believe that the British Association would be a vast gainer by such an expansion of one of its existing functions. Increased authority and prestige would follow its increased utility. The meetings would possess a new interest; there would be new subjects for reports; missionary work less needed than formerly would be replaced by efforts much more suited to the real wants of the time. This magnificent, strong and complicated organisation would become a living force, working throughout the year, instead of practically lying idle, useless and rusting for 51 weeks out of the 52 so far as its close association with its members is concerned.

If this suggestion in any way commends itself to you, then when you begin your work in your sections or general committee see to it that a body is appointed to inquire how the thing can be done. Remember that the British Association will be as much weakened by the creation of a new body to do the work I have shown to have been in the minds of its founders as I believe it will be strengthened by becoming completely effective in every one of the directions they indicated, and for which effectiveness we their successors are indeed responsible. The time is appropriate for such a reinforcement of one of the wings of our organisation, for we have recently included Education among our sections.

There is another matter I should like to see referred to the committee I have spoken of, if it please you to appoint it. The British Association, which as I have already pointed out is now the chief body in the Empire which deals with the totality of science, is, I believe, the only organisation of any consequence which is without a charter, and which has not His Majesty the King as patron.

The First Work of such an Organisation.

I suppose it is my duty after I have suggested the need of organisation to tell you my personal opinion as to the matters where we suffer most in consequence of our lack of organisation at the present time.

Our position as a nation, our success as merchants, are in peril chiefly—dealing with preventable causes—because of our lack of completely efficient universities, and our neglect of research. This research has a double end. A professor who is not learning cannot teach properly or arouse enthusiasm in his students; while a student of anything who is unfamiliar with research methods, and without that training which research

brings, will not be in the best position to apply his knowledge in after life. From neglect of research comes imperfect education and a small output of new applications and new knowledge to reinvigorate our industries. From imperfect education comes the unconcern touching scientific matters, and the too frequent absence of the scientific spirit, in the nation generally from the Court to the parish council.

I propose to deal as briefly as I can with each of these points.

Universities.

I have shown that so far as our industries are concerned, the cause of our failure has been run to earth; it is fully recognised that it arises from the insufficiency of our universities both in numbers and efficiency, so that not only our captains of industry, but those employed on the nation's work generally, do not secure a training similar to that afforded by other nations. No additional endowment of primary, secondary or technical instruction will mend matters. This is not merely the opinion of men of science; our great towns know it, our Ministers know it.

It is sufficient for me to quote Mr. Chamberlain:—

"It is not everyone who can, by any possibility, go forward into the higher spheres of education; but it is from those who do that we have to look for the men who, in the future, will carry high the flag of this country in commercial, scientific and economic competition with other nations. At the present moment, I believe there is nothing more important than to supply the deficiencies which separate us from those with whom we are in the closest competition. In Germany, in America, in our own colony of Canada and in Australia, the higher education of the people has more support from the Government, is carried further, than it is here in the old country; and the result is that in every profession, in every industry, you find the places taken by men and by women who have had a university education. And I would like to see the time in this country when no man should have a chance for any occupation of the better kind, either in our factories, our workshops or our counting-houses, who could not show proof that, in the course of his university career, he had deserved the position that was offered to him. What is it that makes a country? Of course you may say, and you would be quite right, 'The general qualities of the people, their resolution, their intelligence, their pertinacity, and many other good qualities.' Yes; but that is not all, and it is not the main creative feature of a great nation. The greatness of a nation is made by its greatest men. It is those we want to educate. It is to those who are able to go, it may be, from the very lowest steps in the ladder, to men who are able to devote their time to higher education, that we have to look to continue the position which we now occupy as, at all events, one of the greatest nations on the face of the earth. And, feeling as I do on these subjects, you will not be surprised if I say that I think the time is coming when Governments will give more attention to this matter, and perhaps find a little more money to forward its interests" (*Times*, November 6, 1902).

Our conception of a university has changed. University education is no longer regarded as the luxury of the rich which concerns only those who can afford to pay heavily for it. The Prime Minister in a recent speech, while properly pointing out that the collective effect of our public and secondary schools upon British character cannot be overrated, frankly acknowledged that the boys of seventeen or eighteen who have to be educated in them "do not care a farthing about the world they live in except in so far as it concerns the cricket-field or the football-field or the river." On this ground they are not to be taught science, and hence, when they proceed to the university, their curriculum is limited to subjects which were better taught before the modern world existed, or even Galileo was born. But the science which these young gentlemen neglect, with the full approval of their teachers, on their way through the school and the university to politics, the Civil Service, or the management of commercial concerns, is now one of the great necessities of a nation, and our universities must become as much the insurers of the future progress as battleships are the insurers of the present power of States. In other words, university competition between States is now as potent as competition in building battleships, and it is on this ground that our university conditions become of the highest national concern and therefore have to be referred to here, and all the more because our industries are not alone in question.

Why we have not more Universities.

Chief among the causes which have brought us to the terrible condition of inferiority as compared with other nations in which we find ourselves are our carelessness in the matter of education and our false notions of the limitations of State functions in relation to the conditions of modern civilisation.

Time was when the Navy was largely a matter of private and local effort. William the Conqueror gave privileges to the Cinque Ports on the condition that they furnished fifty-two ships when wanted. In the time of Edward III., of 730 sail engaged in the siege of Calais, 705 were "people's ships." All this has passed away; for our first line of defence we no longer depend on private and local effort.

Time was when not a penny was spent by the State on elementary education. Again, we no longer depend upon private and local effort. The Navy and primary education are now recognised as properly calling upon the public for the necessary financial support. But when we pass from primary to university education, instead of State endowment we find State neglect; we are in a region where it is nobody's business to see that anything is done.

We in Great Britain have thirteen universities competing with 134 State and privately endowed in the United States and twenty-two State endowed in Germany. I leave other countries out of consideration for lack of time, and I omit all reference to higher institutions for technical training, of which Germany alone possesses nine of university rank, because they are less important; they instruct rather than educate, and our want is education. The German State gives to one university more than the British Government allows to all the universities and university colleges in England, Ireland, Scotland, and Wales put together. These are the conditions which regulate the production of brain-power in the United States, Germany, and Britain respectively, and the excuse of the Government is that this is a matter for private effort. Do not our Ministers of State know that other civilised countries grant efficient State aid, and further, that private effort has provided in Great Britain less than 10 per cent. of the sum thus furnished in the United States in addition to State aid? Are they content that we should go under in the great struggle of the modern world because the Ministries of other States are wiser, and because the individual citizens of another country are more generous, than our own?

If we grant that there was some excuse for the State's neglect so long as the higher teaching dealt only with words, and books alone had to be provided (for the streets of London and Paris have been used as class rooms at a pinch), it must not be forgotten that during the last hundred years not only has knowledge been enormously increased, but things have replaced words, and fully equipped laboratories must take the place of books and class rooms if university training worthy of the name is to be provided. There is much more difference in size and kind between an old and new university than there is between the old caravel and a modern battleship, and the endowments must follow suit.

What are the facts relating to private endowment in this country? In spite of the munificence displayed by a small number of individuals in some localities, the truth must be spoken. In depending in our country upon this form of endowment, we are trusting to a broken reed. If we take the twelve English university colleges, the forerunners of universities unless we are to perish from lack of knowledge, we find that private effort during sixty years has found less than 4,000,000*l.*, that is, 2,000,000*l.* for buildings and 40,000*l.* a year income. This gives us an average of 166,000*l.* for buildings and 3300*l.* for yearly income.

What is the scale of private effort we have to compete with in regard to the American universities?

In the United States, during the last few years, universities and colleges have received more than 40,000,000*l.* from this source alone; private effort supplied nearly 7,000,000*l.* in the years 1898–1900.

Next consider the amount of State aid to universities afforded in Germany. The buildings of the new University of Strassburg have already cost nearly a million; that is, about as much as has yet been found by private effort for buildings in Manchester, Liverpool, Birmingham, Bristol, Newcastle and Sheffield. The Government annual endowment of the same German university is more than 49,000*l.*

This is what private endowment does for us in England, against State endowment in Germany.

But the State does really concede the principle; its present contribution to our Universities and colleges amounts to 155,600*l.* a year; no capital sum, however, is taken for buildings. The State endowment of the University of Berlin in 1891–2 amounted to 168,777*l.*

When, then, we consider the large endowments of university education both in the United States and Germany, it is obvious that State aid only can make any valid competition possible with either. The more we study the facts, the more statistics are gone into, the more do we find that we, to a large extent, lack both of the sources of endowment upon one or other or both of which other nations depend. We are between two stools, and the prospect is hopeless without some drastic changes. And first among these, if we intend to get out of the present slough of despond, must be the giving up of the idea of relying upon private effort.

That we lose most where the State does least is known to Mr. Chamberlain, for in his speech, to which I have referred, on the University of Birmingham, he said:—"As the importance of the aim we are pursuing becomes more and more impressed upon the minds of the people, we may find that we shall be more generously treated by the State."

Later still, on the occasion of a visit to University College School. Mr. Chamberlain spoke as follows:—

"When we are spending, as we are, many millions—I think it is 13,000,000*l.*—a year on primary education, it certainly seems as if we might add a little more, even a few tens of thousands, to what we give to University and secondary education" (*Times*, November 6, 1902).

To compete on equal grounds with other nations we must have more universities. But this is not all—we want a far better endowment of all the existing ones, not forgetting better opportunities for research on the part of both professors and students. Another crying need is that of more professors and better pay. Another is the reduction of fees; they should be reduced to the level in those countries which are competing with us, to, say, one-fifth of their present rates, so as to enable more students in the secondary and technical schools to complete their education.

In all these ways, facilities would be afforded for providing the highest instruction to a much greater number of students. At present there are almost as many *professors and instructors* in the universities and colleges of the United States as there are *day students* in the universities and colleges of the United Kingdom.

Men of science, our leaders of industry, and the chiefs of our political parties all agree that our present want of higher education—in other words, properly equipped universities—is heavily handicapping us in the present race for commercial supremacy, because it provides a relatively inferior brain-power which is leading to a relatively reduced national income.

The facts show that in this country we cannot depend upon private effort to put matters right. How about local effort?

Anyone who studies the statistics of modern municipalities will see that it is impossible for them to raise rates for the building and upkeep of universities.

The buildings of the most modern university in Germany have cost a million. For upkeep the yearly sums found, chiefly by the State, for German universities of different grades, taking the incomes of seven out of the twenty-two universities as examples, are:—

		£
1st Class ...	Berlin	130,000
2nd Class ...	Bonn / Göttingen	56,000
3rd Class ...	Königsberg / Strassburg	48,000
4th Class ...	Heidelberg / Marburg	37,000

Thus if Leeds, which is to have a university, is content with the 4th class German standard, a rate must be levied of 7*d.* in the pound for yearly expenses, independent of all buildings. But the facts are that our towns are already at the breaking strain. During the last fifty years, in spite of enormous increases in rateable values, the rates have gone up from about 2*s.* to about 7*s.* in the pound for real *local* purposes. But no university can be a merely local institution.

How to get more Universities.

What, then, is to be done? Fortunately, we have a precedent admirably in point, the consideration of which may help us to answer this question.

I have pointed out that in old days our Navy was chiefly provided by local and private effort. Fortunately for us, those days have passed away; but some twenty years ago, in spite of a large expenditure, it began to be felt by those who knew, that in consequence of the increase of foreign navies, our sea-power was threatened, as now, in consequence of the increase of foreign universities, our brain-power is threatened.

The nation slowly woke up to find that its enormous commerce was no longer insured at sea, that in relation to foreign navies our own had been suffered to dwindle to such an extent that it was no longer capable of doing the duty which the nation expected of it even in times of peace. At first, this revelation was received with a shrug of incredulity, and the peace-at-any-price party denied that anything was needed; but a great teacher arose;[1] as the facts were inquired into the suspicion changed into an alarm; men of all parties saw that something must be done. Later, the nation was thoroughly aroused, and with an universal agreement the principle was laid down that, cost what it might to enforce our sea-power, our Navy must be made and maintained of a strength greater than those of any two possibly contending Powers. After establishing this principle, the next thing to do was to give effect to it. What did the nation do after full discussion and inquiry? A Bill was brought in in 1888, and a sum of 21,500,000*l.* was voted in order, during the next five years, to inaugurate a large ship-building programme, so that Britain and Britain's commerce might be guarded on the high seas in any event.

Since then we have spent 120,000,000*l.* on new ships, and this year we spend still more millions on still more new ships. If these prove insufficient to safeguard our sea-power, there is no doubt that the nation will increase them, and I have not heard that anybody has suggested an appeal to private effort.

How, then, do we stand with regard to universities, recognising them as the chief producers of brain-power and therefore the equivalents of battleships in relation to sea-power? Do their numbers come up to the standard established by the Admiralty principle to which I have referred? Let us attempt to get a rough-and-ready estimate of our educational position by counting universities as the Admiralty counts battleships. I say rough and ready because we have other helps to greater brain-power to consider besides universities, as the Admiralty has other ships to consider besides ironclads.

In the first place, let us inquire if they are equal in number to those of any two nations commercially competing with us.

In the United Kingdom, we had until quite recently thirteen.[2] Of these, one is only three years old as a teaching university and another is still merely an examining board.

In Germany there are twenty-two universities; in France, under recent legislation, fifteen; in Italy twenty-one. It is difficult to give the number in the United States, because it is clear, from the tables given in the Report of the Commissioner of Education, that some colleges are more important than some universities, and both give the degree of Ph.D. But of universities in title we have 134. Among these, there are forty-six with more than fifty professors and instructors, and thirteen with more than 150. I will take that figure.

Suppose we consider the United States and Germany, our chief commercial competitors, and apply the Admiralty principle. We should require, allowing for population, eight additional universities at the very lowest estimate.

We see, then, that instead of having universities equalling in number those of two of our chief competitors together, they are by no means equal to those of either of them singly.

After this statement of the facts, anyone who has belief in the importance of higher education will have no difficulty in understanding the origin of the present condition of British industry and its constant decline, first in one direction and then in another, since the tremendous efforts made in the United States and Germany began to take effect.

If, indeed, there be anything wrong about the comparison, the error can only arise from one of two sources; either the Admiralty is thoughtlessly and wastefully spending money, or there is no connection whatever between the higher intelligence and the prosperity of a nation. I have already

1 Captain Mahan, of the U.S. Navy, whose book, "On the Influence of Sea-power on History," has suggested the title of my address.

2 These are Oxford, Cambridge, Durham, Victoria, Wales, Birmingham, London, St. Andrews, Glasgow, Aberdeen, Edinburgh, Dublin, and Royal University.

referred to the views of Mr. Chamberlain and Lord Rosebery on this point; we know what Mr. Chamberlain has done at Birmingham; we know the strenuous efforts made by the commercial leaders of Manchester and Liverpool; we know, also, the opinion of men of science.

If while we spend so freely to maintain our sea-power our export of manufactured articles is relatively reduced because our competitors beat us in the markets of the world, what is the end of the vista thus opened up to us? A Navy growing stronger every year and requiring larger votes to guard our commerce and communications, and a vanishing quantity of commerce to guard—a reduced national income to meet an increasing taxation!

The pity is that our Government has considered sea-power alone; that while so completely guarding our commerce, it has given no thought to one of the main conditions on which its production and increase depend: a glance could have shown that other countries were building universities even faster than they were building battleships; were, in fact, considering brain-power first and sea-power afterwards.

Surely it is my duty as your President to point out the danger ahead if such ignoring of the true situation should be allowed to continue. May I express a hope that at last, in Mr. Chamberlain's words, "the time is coming when Governments will give more attention to this matter"?

What will they cost?

The comparison shows that we want eight new universities, some of which, of course, will be colleges promoted to university rank and fitted to carry on university work. Three of them are already named: Manchester, Liverpool, Leeds.

Let us take this number and deal with it on the battleship condition, although a modern university on American or German models will cost more to build than a battleship.

If our present university shortage be dealt with on battleship conditions, to correct it we should expend *at least* 8,000,000*l*. for new construction, and for the pay-sheet we should have to provide (8 × 50,000*l*.) 400,000*l*. yearly for personnel and up-keep, for it is of no use to build either ships or universities without manning them. Let us say, roughly, capitalising the yearly payment at 2½ per cent., 24,000,000*l*.

At this stage, it is important to inquire whether this sum, arrived at by analogy merely, has any relation to our real university needs.

I have spent a year in making inquiries, as full as I could make them, of friends conversant with the real present needs of each of the universities old and new, I have obtained statistics which would fill a volume, and personally I believe that this sum at least is required to bring our university system up to anything like the level which is insisted upon both in the United States and in Germany. Even Oxford, our oldest university, will still continue to be a mere bundle of colleges, unless three millions are provided to enable the university properly so-called to take her place among her sisters of the modern world; and Sir Oliver Lodge, the principal of our very youngest university, Birmingham, has shown in detail how five millions can be usefully and properly applied in that one locality, to utilise for the good of the nation the enthusiasm and scientific capacity which are only waiting for adequate opportunity of development.

How is this money to be raised? I reply without hesitation, *duplicate the Navy Bill of* 1888–9; do at once for brain-power what we so successfully did then for sea-power.

Let 24,000,000*l*. be set apart from one asset, our national wealth, to increase the other, brain-power. Let it be assigned and borrowed as it is wanted; there will be a capital sum for new buildings to be erected in the next five or ten years, the interest of the remainder to go towards increased annual endowments.

There need be no difficulty about allocating money to the various institutions. Let each university make up its mind as to which rank of the German universities it wishes to emulate. When this claim has been agreed to, the sums necessary to provide the buildings and teaching staff of that class of university should be granted without demur.

It is the case of battleships over again, and money need not be spent more freely in one case than in the other.

Let me at once say that this sum is not to be regarded as practically gone when spent, as in the case of a short-lived ironclad. *It is a loan* which will bear a high rate of interest. This is not my opinion merely; it is the opinion of those concerned in great industrial enterprises and fully alive to the origin and effects of the present condition of things.

I have been careful to point out that the statement that our industries are suffering from our relative neglect of science does not rest on my authority. But if this be true, then if our annual production is less by only two millions than it might have been, having two millions less to divide would be equivalent to our having forty or fifty millions less capital than we should have had if we had been more scientific.

Sir John Brunner, in a speech connected with the Liverpool School of Tropical Medicine, stated recently that if we as a nation were now to borrow ten millions of money in order to help science by putting up buildings and endowing professors, we should get the money back in the course of a generation a hundredfold. He added that there was no better investment for a business man than the encouragement of science, and that every penny he possessed had come from the application of science to commerce.

According to Sir Robert Giffen, the United Kingdom as a going concern was in 1901 worth 16,000,000,000*l*.

Were we to put aside 24,000,000*l*. for gradually organising, building and endowing new universities, and making the existing ones more efficient, we should still be worth 15,976,000,000*l*., a property well worth defending by all the means, and chief among these brain-power, we can command.

If it be held that this, or anything like it, is too great a price to pay for correcting past carelessness or stupidity, the reply is that the 120,000,000*l*. recently spent on the Navy, a sum five times greater, has been spent to correct a sleepy blunder, not one whit more inimical to the future welfare of our country than that which has brought about our present educational position. We had not sufficiently recognised what other nations had done in the way of ship building, just as until now we have not recognised what they have been doing in university building.

Further, I am told that the sum of 24,000,000*l*. is less than half the amount by which Germany is yearly enriched by having improved upon our chemical industries, owing to our lack of scientific training. Many other industries have been attacked in the same way since, but taking this one instance alone, if we had spent this money fifty years ago, when the Prince Consort first called attention to our backwardness, the nation would now be much richer than it is, and would have much less to fear from competition.

Suppose we were to set about putting our educational house in order, so as to secure a higher quality and greater quantity of brain-power, it would not be the first time in history that this has been done. Both Prussia after Jena and France after Sedan acted on the view:—

"When land is gone and money spent,
Then learning is most excellent."

After Jena, which left Prussia a "bleeding and lacerated mass," the King and his wise counsellors, among them men who had gained knowledge from Kant, determined, as they put it, "to supply the loss of territory by intellectual effort."

What did they do? In spite of universal poverty, three universities, to say nothing of observatories and other institutions, were at once founded, secondary education was developed, and in a few years the mental resources were so well looked after that Lord Palmerston defined the kingdom in question as "a country of damned professors."

After Sedan, a battle, as Moltke told us, "won by the schoolmaster," France made even more strenuous efforts. The old University of France, with its "academies" in various places, was replaced by fifteen independent universities, in all of which are faculties of letters, sciences, law and medicine.

The development of the University of Paris has been truly marvellous. In 1897–8, there were 12,000 students, and the cost was 200,000*l*. a year.

But even more wonderful than these examples is the "intellectual effort" made by Japan, not after a war, but to prepare for one.

The question is, shall we wait for a disaster and then imitate Prussia and France? or shall we follow Japan, and thoroughly prepare by "intellectual effort" for the industrial struggle which lies before us?

Such an effort seems to me to be the first thing any national or imperial scientific organisation should endeavour to bring about.

Research.

When dealing with our universities, I referred to the importance of research, as it is now generally acknowledged to be the most powerful engine of education that we possess. But education after all is but a means to the end which, from the national point of view, is the application of old and the production of new knowledge.

Its national importance apart from education is now so generally recognised that in all civilised nations except our own means of research are being daily more amply provided for all students after they have passed through their university career, and more than this, for all who can increase the country's renown or prosperity by the making of new knowledge upon which not only commercial progress, but all intellectual advance must depend.

I am so anxious that my statement of our pressing, and indeed imperative, needs in this direction should not be considered as resting upon the possibly interested opinion of a student of science merely, that I must trouble you with still more quotations.

Listen to Mr. Balfour:—

"I do not believe that any man who looks round the equipment of our universities or medical schools, or other places of education, can honestly say in his heart that we have done enough to equip research with all the costly armoury which research must have in these modern days. We, the richest country in the world, lag behind Germany, France, Switzerland and Italy. Is it not disgraceful? Are we too poor or are we too stupid?"[1]

It is imagined by many who have given no thought to the matter that this research should be closely allied with some application of science being utilised at the time. Nothing could be further from the truth; nothing could be more unwise than such a limitation.

Surely all the laws of Nature will be ultimately of service, and therefore there is much more future help to be got from a study of the unknown and the unused than we can hope to obtain by continuing the study of that which is pretty well known and utilised already. It was a King of France, Louis XIV., who first commended the study of the *même inutile*. The history of modern science shows us more and more as the years roll on the necessity and advantage of such studies, and therefore the importance of properly endowing them, for the production of new knowledge is a costly and unremunerative pursuit.

Years ago we had Faraday apparently wasting his energies and time in playing with needles; electricity now fills the world. To-day men of science in all lands are studying the emanations of radium; no research could be more abstract; but who knows what advance in human thought may follow or what gigantic world-transforming superstructure may eventually be raised on the minute foundation they are laying?

If we so organise our teaching forces that we can use them at all stages from the gutter to the university to sift out for us potential Faradays—to utilise the mental products which otherwise would be wasted—it is only by enabling such men to continue their learning after their teaching is over that we shall be able to secure the greatest advantage which any educational system can afford.

It is now more than thirty years ago that my attention was specially drawn to this question of the endowment of research, first by conversations with M. Dumas, the permanent secretary of the Academy of Sciences, who honoured me by his friendship, and secondly by my association with Sir Benjamin Brodie and Dr. Appleton in their endeavours to call attention to the matter in this country. At that time a general scheme of endowment suggested by Dumas was being carried out by Duruy. This took the form of the "École spéciale des Hautes Études"; it was what our fellowship system was meant to be—an endowment of the research of post-graduate students in each seat of learning. The French effort did not begin then.

I may here tell, as it was told me by Dumas, the story of Léon Foucault, whose many discoveries shed a glory on France, and revived French industry in many directions.[2] In 1851, when Prince Napoleon was President of the Republic, he sent for Dumas and some of his colleagues and told them that during his stay in England, and afterwards in his study of the Great Exhibition of that year, he had found there a greater industrial development than in France, and more applications of science, adding that he wished to know how such a state of things could be at once remedied. The answer was that new applications depended upon new knowledge, and that therefore the most direct and immediate way was to find and encourage men who were likely by research in pure science to produce this new knowledge. The Prince President at once asked for names; that of Léon Foucault was the only one mentioned during the first interview.

Some time afterwards, to be exact at about 11 in the morning of December 2, Dumas's servant informed him that there was a gentleman in the hall named Foucault who wished to see him, and he added that he appeared to be very ill. When shown into the study, Foucault was too agitated to speak, and was blind with tears. His reply to Dumas's soothing questions was to take from his pockets two rolls of bank notes amounting to 200,000 francs and place them on the table. Finally, he was able to say that he had been with the Prince President since 8 o'clock that morning discussing the possible improvement of French science and industry, and that Napoleon had finally given him the money requesting him to do all in his power to aid the State. Foucault ended by saying that on realising the greatness of the task thus imposed upon him, his fears and feelings had got the better of him, for the responsibility seemed more than he could bear.[1]

The movement in England to which I have referred began in 1872, when a society for the organisation of academical study was formed in connection with the inquiry into the revenues of Oxford and Cambridge, and there was a famous meeting at the Freemasons' Tavern, Mark Pattison being in the chair. Brodie, Rolleston, Carpenter, Burdon-Sanderson, were among the speakers, and the first resolution carried was, "That to have a class of men whose lives are devoted to research is a national object." The movement died in consequence of the want of sympathy of the university authorities.[2]

In the year 1874 the subject was inquired into by the late Duke of Devonshire's Commission, and after taking much remarkable evidence, including that of Lord Salisbury, the Commission recommended to the Government that the then grant of 1000*l.* which was expended, by a committee appointed by the Royal Society, on instruments needed in researches carried on by private individuals should be increased, so that personal grants should be made. This recommendation was accepted and acted on; the grant was increased to 4000*l.*, and finally other societies were associated with the Royal Society in its administration. The committee, however, was timorous, possibly owing to the apathy of the universities and the general carelessness on such matters, and only one personal grant was made; the whole conception fell through.

Meantime, however, opinion has become more educated and alive to the extreme importance of research to the nation, and in 1891 a suggestion was made to the Royal Commission which administers the proceeds of the 1851 Exhibition that a sum of about 6000*l.* a year available for scholarships should be employed in encouraging post-graduate research throughout the whole Empire. As what happened is told in the Memoirs of Lord Playfair, it is not indiscreet in me to state that when I proposed this new form of the endowment of research, it would not have surprised me if the suggestion had been declined. It was carried through by Lord Playfair's enthusiastic support. This system has been at work ever since, and the good that has been done by it is now generally conceded.

It is a supreme satisfaction to me to know that in this present year of grace the national importance of the study of the *même inutile* is more generally recognised than it was during the times to which I have referred in my brief survey, and, indeed, we students are fortunate in having on our side in this matter two members of His Majesty's Government, who two years ago spoke with no uncertain sound upon this matter.

"Do we lack the imagination required to show what these apparently remote and abstract studies do for the happiness of mankind? We can appreciate that which obviously and directly ministers to human advancement and felicity, but seem,

1 NATURE, May 30, 1901

2 See *Proc. R.S.* vol. xvii., p. lxxxiii.

1 In order to show how history is written, what actually happened on a fateful morning may be compared with the account given by Kinglake:—"Prince Louis rode home and went in out of sight. Then for the most part he remained close shut up in the Elysée. There, in an inner room, still decked in red trousers, but with his back to the daylight, they say he sat bent over a fireplace for hours and hours together, resting his elbows on his knees, and burying his face in his hands" ("Crimean War," i. p. 245).

2 See NATURE, November and December, 1872.

somehow or another, to be deficient in that higher form of imagination, in that longer sight, which sees in studies which have no obvious, necessary, or immediate result the foundation of the knowledge which shall give far greater happiness to mankind than any immediate, material, industrial advancement can possibly do; and I fear, and greatly fear, that, lacking that imagination, we have allowed ourselves to lag in the glorious race run now by civilised countries in pursuit of knowledge, and we have permitted ourselves so far to too large an extent to depend upon others for those additions to our knowledge which surely we might have made for ourselves."—*Mr. Balfour*, NATURE, May 30, 1901.

"I would remind you that all history shows that progress—national progress of every kind—depends upon certain individuals rather than upon the mass. Whether you take religion, or literature, or political government, or art, or commerce, the new ideas, the great steps, have been made by individuals of superior quality and genius who have, as it were, dragged the mass of the nation up one step to a higher level. So it must be in regard to material progress. The position of the nation to-day is due to the efforts of men like Watt and Arkwright, or, in our own time, to the Armstrongs, the Whitworths, the Kelvins, and the Siemenses. These are the men who, by their discoveries, by their remarkable genius, have produced the ideas upon which others have acted and which have permeated the whole mass of the nation and affected the whole of its proceedings. Therefore what we have to do, and this is our special task and object, is to produce more of these great men."—*Mr. Chamberlain*, TIMES, January 18, 1901.

I finally come to the political importance of research. A country's research is as important in the long run as its battleships. The most eloquent teaching as to its national value we owe to Mr. Carnegie, for he has given the sum of 2,000,000*l.* to found a system of endowments, his chief purpose being, in his own words, "to secure if possible for the United States of America leadership in the domain of discovery and the utilisation of new forces for the benefit of man."

Here is a distinct challenge to Britain. Judging by experience in this country, in spite of the magnificent endowment of research by Mond and Lord Iveagh, the only sources of possible competition in the British interest is the State, which certainly could not put the 1/8000 part of the accumulated wealth of the country to better use, for without such help both our universities and our battleships will become of rapidly dwindling importance.

It is on this ground that I have included the importance of endowing research among the chief points to which I have been anxious to draw your attention.

The Need of a Scientific National Council.

In referring to the new struggle for existence among civilised communities, I pointed out that the solution of a large number of scientific problems is now daily required for the State service, and that in this and other ways the source and standard of national efficiency have been greatly changed.

Much evidence bearing upon the amount of scientific knowledge required for the proper administration of the public departments and the amount of scientific work done by and for the nation was brought before the Royal Commission on Science presided over by the late Duke of Devonshire now more than a quarter of a century ago.

The Commission unanimously recommended that the State should be aided by a scientific council in facing the new problems constantly arising.

But while the home Government has apparently made up its mind to neglect the advice so seriously given, it should be a source of gratification to us all to know that the application of the resources of modern science to the economic, industrial and agricultural development of India has for many years engaged the earnest attention of the Government of that country. The Famine Commissioners of 1878 laid much stress on the institution of scientific inquiry and experiment designed to lead to the gradual increase of the food-supply and to the greater stability of agricultural outturn, while the experience of recent years has indicated the increasing importance of the study of the economic products and mineral-bearing tracts.

Lord Curzon has recently ordered the heads of the various scientific departments to form a board, which shall meet twice annually, to begin with, to formulate a programme and to review past work. The board is also to act as an advisory committee to the Government,[1] providing among other matters for the proper coordination of all matters of scientific inquiry affecting India's welfare.

Lord Curzon is to be warmly congratulated upon the step he has taken, which is certain to bring benefit to our great dependency.

The importance of such a board is many times greater at home, with so many external as well as internal interests to look after, problems common to peace and war, problems requiring the help of the economic as well as of the physical sciences.

It may be asked, What is done in Germany, where science is fostered and utilised far more than here?

The answer is, there is such a council. I fancy very much like what our Privy Council once was. It consists of representatives of the Ministry, the universities, the industries, and agriculture. It is small, consisting of about a dozen members, consultative, and it reports direct to the Emperor. It does for industrial war what military and so-called defence councils do for national armaments: it considers everything relating to the use of brain-power in peace, from alterations in school regulations and the organisation of the universities, to railway rates and fiscal schemes, including the adjustment of duties. I am informed that what this council advises generally becomes law.

It should be pretty obvious that a nation so provided must have enormous chances in its favour. It is a question of drilled battalions against an undisciplined army, of the use of the scientific spirit as opposed to the hope of "muddling through."

Mr. Haldane has recently reminded us that "the weapons which science places in the hands of those who engage in great rivalries of commerce leave those who are without them, however brave, as badly off as were the dervishes of Omdurman against the Maxims of Lord Kitchener."

Without such a machinery as this, how can our Ministers and our rulers be kept completely informed on a thousand things of vital importance? Why should our position and requirements as an industrial and thinking nation receive less attention from the authorities than the headdress of the Guards? How, in the words of Lord Curzon,[2] can "the life and vigour of a nation be summed up before the world in the person of its sovereign" if the national organisation is so defective that it has no means of keeping the head of the State informed on things touching the most vital and lasting interests of the country? We seem to be still in the Palæolithic age in such matters, the chief difference being that the sword has replaced the flint implement.

Some may say that it is contrary to our habit to expect the Government to interest itself too much or to spend money on matters relating to peace; that war dangers are the only ones to be met or to be studied.

But this view leaves science and the progress of science out of the question. Every scientific advance is now, and will in the future be more and more, applied to war. It is no longer a question of an armed force with scientific corps, it is a question of an armed force scientific from top to bottom. Thank God the Navy has already found this out. Science will ultimately rule all the operations both of peace and war, and therefore the industrial and the fighting population must both have a large common ground of education. Already it is not looking too far ahead to see that in a perfect State there will be a double use of each citizen, a peace use and a war use, and the more science advances the more the old difference between the peaceful citizen and the man at arms will disappear; the barrack, if it still exists, and the workshop will be assimilated, the land unit, like the battleship, will become a school of applied science, self-contained, in which the officers will be the efficient teachers.

I do not think it is yet recognised how much the problem of national defence has thus become associated with that with which we are now chiefly concerned.

These, then, are some of the reasons which compel me to point out that a scientific council, which might be a scientific committee of the Privy Council, in dealing primarily with the national needs in times of peace, would be a source of strength to the nation.

To sum up, then. My earnest appeal to you is to gird up your loins and see to it that the science of the British Empire

[2] *Times*, September 30, 1902.

New Series of Single-Pivot MOVING-COIL

GALVANOMETERS.

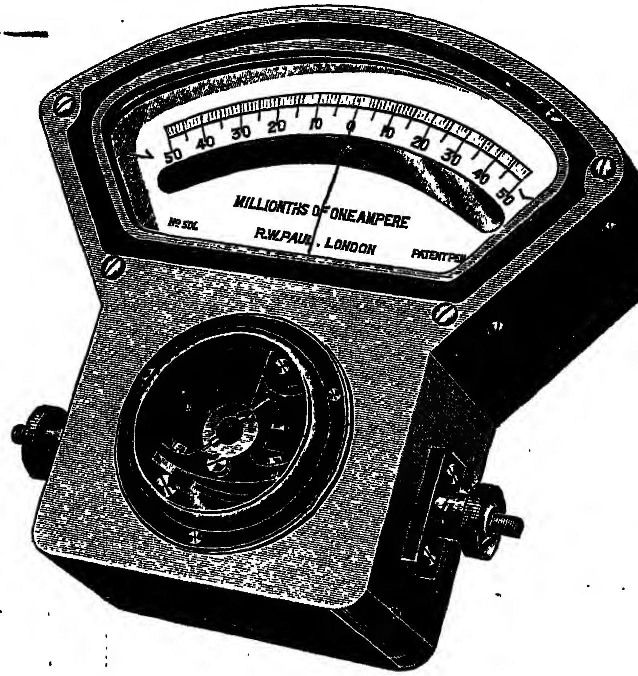
Three Patterns:

Portable, Sector and Vertical Scale.

SUPERSEDING
REFLECTING GALVANOMETERS
for many purposes.

**Reading in MICRO-AMPERES,
Milli-volts, Megohms,
Degrees Centigrade, &c.**

NO SUSPENSIONS OR DELICATE PARTS.



WRITE FOR PARTICULARS.

Robt. W. PAUL, 68 High Holborn, London, W.C.

AND AT NEWTON AVENUE WORKS, NEW SOUTHGATE, N.

THE

KAMMATOGRAPH.

A FILMLESS CINEMATOGRAPH.

500–600 Pictures on one Glass Plate.

The apparatus serves both to take and show these pictures life-size.

☞ NATURE says:—"The camera is very compact, and both as regards price and adaptability is within the reach of any photographer who wishes to secure pictures of rapidly changing scenes and moving objects."

SPECIALITIES MANUFACTURED BY US:—

OXYGEN AND ACETYLENE GENERATORS, PROJECTING LANTERNS, ARC LAMPS, RESISTANCES, AND OTHER SCIENTIFIC APPARATUS.

☞ *Catalogue post free to readers of* NATURE.

L. KAMM & CO., Scientific Engineers and Manufacturers,
27 POWELL STREET, LONDON, E.C.

X-RAY, &c. APPARATUS

OF THE HIGHEST QUALITY AND FINISH ONLY.

As supplied by us to H.M. Government and the leading Hospitals and Workers throughout the World.

We are the ACTUAL MANUFACTURERS, and Guarantee every Coil against breaking down.

LESSONS IN X-RAY, HIGH FREQUENCY, &c. WORK.

COX'S

"Pedestal" Pattern

HIGH FREQUENCY OUTFIT,

as used at the Middlesex and many other hospitals. With Drawer for Electrodes. Price £12. Special Insulated Handle with set of Electrodes for same, £4 10s.

N.B.—Our **INDUCTION COILS** and **APPARATUS** are not only less costly than other makers', but give results unexcelled by any of them.

☞ *Our Illustrated List with Instructions upon How to Work is out of print. A New and Enlarged Edition will be ready shortly, and applications are invited for its receipt free by post on publication.*

HARRY W. COX, LTD.,

FACTORY AND OFFICES:

9, 10 & 11 CURSITOR STREET, CHANCERY LANE, LONDON

R. CLAY AND SONS, LTD., BREAD ST. HILL, E.C., AND BUNGAY, SUFFOLK.

shall no longer remain unorganised. I have endeavoured to point out to you how the nation at present suffers from the absence of a powerful, continuous, reasoned expression of scientific opinion, urging in season and out of season that we shall be armed as other nations are with efficient universities and facilities for research to uphold the flag of Britain in the domain of learning and discovery, and what they alone can bring.

I have also endeavoured to show how, when this is done, the nation will still be less strong than it need be if there be not added to our many existing councils another, to secure that, even during peace, the benefits which a proper coordination of scientific effort in the nation's interest can bring shall not be neglected as they are at present.

Lest some of you may think that the scientific organisation which I trust you will determine to found would risk success in working on such large lines, let me remind you that in 1859, when the late Prince Consort occupied this chair, he referred to "impediments" to scientific progress, and said, "they are often such as can only be successfully dealt with by the powerful arm of the State or the long purse of the nation."

If the Prince Consort had lived to continue his advocacy of science, our position to-day would have been very different. His early death was as bad for Britain as the loss of a great campaign. If we cannot regain what we have lost, matters cannot mend.

I have done what I feel to be my duty in bringing the present condition of things before you. It is now your duty, if you agree with me, to see that it be put right. You can if you will.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY CHARLES VERNON BOYS, F.R.S., PRESIDENT OF THE SECTION.

THE first duty of every occupant of this Chair is a sad one. Year by year the record grows of those who have devoted their lives to the development of mathematical and physical science, of those who have completed their work. The past year has added many names to the record—more, it seems, than its fair share. The names include some of the most brilliant and active of our race, of those to whom this Association is deeply indebted, and also of our fellow workmen in other countries whose loss is no less to be deplored.

Lord Salisbury's devotion to the empire, of which this is not the occasion to speak, left him but little time for those scientific pursuits in which he took so keen an interest. Once, however, as President of this Association, he showed our members that, unlike the majority of our statesmen, science was not to him a phantom. His Address at Oxford will remain in the memories of all who heard it. The eloquence, the humour, the satire, the subtlety provided an intellectual treat of the rarest kind.

Of Sir George Gabriel Stokes and his work it is not possible for me to speak. Any attempt on my part to appreciate or gauge the value of the work of such a giant would be an impertinence. This can only fitly be done by one of our leaders, and Lord Kelvin has paid a fitting tribute in the pages of NATURE. I can only record the fact that Stokes was for seven years Secretary, and twice President of this Section, and in 1869 was President of the Association.

Dr. Gladstone, for fifty-three years a member of this Association, was not only an unfailing attendant at our meetings, but an active member whose steady stream of original communications on subjects connecting physics and chemistry earned for him the designation of Creator of Physical Chemistry. His investigations on spectroscopy, refractivity and electrolytics are known to every student of physics. His researches upon early metallurgical history, while of less importance to the progress of science, are none the less interesting. An ardent apostle of education, he was for twenty-one years a member of the London School Board, and three years vice-chairman. Dr. Gladstone was the first President of the Physical Society. He has been President of the Chemical Society, and at the last meeting of the British Association at Southport—as also in 1872—he was President of the Chemical Section. So long ago, he said, in urging the importance of science as a factor in education, that the so-called educated classes were not only ignorant of science, but had not arrived at the knowledge of their own ignorance.

It is not possible to pass on without paying a tribute, in which all who knew Dr. Gladstone will share, to his character no less than to his genius.

Sir William Roberts-Austen was probably one of the most active members that this Association has known. Not only had he for many years made the subject of metals and alloys his own, but he worked for the Association in many ways. At three meetings have audiences been charmed by his fascinating and brilliant evening lectures, all relating to metals. He was President of the Chemical Section at the Cardiff meeting in 1891, and not only did he perform these duties, but he accepted the more laborious and more thankless task, for which his unfailing courtesy and tact so well fitted him, of acting as our General Secretary for four years. His labours in the important field of research which he tilled were appreciated by numerous technical societies and institutions of which he was an honorary member, or had been president or vice-president. Many branches of the public service had the advantage of his skill and experience, which received the official reward in 1899.

Dr. Common's skill as a designer and constructor of instruments was well known. His instinct or judgment in producing planes and figured concave mirrors of great dimensions was rare, for this is an art almost unknown in the laboratory. His generosity and his valuable advice have been appreciated by many besides myself.

Rev. H. W. Watson, Second Wrangler and Smith's Prizeman in 1850, was a Vice-President of the British Association in 1886. Mathematical physicists are familiar with the joint work of himself and Burbury on "Generalised Co-ordinates," and with his mathematical articles.

In Otto Hilger, the brother of the late Adam Hilger, who between them brought to this country German thoroughness and French skill in instrument manufacture, we have lost one of our first and most valuable constructors. Noted for the high class of all the optical work turned out by the firm, Otto Hilger was not afraid of attacking the problem of manufacturing the Michelson echelon grating. This little bundle of glass plates requires for its success perfection and precision commensurable only with the genius of the inventor. This Otto Hilger supplied.

Dean Farrar, a life member of the British Association, whose activity lay in another direction, showed his appreciation of the value of science in education by appointing the first science master at Marlborough when he became headmaster in the year 1870. As I was a boy at the school at that time, I can speak of the incredulity with which such an announcement was at first received and of the general feeling that such an action was akin to a joke. I was, however, by no means the only boy who hailed the news with delight. We devoured the feast of chemistry and physics put before us by Rodwell and the books which at once became available. Out of gratitude to the late Dean of Canterbury I recall this episode.

James Wimshurst, the inventor of the influence machine which has carried his name into every corner of the scientific world, was not a member of this Association, but he fostered and encouraged the scientific spirit in young men who, by good fortune, came to know him. I do not think I have heard anyone spoken of with such gratitude and appreciation as Wimshurst, by men who in their younger days were allowed the run of his well-equipped workshop.

James Glaisher, best known as a balloonist in the sixties, has died at the great age of ninety-three. The balloon ascent with Coxwell on September 5, 1862, when they attained the altitude of 37,000 feet, will long remain in the popular imagination, not on account simply of the great altitude, but by reason of the sensational account of their having been paralysed with cold, and of their being able to stop the ever-increasing ascent only by the presence of mind of Coxwell, who, with his limbs frozen, seized the valve rope with his teeth, and so let out the gas.

While this event remains in everyone's mind, the more prosaic work of Glaisher in astronomy, meteorology, and photography, when most of us were children, and many yet unborn, led to his being elected president of various learned societies.

He gave one of the evening lectures of the British Association in 1863, the subject being balloon ascents.

A. F. Osler, the inventor of the self-recording direction and pressure anemometer and rain gauge, whose active meteorological work was carried out in the first half of the last century, when he contributed papers to the British Association and the Literary and Philosophical Society of Birmingham, has died at the still greater age of ninety-five. He was Vice-President of the British Association in 1865.

Of other countries, America has lost Prof. J. Willard Gibbs, a mathematical physicist whose very learned and original contributions to the knowledge of the world on the thermodynamical properties of bodies, on vectors, the kinetic theory of gases, and other abstruse subjects, have received the highest recognition that the learned societies of this country can bestow. Prof. Harkness, the astronomer, and Prof. Rood, the skilled experimental physicist of Troy, have also maintained the high standard that we now look for in American science.

Germany has lost Prof. Deichmüller, Professor of Astronomy at Bonn, at an early age. Sweden has lost Prof. Bjerknes, whose hydrodynamical experiments showing attraction and repulsion were so much admired when he performed them at a meeting of the Physical Society some twenty-five years ago. Switzerland has lost Prof. C. Dufour, the astronomer; and Italy has lost Prof. Luigi Cremona, a foreign member of this Association, Principal of the Engineering School in Rome, whose contributions to pure geometry and to its applications have made him famous.

Of the events of the last year, one stands out beyond all others, not only for its intrinsic importance and revolutionary possibilities, but for the excitement that it has raised among the general public. The discovery by Prof. and Madame Curie of what seems to be the everlasting production of heat in easily measurable quantity by a minute amount of a radium compound is so amazing that, even now that many of us have had the opportunity of seeing with our own eyes the heated thermometer, we hardly are able to believe what we see. This, which can barely be distinguished from the discovery of perpetual motion, which it is an axiom of science to call impossible, has left every chemist and physicist in a state of bewilderment. Added to this, Sir William Crookes has devised an experiment, characteristic of him, if I may say so, in which a particle of radium keeps a screen bombarded for ever, so it seems, each collision producing a microscopic flash of light, the dancing and multitude of which forcibly compel the imagination to follow the reasoning faculties, and realise the existence of atomic tumult. Thanks to the industry and genius of J. J. Thomson, Rutherford and Soddy, Sir William and Lady Huggins, Dewar and Ramsay, and others in this country, besides Prof. and Madame Curie and a host of others abroad, this mystery is being attacked, and theories are being invented to account for the marvellous results of observation; but the theories themselves would a few years ago have seemed more wonderful and incredible than the facts, as we believe them to be, do to-day. An atom of radium can constantly produce an emanation, that is something like a gas, which escapes and carries with it wonderful properties; but the atom, the thing which cannot be divided, remains, and retains its weight. The emanation is truly wonderful. It is self-luminous, it is condensed by extreme cold and vaporises again; it can be watched as it oozes through stopcocks or hurries through tubes, but in amount it is so small that it has not yet been weighed. Sir William Ramsay has treated it with a chemical cruelty that would well-nigh have annihilated the most refractory or permanent known element; but this evanescent emanation comes out of the ordeal undimmed and undiminished.

Not content with manufacturing so remarkable a substance, the radium atom sends out three kinds of rays, one kind being much the same as Röntgen rays, but wholly different in ionising power, according to the experiments of Strutt. Each of these consists of particles which are shot out, but they have different penetrative power; they are differently deflected by magnets and also by electricity, and the quantity of electricity in relation to the weight is different, and yet the atom, the same atom, remains unchanged and unchangeable. Not only this, but radium or its emanations or its rays must gradually create other bodies different from radium, and thus, so we are told, one at least of those new gases which but yesterday were discovered has its origin.

Then, again, just as these gases have no chemical properties, so the radium which produces them in some respects behaves in a manner contrary to that of all proper chemicals. It does not lose its power of creating heat even at the extreme cold of liquid air, while at the greater degree of cold of liquid hydrogen its activity is found by Prof. Dewar to be actually greater.

Unlike old-fashioned chemicals which, when they are formed, have all their properties properly developed, radium and its salts take a month before they have acquired their full power (so Dewar tells us), and then, for anything we know to the contrary, proceed to manufacture heat emanations, three kinds of rays, electricity, and gases for ever. For ever; well, perhaps not for ever, but for so long a time that the loss of weight in a year, calculated, I suppose, rather than observed, is next to nothing. Prof. Rutherford believes that thorium or uranium, which act in the same kind of way, but with far less vigour, would last a million years before there was nothing left, or at least before they were worn out; while the radium, preferring a short life and a merry one, could not expect to exist for more than a few thousand years.

In this time one gramme of radium would evolve one thousand million heat units, sufficient, if converted into work, to raise five hundred tons a mile high; whereas a gramme of hydrogen, our best fuel, burned in oxygen, only yields thirty-four thousand heat-units, or one thirty-thousandth part of the output of radium. I believe that this is no exaggeration of what we are told and of what is believed to be experimentally proved with regard to radium; but if the half of it is true the term "the mystery of radium" is inadequate: the miracle of radium is the only expression that can be employed.

With all this mystery before us, which I must confess myself wholly unable to follow, I feel sure that members of the Association who are interested in the work of this Section will welcome the discussion, for which our secretaries have been able to arrange, and hear from the lips of Prof. Rutherford the conclusions to which his researches have at present brought him. No one is more fitted than Prof. Rutherford to open such a discussion, for no one has attacked the theoretical side with such originality and daring, or with such ingenuity of experiment.

As an example of the activity of mind and of research to which the activity of radium has given rise, I may mention the fact that the last number of the *Proceedings* of the Royal Society is wholly concerned with radium, there being four papers, all of the first importance, dealing with entirely different phenomena.

It is not my purpose to review these or the subject of radium generally; I am in no way fitted to do so. But I cannot well let the present opportunity pass of referring to another mystery of which a conspicuous example is now leaving us. I refer to the mystery of the comet and its tails. What is a comet? of what does its tail consist? Gravitational astronomy has told us for many years past that compared with the planets or their satellites a comet does not weigh anything. It weighs pounds or perhaps hundreds, thousands, or millions of tons; but in comparison with inconspicuous satellites it weighs nothing. Yet some of them as they approach the sun from remote regions begin to shoot out streamers which pour away as though repelled by the sun, not being left as a trail behind the comet, as is so often supposed. These streamers, ejected towards the sun, bend round and pour away at speeds which are enormous compared with that of the comet itself, thus producing the tail. Now these streams separate very often, and give rise to comets with two or three tails. Let me read one paragraph from "The History of Astronomy," by Miss Clerke:—

"The amount of tail curvature, he [Olbers] pointed out, depends in each case upon the proportion borne by the velocity of the ascending particles to that of the comet in its orbit; the swifter the outrush the straighter the approaching tail. But the velocity of the ascending particles varies with the energy of their repulsion by the sun, and this again, it may be presumed, by their quality. Thus multiple tails are developed when the same comet throws off, as it approaches perihelion, specifically distinct substances. The long straight ray which proceeded from the comet of 1807,

for example, was doubtless made up of particles subject to a much more vigorous solar repulsion than those formed into the shorter curved emanation issuing from it nearly in the same direction. In the comet of 1811 he calculated that the particles expelled from the head travelled to the remote extremity of the tail in eleven minutes, indicating by this enormous rapidity of movement (comparable to that of the transmission of light) the action of a force much more powerful than the opposing one of gravity. The not uncommon phenomena of multiple envelopes, on the other hand, he explained, are due to the varying amounts of repulsion exercised by the nucleus itself on the different kinds of matter developed from it."

It is impossible not to be struck by the similarity both of phenomenon described and of language used in this paragraph and in almost any of the papers on radium. I know this mere superficial similarity is worth very little, if anything; but for centuries the sky has shown us a phenomenon still not entirely understood, and the inability to remove all difficulty by the aid of radium or similar material is no reason for dismissing the idea of connection without further thought.

The comet's tail is still a mystery. Let me take the most recent explanation, which was set forth only three months ago in the *Astrophysical Journal* in the United States. Those admirable experimentalists Nichols and Hull have for some years been investigating the back pressure exerted by the action of light upon bodies on which it falls. In this they have followed the Russian physicist Lebedew, but in minuteness and delicacy of measurement, and in their successful elimination of disturbances, their results are unequalled. It is sufficient to say that, difficult and minute as the experiment is, their success is such that the discrepancy between the calculated force and that which they have found is under 1 per cent. Perhaps I may express some satisfaction that in this measurement use was made of the quartz fibre.

Having now definite and accurate confirmation of the existence of the force produced by the action of light, or rather radiation, Nichols and Hull proceed to examine the question as to how far such repulsion may be competent to overcome the gravitative attraction of the sun and drive away the matter which pours out from the comet. It is interesting to note here that Kepler put forward this very idea, and that Newton, the inventor of the corpuscular theory of light, looked upon the suggestion with some favour.

Coming now to this recent paper of Nichols and Hull, we find first the consideration of the relation of the attraction by gravitation, and the repulsion by light upon particles of different sizes and densities. Density has no influence on the action of light, while it is favourable to gravitation, and therefore unfavourable to tail formation. Size is favourable to both, but more to gravitation than to light, for if the diameter of a particle be doubled, one is increased eightfold and the other only four. So size favours gravitational attraction. Conversely, of course, smallness favours repulsion by light, which relatively should get greater and greater as the particles diminish in size. At last, then, a degree of smallness may be reached in which the repulsion by light will actually be equal to the attraction by gravitation, and such a particle would remain in space, its motion unaffected by our sun. Let the diminution of size continue, and then the repulsion will be in excess, and if the law were to continue it would with sufficient diminution become relatively as large as we please.

The law, however, does not continue. Schwarzschild has shown that when the particles are small enough, light does not act upon them in the same way. Owing to diffraction, the effect of light is unduly great for a certain very small size of particle, while it fails almost entirely when the particle is made much smaller. Thus it is that the indefinite increase in the repulsion by light as compared with the attraction by gravitation with diminution of size of particle is checked, and when, according to theory, with a particular density of particle, the light pressure is about twenty times as great as gravitational attraction, further diminution of size ceases to favour the action of light, and it begins to fall off again. The distance of the particle from the sun has no influence upon the relation between the two kinds of forces, for they rise and fall together. Nichols and Hull, therefore, while not denying that other causes may operate, believe that light pressure is adequate to account for the phenomena, and that where the material coming from the head or comet proper is of two or three kinds, whether of density or of size of particle, the separation of the two or three tails should naturally follow.

This theory presupposes that the nucleus of a comet will be able, owing to the evolution of gas under the sun's heat, to send out enormous quantities of dust, the finer and lighter the better, so long as it is not unduly small with respect to a wave-length of light. Such dust would account for any reflected solar light that the spectroscope may show, but it is not easy to see how the spectrum of hydrocarbons, of sodium, and of other metal, should be produced for lack of temperature. It is not easy to see why fortuitous dust should be graded of such sizes as to give well separated and defined tails; it is not easy to see how the dust could be produced in sufficient quantity to provide visible illumination to millions of millions of cubic miles of space through which it may be passing at ultra-planetary velocity, even though in looking through a million miles or so one grain of dust in a hundred miles might suffice to supply the light.

Other theories of the comet's tail require an electrified sun, the existence of which is explained by Arrhenius as being caused by the emission by the sun of negatively charged electrons which, picking up condensing gases as Aitken's dust picks up moisture from the atmosphere, are driven away by the light pressure. Arrhenius believes that these acting on the matter in the tail would give rise to the bright line spectra which have been observed. The result of all this escape of negative electricity is a positively charged sun, but what limits the charge in the sun it is as difficult to see, as it is, why the electrostatic attraction helped by gravitation does not ultimately stop the action. I may be displaying my ignorance, of which I am sufficiently sensible, but I am not aware of any evidence for the existence of the stream of electrified grains or drops imagined by Arrhenius.

Nichols and Hull, while calling to their aid the researches of Schwarzschild to give them a repulsive force some twenty times as great as gravitative attraction, do not seem to have given due weight to the extremely small range of size of particle for which this high effect is available. The maximum effect for any wave-length according to Schwarzschild is produced, when the size is such that a wave-length will just reach round it; that is, with ordinary light when the diameter is between one hundred thousandth and one hundred and fifty thousandth of an inch. If the diameter is two-and-a-half times the wave-length the action of light is only equal to gravity with a material of the density of water; or again, if it is reduced to one-eighth of a wave-length it again becomes equal, and in these two cases there is no resultant action. With either larger or smaller particles gravity rapidly gets the better of light, while the high advantage of light over gravity is confined to very narrow limits.

What the sifting process can be that will give rise to such a quantity of this microscopic dust we can hardly expect to be told, nor why even if the material should in some mysterious way be graded, the ungraded wave-lengths of the solar spectrum should allow of the marked separation in some instances of comets' tails.

One thing, however, they do assert, and that is that the light pressure can have no action on a gas, so that if what we see is considered to be gaseous the light pressure theory must be thrown over for some other.

I cannot leave this excursion of Nichols and Hull into a speculative domain of science without expressing my admiration of the experimental work which they have accomplished, and my appreciation of the ingenuity and daring with which they have attempted the hitherto unheard-of feat of making a comet.

While the theory just referred to may be the most recent it must not on that account be supposed to displace all that has gone before; the authors themselves do not suggest this; it is the last thing that would occur to them. They have referred to the researches of Bredechin that occupy so large a proportion of the annals of the Observatory of Moscow.

It is impossible to read even a tithe of these without feeling that the subject of comets and their tails is one which

Bredechin, by his amazing industry, has made his own property, and that any stranger casually passing by and taking a random shot should receive the severe penalty awarded to poachers in this country. Bredechin has dealt unmercifully —I do not say unjustly—with the author of at least one such random theory.

It is therefore with the greater diffidence and more urgent plea for forbearance that I venture to draw certain parallels and hazard certain suggestions which I admit freely have not reached a stage at which detailed comparisons with known comets are possible.

It does not seem possible now to contemplate the phenomena of the comet, of the divided tails, of their tenuity and transparency, of the pale luminosity, partly reflected solar light, partly light as from a glowing gas; of the gradual wearing out and disappearance of those comets which constantly pay visits to solar regions, with all the mysteries of radium now so much in evidence without tracing the features in which they resemble one another. By radium, of course, I mean any material with the remarkable radioactive properties that radium exhibits with such pre-eminent splendour, whether known in the laboratory or not.

How many physicists have been peering at comets through radium spectacles, or how many astronomers detect the sparkle of radium in the fairy tresses of their hirsute stars I know not. One writer, however, T. C. Chamberlin, so long ago as July, 1901, looked upon a connection between radio-active materials such as were then known and comets as at least worth considering. Chamberlin's paper in the *Astrophysical Journal* was mainly on the tidal disruption of gravitating bodies and the possible evolution of comets, nebulæ and meteorites, and he did not pursue this consideration in any detail; indeed, the enormous accumulation of new properties of radium was not then available.

Whatever may be imagined as to the constitution of a comet, difficulties still remain. All I suggest now is that the curious properties of radium and of similar bodies should be kept in mind. Radium at least supplies the means by which, if the increasing warmth or the tidal action of the sun should awaken its activity, Rutherford's α-rays should be shot out at the speed that he has measured of a thousand million inches a second, *i.e.* one-twelfth the velocity of light. These α-rays, according to Rutherford, consist of helium; they weigh each twice as much as a hydrogen atom, and so the same weight of comet matter that would make one of Nichols and Hull's best particles, *i.e.* one that would be just visible with a microscope, would be sufficient for about 400 millions of Rutherford's α-ray particles, an advantage surely where diffuseness seems so miraculous.

These particles, shot out at a velocity one-twelfth that of light, go so fast that, if they were to start horizontally on the surface of the earth, the gravitative attraction of the earth would curve their path to the infinitesimal extent of a curve with a radius of forty thousand million miles. Yet so great is the electric charge they carry that a visible curvature can be imposed upon them in a practicable electrostatic field.

Now imagine these transferred into space at a distance from the sun, for instance, equal to that of Venus. Gravity there due to the sun is only one-thousandth of what it is here, so gravity there would be, to the same extent, less able to impose visible curvature on their paths. But their electric charges are still available, and unless I have made an arithmetical blunder of a considerable order, it would require no very heavy electrification of the sun to bend these rays round in a curve with a radius of 1000 miles. An electrostatic field of under two ten-thousandths of a unit should be sufficient, a field which would be produced if the sun were only charged with a surface density of one electrostatic unit on every three square centimetres.

Whether these figures are correct or not—and I know the risk of getting just thirty thousand million times too large or too small a result—does not much matter. An electrified sun, which after all others besides Arrhenius have postulated, would be sufficient to turn the rays and send them away at rapidly increasing speed so as to form the tail. The speed would in a short time reach the velocity of light if it were not for the change in properties of matter which supervenes when any such velocity is nearly reached. Thus, according to the ratio of charge to mass, particles such as Rutherford's α-rays would be sent away each with its limiting velocity, giving rise to streaks more or less well defined, and double, triple, or multiple according to the number of kinds of ray which the various radio-active materials were able to generate.

Not only should streaks pointing away from the sun be formed, but any negatively charged rays such as radium is said to give out should form a tail directed towards the sun. Perhaps this might be expected to be general, but while not common one was described by Hind in the comet of 1823–24, and three or four more have been observed.

The head or coma would be the envelope of all the independent orbits, leaving the nucleus in all directions—orbits which while their velocities are still of the Rutherford order would be hyperbolas convex to the sun.

If this should not appear to be absolute nonsense it would seem as if another difficulty should become less than it has been. I refer to the visibility, luminosity, and spectral character.

Lodge, as an interpreter of Larmor, tells us that an electrified ion subject to acceleration, whether transverse or in the line of motion, radiates energy. The streamers from the nucleus subject to the greatest acceleration may be bright almost as the nucleus itself; then, as they have become dissipated into regions where far less acceleration becomes possible, the radiation falls off and the tail is lost in space.

The observations made last month by Sir William and Lady Huggins of the spectrum given by a piece of radium in the air may have some bearing upon the luminosity of the comet. It is possible that the internal motions set up by the separate parts, each pursuing its individual orbit, may produce collisions numerous and violent enough to account for all the light that is seen, and for temperature sufficient to bring out the spectral lines that have been identified. Whether this is so or not, radio-active bodies and their emanations can produce light independently of such action; and now these observers have found that in the case of radium in air this light gives the spectrum, line by line, of nitrogen. Is it possible that the enveloping nitrogen has had its atoms so harried by the activity of the radium as to give a response hitherto only awakened by electric discharge? The ability to obtain such a response opens up a new possible interpretation of these spectra, which hitherto have been assumed, with our laboratory experience only to guide us, to have required for their production temperature above a red heat. If further observation should confirm this, the hydrogen, the hydrocarbon, and possibly even the sodium or iron spectrum that has been observed, may have come from cold atoms; and it is not even quite beyond the limits of imagination to picture, not from the comet matter itself, but from loose residual and highly attenuated matter through which the comet is passing.

There is one other feature of this remarkable observation of equal interest. The lines of the spectrum were not exactly in their proper place, but were all shifted towards the red end of the spectrum about twice the distance between the D lines. If only one or two lines had been so observed a different origin might well have been suspected; but when the whole series are faithfully reproduced it is reasonable to look upon the spectrum as modified to that extent as though the works of the nitrogen atom had not only been set in movement, but had been loaded with the radium emanation.

Before dismissing these random speculations on the possible connection between radio-activity and comets I would ask your leave to refer once more to Bredechin's conclusions. He has found that it is merely necessary to postulate three kinds of matter, issuing from the nucleus with three initial velocities, and subject to repulsion from the sun with three sets of forces of repulsion—*i.e.* as compared with ordinary gravitative attraction—for the whole of the phenomena of all sorts of comets to be very completely accounted for. His highest initial velocity is only about five miles a second, and his lowest about a quarter of a mile a second. His highest repulsion, after deducting gravitative attraction, is only eleven times gravity, and his lowest only a fifth of gravity. If, then, with such velocities and forces the phenomena can be exactly accounted for, it would seem futile to consider the possibility of initial velocities from 4000 to 80,000 times as great and effective repulsions of a corresponding order being able to produce effects with anything in common. This is not necessarily the case, for with the comparatively slow separation of the atoms of Bredechin's matter from the nucleus, each one describing its own hyperbola convex

to the sun, the tail at any moment represents the then position of any number of atoms which left the nucleus for some distance back, whereas with the enormous velocities and effective forces now discussed the comet moves so slowly in comparison that the tail would practically represent the path at the time.

It has taken me far longer to throw out this not very luminous ray than I had expected or than it is worth. I fear that it is a sort of ray in which the ratio of its dead weight to its vitalising charge is too small to enable it to penetrate the lightest screen of examination.

These are the days of rays, and now before we have quite become familiar with the rays of radio-active bodies Blondlot has presented us with N rays, which issuing from the mantle of an incandescent gas burner penetrate wood or aluminium, and then increase the light without increasing the heat of hot bodies on which they fall.

Passing now from the amusement of speculation to more serious duties, I find myself confronted with the difficulties that prevent us in this country from succeeding as we used to do in the international struggle—a struggle the issue of which is daily becoming more and more a question of brains, of education, of skill and enterprise in manufacture—and finally of that great virtue extolled by the President of the United States, strenuousness.

It is the duty of everyone who sees the way in which we are being outstripped in the race to do what in him lies to scrape off the rust which is clogging our educational machinery. I now refer to the defects which hamper the intellectual progress of the majority of our youth. I believe the public school mathematics in this country stands on a level of its own, well below that of any other. In England, owing to our complicated system of weights and measures, which our Ministers and our Parliament dare not abolish for our own good, the scanty hours allowed for mathematics are devoted to the learning of tables which should never have to be learned at all, to compound reductions designed merely to puzzle but not to lead to any new step; and, even if our present system were not futile enough, to learning lists of antique values which serve the useful purpose of giving the boys something to do. The result is that beyond having time to acquire a few elementary algebraical rules the boy is never introduced to algebra proper; he has no idea of algebraical reasoning; his trigonometry often does not exist, and the very sound or suggestion of coordinate geometry or of the differential calculus, which might be well within his reach, produces a shiver of dismay. Geometry is presented for the first time in the form of Euclid, a form as repulsive to most boys as it well could be. I must confess to having been attracted and not repelled by Euclid; but the boy does not care for time. Now that I look at Euclid again I have also to confess that any lingering regard for an old friend vanishes before the archaic language and the unnecessary circumlocution. If Euclid must be retained let it be translated into English, the English that any parent would use in explaining the ideas to his son; let it be illustrated by constant reference to real things so as to appeal to the boy who does not revel in the abstract. Let the ideas and the terms first be presented in the form of experiments and of measurements with instruments; let the schoolmaster dare to throw over the intolerable conservatism which prevents our doing anything ten times as well lest some item should prove to be a trifle worse; in fact, let us take some heed of the possibly extreme, but none the less genuine and valuable preaching of Prof. Perry. I have so far referred only to the miserable use that is made of the odd hours grudgingly given to what is called mathematics. Is it any use to repeat the long-standing complaint of the way in which the schoolmaster insists upon overdoing his Latin and Greek under the belief that they are at least essential to intellectual development if, indeed, they do not supply the only stimulus? As society is constituted they are essential to education as an extensive knowledge of Confucius is essential to an educated Chinaman, so that we may mix one with another, appreciate the works of our great authors, understand the same allusions, and have the same kind of knowledge of the development of our civilisation. Few men of science, perhaps none, wish to see all of this, some of which is essential to a general education, abolished; all that we ask is that the schoolmaster shall not continue to impose upon the community the unbalanced learning which corresponds to mathematics and science without letters. The time given to classics is exorbitant; more must be reserved for those pursuits which draw out the habit of independent thought, creation and originality. It would be well if every schoolmaster could read an admirable article by James Swinburne on the two types of mind fostered by the two complementary types of education, but this is buried away in an inaccessible number of the *Westminster Review*.

The classic is unfortunately still in possession, and where, as is still often the case, he is innocent of any appreciation of the educational value of post-Newtonian studies it is not surprising that he thrusts into odd moments the subjects he does not understand, and which he therefore despises, and that the boys committed to his charge and living in such an atmosphere are half ashamed of showing any interest in the scanty science which is within their reach. It is almost impossible to believe that such can be the case, but I have referred to the impression to which the appointment of the first science master at my own school gave rise. I now refer to the contribution to a discussion on education but a year or two ago by that experienced teacher, Principal Griffiths. Fortunately our public schools are not the only ones in the country. Smaller and less fashionable schools pay more attention to education and suffer less from what, in defiance of all rule, I can only call didactatorial method.

I am not aware that the result of this almost total exclusion of tabooed subjects in favour of Latin and Greek is producing a standard of classical attainment in our youth greatly in advance of that to be found in other countries, but it is certain that in history, modern languages, mathematics, and science the product of our public schools is sadly deficient.

There is another point related to our deficient general scientific training on which I wish to offer some remarks, and that is in relation to manufacture. It is the fashion among some of our scientific people to talk of our manufacturers as if they were a very ignorant lot and to suppose that one word from some professor who has never seen outside a laboratory would be sufficient to put them right. Now in my somewhat varied experience I have had occasion to become acquainted with corners of our great manufacturing areas, and while my experience is small and not enough to generalise upon, it is nevertheless several times as great as that of some who are ready to adopt the superior attitude, but have none.

The loss of one industry after another is only too patent. In so far as this may be due to want of enterprise in our men of business we are not concerned with the cause in this Section; in so far as it may be due to want of that little assistance which the fiscal arrangements in other countries make possible for our rivals again we are not concerned in this Section; in so far as our patent laws are unique among those of manufacturing nations in allowing the foreigner to manufacture in his own country under the protection of our patent law, so that the most valuable school we possess, the manufactory, as well as the manufacture, is conducted to the advantage of our rivals—a point which I suppose it is unnecessary to commend to the notice of Mr. Chamberlain—with this, too, we have no concern in this Section; but in so far as this, or the want of enterprise or of foresight that leads to it, is due to ignorance and to want of appreciation of scientific advance we are very much concerned with it. If I may refer to my own limited experience, there is a lamentable contrast in the manner in which a great number of our own countrymen look at any proposition put before them and that in which the alert American does. It is useless to explain that which would be self-evident to a man with a moderate knowledge of chemistry and physics such as our schools ought to supply, or for which they should at least lay the foundation, for the words have no meaning; they are merely words. He distrusts anything new; he has heard of a new process before that did not work out well; experience on the Continent to him is no experience at all, for he believes the inhabitants in such distant parts of the earth are not capable of knowing as well as the enlightened Englishman whether a thing is properly done or not, and so he goes on as he did before, perfectly content. This attitude would not be possible with the most elementary understanding of common principles.

But there is another side to this picture. Anyone who has discussed any scheme with the board of directors, the manager, the engineer, and the chemist of one of our great manufactories must have been struck with the concentrated ability there found in harness. It has often seemed to me that it is a great misfortune that our professors of mechanics, of physics, and of chemistry are in so many instances precluded from a better acquaintance with the working of these great machines—a misfortune not for the works, at least directly, but for the professors, and more especially for their pupils.

Nowhere are scientific problems of greater complexity constantly having to be solved than in a great manufactory; nowhere is such concentrated talent necessary as in a works organised and carried on in competition with all the world. I look upon these as our most valuable schools, and the closer the touch between them and those whose province it is to teach, the better for the teacher and the pupil.

It is, perhaps, hardly desirable to mention any one where there are so many. I am tempted to dwell upon the problem which has been at last successfully solved by Parsons, this being the joint product of the school and of the works; but there is one picture—a contrast, I will not say of light and shade, but of colour and colour—to which I must refer. I remember in my early days, in the surroundings of a classical atmosphere, the general feeling of contempt for the manufacturer, the intellectually inferior creature who only made money, but who knew nothing of τύπτω or τέτυμμαι. I am not sure that some such feeling does not still exist among those whose horizon is limited to the Latin and Greek that they have learned—or should I say limited *by* instead of *to*? This recollection came back to me when not long ago I was visiting one of the best organised and most skilfully conducted works in the country—I mean Willans and Robinson—when I remembered that another great manufactory, conducted on American lines, was near by, and when across the road I saw the walls of one of our most famous English schools. I pictured the old contrast: on the one hand the conviction impressed upon me when a boy that there is something intellectually superior in the struggle with a paragraph of Xenophon or a page of Homer, while manufacture is merely mechanical, sordid and base, with what I believe to be the reality on the other. I wondered in what spirit the erection of these works was viewed at the school and to what extent the high intellectual attainment there so essential and so evident is properly appreciated.

Of the last of the three headings, Strenuousness, we have plenty, but at school it is most apparent in cricket and football, and in after life in various expensive ways of murdering defenceless animals.

However, a change is already beginning to be felt. The public schools no longer withhold the elements of chemistry and physics, and those who have benefited, even in small degree, are taking responsible places vacated by those who had no such opportunity. The numerous polytechnics are providing more serious instruction to thousands of our young men, and it may be hoped that in time even the official—I mean the mere official whose only conception of activity is centred in obstructing progress and enlightenment—will have some appreciation of things as well as of words.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY PROF. SYDNEY J. HICKSON, M.A., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

AT the last meeting of the British Association which was held in Southport, the President of Section D, Prof. E. Ray Lankester, delivered an impressive address on the provision in this country for the advancement of Biological Science, in which he pointed out the very inadequate encouragement which existed at that time for those who, by education and inclination, were fitted to pursue original investigation in Zoology and Botany. Twenty years have passed since that Address was written, and yet we have to acknowledge that, notwithstanding the important part which our branch of Science has played in contributing to the sum of useful human knowledge during the last two decades, the progress made in the direction indicated by Prof. Lankester is far from satisfactory. I do not propose in this Address to make any detailed statement of the number of posts in this country that are now open to zoologists, or of the amount of the present-day endowments for the encouragement of Zoological Science as compared with those of twenty years ago; but I wish to point out that neither in the older Universities of Oxford and Cambridge, nor in the Colleges and National Institutions situated in London, nor in the newer Universities and Colleges of the provinces, have any new posts been created or adequately endowed which enable the holder to devote a reasonable amount of his time to the pursuit of biological knowledge. It is true that there are a few more posts now than there were, in which a small stipend or salary is offered to young trained zoologists for their services as teachers of Elementary Biological Science to medical students and others; but the emoluments of such posts are so small, depending as they do, almost entirely, upon a share of the fees paid by the students, and the duties so arduous and prolonged, that they really offer very little inducement to the pursuit of continuous and systematic original research.

In one respect, however, we may notice and acknowledge, with gratitude, an improvement in our position. In the laboratory accommodation, both in our Universities and on the sea coast, we are a good deal better off than we were. Twenty years ago there was no biological laboratory on the whole of the long line of the British Coast. Now, thanks to the efforts made by biologists and their friends, we have at Plymouth an institution for the study of the marine fauna and flora under favourable conditions, and similar institutions at Port Erin in the Isle of Man, at Piel, at Millport, and at St. Andrews, and a provisional laboratory for the study of fishery problems at Grimsby. New laboratories for the study of zoology have also been built at Oxford, at Cambridge, at the University of Manchester, at Edinburgh University, and elsewhere, and I may add that a fine new laboratory is now in course of construction for the department of Zoology in the University of Liverpool.

These new institutions, however, only emphasise, they certainly do not ameliorate, the weakness of our position in having so little encouragement to offer to competent and well-trained men who wish to devote their lives to the advancement of Zoological Science. Moreover, I would point out that these institutions have been built and are being maintained almost entirely by funds supplied by private benefactors, or out of the inadequate resources of the Universities.

The Treasury has made a provisional grant of 1000*l*. per annum towards the maintenance of the work done by the Marine Biological Association, and it may be supposed that a small share of the annual Government grant made to the University Colleges and Scotch Universities goes to the support of the zoological departments; but, apart from this, there has been no increase in the support given to us from public funds.

If we were to compare our progress in the matter of the public appreciation of our science during the past two years with that in other countries, we should find that our position is by no means satisfactory. In Germany, France, Belgium, Holland, and more particularly in the United States of America, progress has been rapid and continuous. The number of persons in these countries who by the aid of university or public endowments are able to devote themselves to original work in zoology has considerably increased of late years, and the number of magnificently equipped institutions that have been built for their accommodation and convenience makes our efforts in the same direction appear very small.

It would not be difficult for me to bring facts and figures before you in support of these general statements; but my object is not so much to lament over the past and to mourn for the present position of our science in this country, as to suggest directions in which we may work together for its development and progress.

Upon one matter, however, I think we may congratulate ourselves. If the research done by English zoologists has not been as great in amount as it might have been, I think it may be truly said that we have fully maintained its standard as regards quality.

The contributions that have been made to the Science of Zoology by our countrymen during the past twenty years in general interest and in theoretical importance are of such a nature that any civilised race might well be proud of

them, and I venture to say they compare favourably with those of any other country. I may remind you that the discovery and description of the Okapi, Cænolestes, Nyctotherus Rhabdopleura, Cephalodiscus, Limnocodium, and Pelagohydra, the rediscovery of Lepidosiren and Ctenoplana, the most important features of the development of Balanoglossus, Lepidosiren, Amphioxus, Peripatus Hatteria, and some of the Marsupialia, and that the discovery of the important character of the fauna of the deep seas involving the discovery of many new genera and species, were the work of British zoologists. Moreover, that the prolonged and painstaking investigations carried on in our laboratories have thrown much light upon the character and relations of cœlomic cavities, the homologies of the nephridia and genital ducts, and many other important morphological problems.

In the field of evolutionary theories we have done much important work in the study of the facts of protective and aggressive mimicry in insects, in the statistical estimation of variations, and in the experimental inquiry into the value of current theories of heredity.

The list is far from complete; but with such a record of good work done with the scanty means at our disposal there is no reason to suppose that the science is on the decline in this country, or that our countrymen are not as capable as any others of grasping the importance of biological problems and ultimately wresting from Nature the secrets that are hidden.

Whilst we may thus congratulate ourselves upon the achievements of the past and upon our strength and ability to carry on good work in the future, I cannot help feeling that the time has come for us to make a united effort to place before the general public of this country, and more particularly the educated and influential part of it, the disadvantages under which we suffer, and our need for help in the further development of our subject.

We have all realised that in this country, more than in any other that is called civilised, there prevails among all classes an extraordinary ignorance of the first principles of biological science. It is this ignorance on the part of the general public, I believe, which prevents us from gaining that sympathy for our aims and that assistance for our efforts which we think is necessary not only for the reputation, but also for the welfare of our country. We must remember that the science of Natural History is as a closed book to most of those who after a public school and university education have attained to positions of trust and responsibility in the government of our country and our cities. Moreover, and this is perhaps the most serious aspect of the question, there are many who have gained a high position as men of science, and whose opinion is frequently quoted as authoritative on questions affecting science in general, who are more ignorant of the first principles of the science of biology than the Dutch schoolboy of fifteen years of age.

It appears to me, then, that it is of fundamental importance for the zoologists of this country to consider and report upon the necessity for the extension and improvement of the teaching of Natural History in our schools and colleges. We shall have to meet the objections that there is not time for Natural History in the school curricula, and that it is not a suitable subject for the instruction of boys and girls. These objections can be met, I believe, and overcome.

In many foreign countries Natural History is a compulsory school subject for all scholars. In Holland, for example, by the law of April 28, 1876, all scholars of the gymnasia during the first and second years devote two hours per week to the study of Natural History, and in the fifth and sixth years all students preparing for natural, mathematical, and medical sciences courses devote two hours per week to the science. In the superior middle-class schools one hour a week is devoted to the science in the first and second classes, and two hours per week in the remaining three years. If, therefore, time can be found in the middle and upper class schools for the study of Natural History in a country like Holland, where the general education is so excellent, surely time can be found for it here.

It is also a matter for general regret that some course of Elementary Biology is no longer compulsory for those who are proceeding to degrees in science in our universities, and I cannot help feeling that a very retrograde step was taken a few years ago by the authorities of the University of London, when Biology was made an optional subject in the Intermediate Examination for the degree of Bachelor of Science. We cannot expect to receive that sympathy in our pursuits and appreciation of our discoveries which we expect from our fellow-men of science if we tacitly admit that an elementary knowledge of the laws of living bodies is not a necessary part of the equipment of a man of scientific culture.

I think we must all admit that the time is ripe for a full discussion by biologists of the particular form of teaching and study which is most suitable for schools and elementary university examinations. It is a matter in which we are all interested; it is a matter affecting most intimately the interests of those who will be our pupils in the future, and we should be careful to see that no ill-considered or fantastic schemes of study are thrust upon the authorities by unauthorised persons at this very critical period in the educational history of our country.

There are other matters, however, which also demand our careful attention. The growth of our great cities and the improvement in our ideas of sanitation have brought forward as important problems for consideration the purity of the water-supply and the disposal of sewage. The municipal authorities at last realise that these problems can only be satisfactorily met by elaborate scientific investigation, and they have found that it is not only desirable for sanitary reasons, but also—and this has probably the greater weight—profitable to call in men of science for consultation and advice. At present, however, these problems are approached from only two points of view—the chemical and the bacteriological—the effect or effects of other organisms than bacteria upon the character of the sewage effluent and the purity of water for drinking purposes being, so far as I have observed, neglected. I was very much impressed with the fact that at the meeting of the Sanitary Institute last year in Manchester the speakers used the expression "bacteriological examination" and "biological examination" as if they were synonymous, and no mention was made either of the animals or plants which are invariably present, and materially assist if they are not actually necessary for the maintenance of the most suitable balance of life in these waters. The time has come when an inquiry should be made of the organisms other than bacteria that are normally present both in the waters at the sewage works and in the large reservoirs which supply cities with drinking-water.

I may be allowed here to quote two cases that have recently come under my notice which will show the kind of work that might be done and the nature of the results which may be expected to follow such an inquiry.

Some years ago complaints were made that the water supplied by the borough of Burnley had an offensive smell. This smell was of such a nature that it was impossible to use the water for the manufacture of soda-water.

The smell was traced to the Hecknest reservoir, where the common water snail, *Limnaea peregra*, was present in enormous numbers. The problem to be solved was how to destroy or reduce the numbers of the Limnæa without interfering in other respects with the purity of the water. The authorities of the corporation asked the advice of a trained zoologist, who made certain recommendations which were adopted, and at a minimum cost the nuisance was abated, and during the six years that have elapsed has not recurred. I will not detain you with a full description of the cause and the cure of this particular pest, but I may say that the recommendations that were made were based on the knowledge of the life habits and reproduction of the Limnæa, and were therefore of a purely zoological character.

Two years ago the Chairman of the Water Committee of the Corporation of Manchester reported that the mains had become partially choked by the growth of an organism which he called a "moss." No less than 700 tons of this "moss" were removed from the mains by a laborious and expensive process. It is not necessary for me to inform this Section that the organism was not a moss. It was probably not even a vegetable, but an animal belonging to one of the genera of fresh-water Polyzoa. In this case, however, so far as I am aware, not only were no steps taken to identify the organism, but no investigations were made to discover its origin or to prevent the return of the

trouble in the future. I could give you several other examples which show that our ignorance of the general balance of animal and vegetable life in the large reservoirs is profound, and that a systematic inquiry conducted by competent persons would most certainly lead to knowledge which would be of great scientific importance, and in the long run remunerative to the community.

I do not think that we can expect that any one of the municipal authorities will feel justified in bearing the cost of such an investigation. The problems that one corporation has to face are very much the same as those that others have met; and each corporation hopes to profit by the successful and neglect the unsuccessful experiments of its neighbours. An investigation such as this, which is really for the benefit of the whole community, should be conducted by a central authority at the public expense.

The scientific investigation of the problems that are connected with the maintenance and extension of our sea fisheries is another matter that requires the very careful attention of the zoologists of the present day. The valuable work that has already been done by the officers of the British Marine Biological Association, the Lancashire Sea Fisheries Committee, the Scottish Fishery Board, and other bodies is of a nature sufficiently encouraging to justify us in asking for the necessary means and appliances for still further developments of the inquiry. There is, however, a great need for a free discussion by those who are competent to speak on the subject to determine and, if possible, to come to some conclusion upon the question of the best and most profitable lines that the inquiry should take in the immediate future, and the establishment of such co-operation as is necessary by the different authorities to prevent duplication where it is unnecessary, and simultaneous observations of similar phenomena on different parts of the coast when it is considered desirable. The report of the Committee on Ichthyological Research, 1902, has shown that there is already in this country a good deal of activity in various branches of investigation of the fisheries problems, but the authorities are not on all points in agreement as to the best plan or course to pursue in future. I cannot but hope that if some conference were held, at which those zoologists who have made a special study of these matters were present, the principal differences of opinion might be cleared up and a unanimous report presented to the authorities.

I have felt very strongly for some time past, and I know there are many of my colleagues who agree with me, that the zoologists of this country are under some disadvantage in not being provided with the necessary machinery for full discussion of matters which affect the welfare of the science as a whole. There are several societies which receive, discuss, and publish papers on various branches of zoological research, but they do not, and from the nature of their constitution cannot, give effective utterance to the general or unanimous opinion of professional zoologists on matters of their common interests. There is no society which all serious students and teachers of zoology feel is the one society which it is their duty and in their own interests to join. Some join the Zoological Society of London, others the Linnean Society, others, again, the Royal Microscopical, Entomological, or Malacological Societies, or some combination of two or more of them. There is no common ground on which we meet for the discussion of such subjects as those I have just mentioned in this Address. In the early days of the British Association this Section supplied the needs which we feel now. It was the Society, if I may call it such, which all the zoologists of the time made a special effort to attend. Important matters were fully discussed by the most competent authorities, and people felt that the prevalent opinion on any subject expressed by Section D was the prevalent opinion of men of science throughout the country.

In concluding this portion of my Address, I may express the hope that when the Association meets next year at Cambridge some steps may be taken to render the organisation which we already possess in connection with this Section more generally useful and more efficacious than it is at present.

In the opening sentences of my Address I used an expression which some of my hearers may have considered open to criticism. Let me take this opportunity of saying, then, that by using the expression "useful human knowledge" I did not intend to express an opinion that there is any knowledge of the character that is expounded and discussed in these sections of the Association which can be called useless knowledge.

A distinction, however, is frequently drawn between knowledge that can be directly applied to the arts and crafts and knowledge which, on the face of it, appears to us at present to be only of general scientific interest. For example, in the award of the Exhibition (1851) Scholarships and Bursaries, the candidates must still give evidence of capacity for advancing science or its application by original research in some branch of science, *the extension of which is especially important to our national industries.* We can rejoice most cordially in the successful developments of the technical institutions in the country, we can heartily join hands with our colleagues in other sciences in urging upon the authorities the encouragement of those branches of science which have a direct bearing upon our industries, but we have a no less important duty to perform in claiming for those branches of science that have apparently no such direct application the needful sympathy and encouragement. I venture to say that at the time the Association last met in Southport no one would have ventured to predict that the study of the anatomy and life-history of the Diptera, or the general biology of the minute sporozoa, would have any direct bearing upon the development of our industries. But to-day, by our knowledge of the mosquito Anopheles, and the sporozoan parasite it carries, we are in a position to destroy or ameliorate the malaria pest which has hindered the commercial development of so many of our colonies in tropical countries, and by encouraging the development of such countries we are assisting to a very material extent our home industries and the general trade of the country. In this, as in so many other cases, the benefit to industry and commerce has come from an unexpected quarter of the field of zoological research. Those who were working within the narrow limits of what is called applied science could never have discovered the facts which we now regard as of extreme importance, however well equipped they were with laboratories and appliances and endowments for research.

It will be of very little profit to this country to endow munificently the technical institutions and those branches of science to which the adjective "applied" is given, to build British "Charlottenburgs," and to attract by handsome salaries the most distinguished professors to the study of the application of science, if at the same time we starve and allow to sink into insignificance the fundamental sciences upon which the whole superstructure rests. It does not need a prophet to foretell that a great disaster will occur if we add story to story of our house of education without widening and broadening the basis upon which it rests.

Many of us, I am afraid, are too much inclined to believe that the intellectual portion of the community has at last awakened to the importance of the work in the fields of pure science, that the old prejudice against us who indulge what is called our harmless curiosity is dying out, and that our science is bound to receive a fair share of encouragement and attention in the progress of the modern developments of science and learning.

The distinction that is drawn between pure and applied science is, however, in danger of being broadened and deepened rather than diminished by the recent activity in the foundation of schools and colleges for technical instruction. There are, it is true, several eminent and distinguished persons who recognise the danger and do their best to avoid it, but this fact is not in itself sufficient to justify us in any relaxation of our efforts on behalf of the maintenance and development of those branches of the sciences which are usually supposed to have no direct or technical application.

In the wide field of zoological research there are many subjects now being investigated and discussed which, at present, seem to us to have but a remote bearing upon any practical problem of industry or medicine. Of all these subjects there are two which have excited during the past ten years extraordinary interest, and are from many points of view subjects of greatest possible importance. I refer to the subject of the natural variations of animals and plants, and the problem of the hereditary transmission of characters from generation to generation.

At present there appears to be some doubt whether the workers in these subjects are really agreed as to the general propositions of the problems, the definitions of the terms employed, and the standard of proof that is requisite in each step of progress. It is true that in most, if not in all, biological problems we are at the disadvantage of being unable to define or measure anything with the same mathematical accuracy that our friends, the chemists and physicists, are accustomed to. We cannot say for example that the chela of a particular species of crab is so many millimetres in length, in the manner the chemist determines the atomic weight of a new metal, as the length of the chela is found to vary within a certain range in all species that have been investigated; nor can we define such common expressions as a species, a variation, or even a cell with the same conciseness as a physicist defines the ohm, the volt, specific gravity, or the mechanical equivalent of heat. As a consequence it is not surprising that when our problems have been studied and a solution reached the resultant "laws" exhibit so many exceptions that they are really not worthy to be called "laws" at all. We may see the truth, but we see it as through a glass, darkly.

There is perhaps no word in the whole of our vocabulary which is used in so many different senses as the word "variation," and yet when it is used an attempt is only rarely made to define the sense in which it is employed.

When we study the adult progeny of a single pair of parents we notice that they differ from one another as regards any one particular character within a certain range. Thus the eight children of a single pair of human parents may vary in weight from, say, 130 lbs. to 200 lbs., and we may find that the average weight of the eight children is approximately the same as the average weight of the two parents. If parents and children were all of exactly the same weight—an impossible supposition—it would be said that they exhibited no variation in this respect, but, as they always do vary in weight, it is said that they exhibit "variations" in weight. Now, such variations may be due partly to differences in the muscular training, the nourishment, the general health, and other post-natal causes; but it is assumed, and there are doubtless good reasons for the assumption, that if all these post-natal influences had been equal throughout life there would still remain variations in weight of lesser amplitude than is usual, but nevertheless substantial.

The variation of the adult in weight, therefore, is a compound quantity, partly due to the influence of external conditions upon the growing body, and partly due to a quality or character present at birth and usually supposed to be inherited with the germ-plasm from one or both parents. The former may be called the artificial part of the variation, or for brevity the artificial variation, and the latter the natural or inherited variation. In the character of weight in human beings there can be no doubt that artificial variation is predominant, the character being a very fluctuating one and liable to profound modification in the varying vicissitudes of civilised human life.

In the character of stature the artificial variation is probably much less predominant. The children of tall parents grow into tall men and women, however handicapped in early life by ill-health or insufficient nourishment, and the children of short parents remain short in adult life, however healthy and well fed in their youth. Nevertheless, he would be a bold man who would assert that the character of stature is uninfluenced by the environment, and that the short people would not have been taller had the conditions of their life in childhood been more favourable, or the tall people shorter if the conditions in their early life had been less favourable.

Finally, we have, in the colour of the iris, the shape of the ear, and the size of the teeth, characters which are usually considered to be unmodified by post-natal conditions, or at least so slightly modified by them that the differences observed in them may be regarded as almost pure natural variations. Now, if we turn our attention to characters such as weight, which we feel certain are influenced very profoundly by the environment, we might be tempted to exaggerate the importance of the environment in moulding or forming the characteristic features of the adult organism, as, in the opinion of many authorities, Lamarck did, and many of his followers are still doing. If, on the other hand, we confine our attention to such characters as the colour of the iris or the shape of the ear, we might be tempted to under-estimate the influence of the environment.

This brings us to the important question whether the characters of the adult that are due to the influence of the environment, and that part or degree of any character which is more or less modified by the conditions of the earlier stages of life are or are not transmitted by parents to their offspring. Time will not permit me to discuss this difficult problem here. Rightly or wrongly, I agree with those who maintain that acquired characters are not inherited, and I intend to assume for the purpose of the argument that follows that they are not inherited. I will also assume, and I must say that the facts seem to be conclusive in favour of this assumption, that the characters which are usually supposed not to be influenced, or to be only slightly influenced, by the environment are capable of transmission by heredity.

We have, then, in most variations a part that can be transmitted and a part that cannot be transmitted by heredity from parents to offspring, and we find in every plant and animal an enormous difference in the proportions of these two parts in different organs. It is not difficult to see the general reasons for these differences. It is clearly important that some organs should be plastic—*i.e.* capable of changing in form and size to meet the varying changes in the environment, and that others should remain relatively constant in spite of changes in the environment. Thus the shape and size of the branches of an oak in a plantation will vary enormously, according to the light and space they have for their development, whereas the anthers, the pistils and fruit will be relatively constant in form and colour. It is clearly important for a chamæleon that the colour of its skin should vary according to the colour of its environment; but it is none the less important that the shape and muscular organisation of its tongue should remain relatively constant throughout life.

An essential point, however, for us to consider is whether there are any characters in animals or plants upon which the environment exercises no influence at all or exercises such a slight influence that it may be safely neglected. The method to adopt in order to settle this point would be to compare at a definite period of their lives the statistics of variation in a family or population which has been brought up under identical circumstances with those of a similar family or population at the same period of life which has been brought up under differing circumstances. If this were done we could determine with considerable accuracy the proportion of the variation of any character of the individuals that is due to the environment and that which is natural and inherited.

Unfortunately it is impossible to bring up a population under identical circumstances. If we take, for example, the individuals of a single hive of bees, which have the same parents, pass through the early stages of their development in cells which are almost identical in size and are regularly fed by the workers during the whole of their larval life, there is still a considerable probability that the individuals do not have a treatment which can, with any pretence to accuracy, be called identical. The food that is collected by the worker-bees frequently comes from varied sources or from flowers in different stages of their growth, and it is impossible to believe therefore that it has always identical nutritive properties; the larvæ are not of the same age, and seasonal changes may affect the larvæ differently, some being checked in the early stages of their development more than others.

But even if we could, with justice, assume that the conditions of life for the individual bees in a hive are identical from the time of hatching up to the time when the adult characters are assumed, there still remain two sets of variable conditions which must affect the development independently of the influences brought by the two parents in the germ-plasms.

In the egg of the bee there is a considerable quantity of yolk, and this yolk is the food material upon which the embryo is nourished throughout the earlier stages of its development. There is no evidence that the yolk in the eggs of this or of any other animal is constant either in quality or quantity. On the other hand, the extraordinary variations or abnormalities, as they are usually termed,

which the embryologist meets with in the segmentation of the egg suggest that there are considerable differences in these respects between the eggs laid by a single parent in a single act of oviposition. Moreover, the manner in which the young eggs of the insects are nourished in the tubular oviduct before they are ready for fertilisation gives very little support to the view that the amount of yolk deposited in each egg is identical.

The second consideration under this heading is possibly of even greater importance. Vernon[1] has shown that the size and other characters of echinoderm larvæ vary very considerably according to the freshness or staleness of the conjugating ova and spermatozoa. For example, he found that when the fresh spermatozoa of Strongylocentrotus fertilised the eggs which had been kept eighteen hours of the same animal, the larvæ differed from the normal larvæ, −17·6 in body length and −15 per cent. in arm length, and when the fresh eggs were fertilised by spermatozoa which had been kept eighteen hours the resulting larvæ differed from the normal by +11 per cent. in body length and by −32·8 per cent. in arm length.

This consideration is practically eliminated in the case of the worker-bees by parthenogenesis, but it cannot be set aside in the case of the drones nor in the cases of the broods of other animals which do not exhibit the phenomenon of parthenogenesis. A comparison of the curve of variation of some character, common to both, in drones and worker-bees from one hive would perhaps throw some light on the general importance of this character.

Before leaving this part of the subject, I must call attention to two results bearing upon it, obtained by De Vries in his botanical investigations, and related by him in his very important work entitled "Die Mutationstheorie." This observer found that the younger the seedling is the greater is the influence of external circumstances upon its adult characters, and in the second place that an even greater influence is exerted upon the characters of a plant by the external circumstances affecting the mother-plant. If these results hold good for animals as they do for plants, we should expect to find, then, that the external circumstances affecting the mother at the time she is maturing the eggs in her ovaries and the external circumstances affecting the embryo before and during the larval period are of far greater importance in affecting the curve of variation of the adults than are the external circumstances affecting the young in their period of adolescence. We must come to the conclusion, from these considerations, that the general variability of a brood or progeny of a single pair of parents must be very largely the effect of the varying conditions affecting the gametes from the earliest stages of their genesis in the gonophore, the fertilised ovum, and the early stages of development. We find, however, as I have already pointed out, that some characters are much more influenced by external circumstances than others. Weight and stature in human beings, for example, are probably much more influenced than the colour of the iris or the shape of the fingers. We may, indeed, recognise two kinds of characters, connected, of course, by a complete series of intermediate links, which may be called, for convenience sake, plastic characters and rigid characters.

Now, in some animals, the characters that are rigid are much more numerous than they are in others. For example, adult salmon or perch are much more variable in size and weight than adult herrings or mackerel; some species of butterflies are much more variable in the colour and pattern of their wings than other species; some species of birds are much more variable in their plumage than others are. Several other examples could be chosen to illustrate this point from the higher groups of animals; but I wish particularly to call your attention to several instances found in the Cœlenterata, because it was the special study of this group of animals that led to the train of thought I have ventured to put before you.

In all the sedentary forms of Cœlenterates the mouth is surrounded by a circlet of tentacles. These organs are used for catching and paralysing the prey and passing it to the mouth to be swallowed. They are also very delicate, and indeed the only specialised organs of sense performing a function similar to that of the feelers or antennæ of Arthropoda. There can be no exaggeration in saying, therefore, that they are of the utmost importance to the animal. In some groups of Cœlenterata, however, we find that they are fixed in number, but in others that they are variable.

[1] H. M. Vernon: "The Relations between the Hybrid and Parent-forms of Echinoid Larvæ." *Phil. Trans.* 1898, B. p. 465.

In the Alcyonaria, for example, the number of tentacles of the adult polyp is eight. I have examined many thousands of polyps belonging to the suborders Stolonifera, Alcyonacea, Gorgonacea, and Pennatulacea, and I have not found a single example of an adult polyp with either more or less than eight tentacles. This is a character, then, which is remarkably well fixed in the Alcyonaria. It does not fluctuate at all. The tentacles of the Hydrozoa, and of many of the Zoantharia, on the other hand, fluctuate considerably in number. In some forms, such as Tubularia among the Hydroids, and Actinia among the Zoantharia, the number of tentacles is considerable, and it is not, perhaps, surprising to find variations in their number. But in many cases, when the number of tentacles is small, there is also frequent variation. In *Hydra viridis*, for example, the number of the tentacles is 6, 7, or 8, and more rarely 5 or 9.

Again, in the Alcyonaria, the number of mesenteries of the adult polyp is always eight; never more and never less.

In the Zoantharia, on the other hand, the number varies not only in different suborders and families, but even in different individuals of the same species from a single locality. Parker found, for example, that the number of non-directive mesenteries in the sea-anemone *Metridium marginatum*, collected at Newport, R.I., varied from four to ten pairs in those forms with the normal number (2) of directive mesenteries, and that there were further variations in the number of non-directive mesenteries in those forms with an abnormal number of directive mesenteries. In fact, of the 131 adult specimens collected, only 40 or about 33 per cent. exhibited the arrangement of mesenteries which is regarded as normal for the species. On the other hand, Clubb found that of the specimens of another common sea-anemone, *Actinia equina*, only 4·24 per cent. showed variations from the normal mesenterial arrangement for the species. We have then, in these examples, a set of organs which are very variable in one genus (Metridium), much less variable in another (Actinia), and perfectly fixed or rigid in another series of genera (the Alcyonaria).

Passing on, now, to the character "shape." Not many years ago the systematic zoologists, who directed their attention to the sedentary Cœlenterates, based their specific diagnoses very largely on the shape of the colonies. Thus we have introduced such names as *Millepora alcicornis, M ramosa, M. plicata, Madrepora cervicornis, M. prolifera, M. palmata, Alcyonium digitatum, A. palmatum*, &c. Zoologists are now agreed, however, that the shape of these colonies is so variable that in most genera it is of very little value for the separation of species. In fact, I have elsewhere given reasons for holding the view that the widely distributed and very variable genus Millepora is represented by only one true species. But what is true for most sedentary Cœlenterates is not true for all colonial Cœlenterates. In most of the genera and species of Pennatulida, for instance, the shape of any one individual of a species is almost identical with that of any other. A *Funiculina quadrangularis*, from the west coast of Scotland, is similar in shape to one of the same species from the coast of Norway. A *Pennatula murrayi*, from the reefs of Funafuti, is similar in shape to one from Ceram. In other words, the character "shape" is extremely plastic in Millepora and Madrepora, but very slightly plastic or almost rigid in Pennatula and Funiculina.

This difference in the plasticity of the character "shape" in Millepora and the Pennatulids must be associated with the fact that the young Millepora colony is unable to move from the spot where the larva settles, whereas the Pennatulid is capable of moving from place to place throughout life. The Millepora colony must either accommodate itself to the environment in which it begins life or perish, but the young Pennatulid can, within certain limits, travel to the environment that suits itself.

The shape of a growing coral or sedentary Alcyonarian on a reef must accommodate itself to the depth of water, the position of neighbouring zoophytes to itself, the direction of the tides, and other influences; and such a power of accommodation is essential for the species in the struggle

for existence on the coral reef. But in the case of the Pennatulid, the natural or normal shape is adapted to a less variable series of environmental conditions, and it has sufficient power of movement to shift itself into localities where the environment is suitable for it. In other words, the power of movement is associated with a loss of plasticity of the character "shape."

But the growth of corals may be affected in other ways. A great many of these forms of life harbour a small fauna of epizoic crustacea, mollusca, and worms, and the ramification or surface is often affected by these in a remarkable way. I have elsewhere pointed out that the character of certain specimens of Millepora, which is known as verrucose, is due to a modification of the growth round epizoic barnacles. Semper has shown that the curious cage-like growths seen on the branches of Seriatopora and Pocillopora are galls produced by the action of certain species of crabs. In a recent paper I have also given reasons for believing that the tubular character of the stem and some of the branches of the genus Solenocaulon is due to the action of certain crustacea belonging to the family Alpheidæ, and that when these Alpheids are not present the form with a solid stem hitherto known as the genus Leucoella is produced.

But whilst some genera of corals and Alcyonaria are plastic in this way, others are not. These coral galls may be found on the Milleporas and Madreporas of a certain portion of a reef and be absent from all the other genera of neighbouring corals. The crab-galls that are found so commonly and in such abundance upon Pocilloporas and Seriatoporas in certain parts of the Pacific and elsewhere are found only in cases of extreme rarity in other corals.

Many other cases could be given to show that in some genera the cœnenchym is remarkably plastic or accommodating to these epizoites, whereas in others it is resistent and rigid.

The size and shape of the spicules have been taken as characters for the determination of the species of Alcyonaria. It is true that in some species the spicules are remarkably constant in size and shape, but in others they are extremely variable. The remarkable torch-like spicules of the cœnenchym of *Eunicella papillosa*, the club-shaped spicules of Acrophytum, and the needle-shaped spicules of many species of Pennatulids are remarkably constant in size and shape, but in Sarcophytum, the new genus Sclerophytum, Siphonogorgia, Spongodes, and a great many others, the size and shape of the spicules are extraordinarily variable. In the matter of colour, too, we find the same thing. The genera Tubipora and Heliopora are widely distributed in the shallow waters of the tropical seas and are very variable in many of their characters, and yet there is not a single specimen of Tubipora known that is not red, nor a single specimen of Heliopora that is not blue. The same may be said for several other species. On the other hand, many species of Alcyonaria are extremely variable in colour. Thus, *Muricea chamaeleon* is, according to Von Koch, sometimes yellow, sometimes red, and in some cases specimens show both red and yellow branches. The specimens of *Melitodes dichotoma* in Cape waters are sometimes red and sometimes yellow. In a small species of Melitodes from the Maldive Archipelago there is a very remarkable degree of variation in colour both in the nodes and internodes, the details of which I have briefly described in vol. ii. of Mr. Gardiner's Results. In the genus Chironephthya, also from the same Archipelago, the variations in colour are very remarkable, the spicules of the general cœnenchym showing various shades of red, pink, yellow, and orange, and the crown and points purple, yellow, and orange colours which sometimes agree, but usually do not agree, with the general colour of the cœnenchym. The variability of the genus is particularly interesting, as in Siphonogorgia, the genus which comes nearest to it, and is, in fact, difficult to separate from it, the colour of the cœnenchym is almost invariably red.

To summarise this knowledge of variability in the Cœlenterata we may say that we find either extreme plasticity or remarkable rigidity in many of their most important characters. Such important and essential organs as the tentacles, stomodæum, mesenteries, &c., are in some groups very variable indeed, and in others as stationary or fixed; we find the same with organs such as the spicules of Alcyonaria, which are, so far as we can judge, of less essential importance, and in characters, such as colour, which must be, in the sedentary forms at least, of minor importance.

If we compare this with what we find in the higher groups of animals we observe a great contrast. In fishes, to take an example at random, we may find that in such characters as the size and weight of the adults, there may be great or considerable variability, but in the essential organs, such as the heart, brain, and stomach, there is almost complete rigidity. I do not mean by using the expression "rigidity" to imply that minor variations in size and shape do not occur, but that major variations, such as a doubling of the stomach, a bifurcation of the cerebral hemispheres or other variations, which it would be considered grotesque to suggest even, do not and cannot occur. But even in minor characters, such as colour, the possible range of variation in a fish is far less than in Cœlenterates. We may find in the mackerel, for example, that individuals differ in the shade and range of the green pigment, but we do not find in any species of fish that some individuals are red, some yellow, some purple, &c.

The contrast in this respect between the Cœlenterate and the fish must be associated with their different degree of complexity of structure. In a complicated organisation such as that of a fish, the brain, heart, and stomach must mutually work together; they must be co-ordinated in form and action. Any profound variation or abnormality of one would interfere with the action of the others and would therefore be incompatible with continued existence. In the Cœlenterate, however, the doubling of the siphonoglyph, the duplication or quadruplication of the mesenteries does not, in some cases, interfere materially with the action of the other organs of the body. If we were to alter the size or shape of some part of a simple machine it might be able still to do its work the better or the worse for the change, but if we were to alter the corresponding part of a complicated machine it would probably throw it out of gear and prevent any work being done at all.

From this consideration we gather that in the process of the evolution of the higher forms of life there has been a gradual diminution in the range of variation of the different characters of the body, a gradual diminution of the response of these characters to changes of the environment. Characters which, in the early stages of evolution, were probably plastic become rigid.

The gradual evolution of the power of co-ordinated movement has been undoubtedly accompanied by a loss in the variability of the shape of the body, the gradual evolution of a blood vascular system and nervous system has led to a loss of variability in the alimentary canal with which they are associated. In the majority of cases, however, we are much too ignorant of the facts of the co-ordination of the parts of the body or of the co-ordination of any one part to the environment to be able to frame an hypothesis as to why any one character has become rigid. It is difficult to see the reason why the number of the tentacles and mesenteries in Alcyonian polyps has become fixed at eight, while in other Cœlenterates these characters are so variable, or why the colour of Tubipora is always red, and of Melitodes variable.

The study of species, however, teaches us that, in all cases, except perhaps in some examples of degeneration, the plastic condition of the characters was antecedent to the rigid, that in the earlier stages of evolution the condition of extreme plasticity and ready response to changing external conditions were necessary for the survival of the species; and that in the later stages, when special adaptations to special circumstances were developed, a certain rigidity or indifference to changing external conditions was equally necessary for its survival.

Now, the study of the various orders of Cœlenterates conveys a very strong impression that the part played by the environment in the production of the variations of the adult is much greater in proportion than it is in the higher groups of animals. It is true that direct proof of this is wanting. Such a direct proof can only be obtained by experiments in rearing and breeding under varying conditions, and there are at present many serious difficulties to overcome before experiments of this nature can be satisfactorily made.

Nevertheless, the circumstantial evidence in favour of the truth of this impression is, to my mind, so strong that we are justified in considering its bearing upon the general question. It is quite impossible for me on this occasion to set before you at all adequately the general nature of this circumstantial evidence. To do so would involve statements concerning the actual variations of a large number of species already observed in one locality and in several widely distributed localities, with a discussion of the possible direct influence of the conditions of such localities, so far as they are known, upon each of the principal variations. Such statements would necessarily be of such a special and technical kind that, even if time permitted me to make them, they would not be suitable for an Address of this character. I may be permitted to say, however, that I am collecting and preparing the evidence for publication on this point at a later date. There can be no doubt, however, from the evidence I have already submitted to you in part, that some species are far more influenced by changes in the environment, or, to simplify the expression, are far more plastic than others; and we may conclude that in the evolution of other groups of animals the earlier forms were far more plastic than their modern descendants. In the earlier stages of evolution there must have been in the first instance a lessening of the power of change in structure according to change of environment. The fixity or rigidity of certain characters thus produced enabled a more elaborate co-ordination both in form and action to occur between one set of organs and another. It permitted a further localisation and specialisation of functions, or, in other words, further differentiation of the animal tissues.

Accompanying this differentiation there was a loss in the power of regeneration. As Trembley showed many years ago, a Hydra can be cut into many pieces, and each by the regeneration of the parts that are missing will give rise to a complete individual. The Earthworm can, when cut in half, regenerate a new tail but not a new head region. An Arthropod dies when cut in half, but has the power of regenerating new appendages in place of those that are lost. But in Vertebrates there is very little power of regenerating new appendages, and the general powers of regenerating new parts are reduced to a minimum.

Now, whether the loss in the plasticity of characters was the cause of the loss in the power of regeneration of lost parts, or the loss in the powers of regeneration was the cause of the loss of plasticity, is a problem upon which I do not feel we are competent to express a definite opinion; but that the two series of phenomena are intimately associated is, I believe, a generalisation that is worth a good deal of further thought and study.

In Vertebrates, however, although the power of regeneration of lost parts is at a minimum, it is not by any means entirely wanting. The muscles, nerves, epithelia, and other tissues, are able to repair injuries caused by accident and disease. And similarly, although the power of response of various organs to the changes of external conditions in Vertebrates is very much diminished as compared with that in the lower groups of the animal kingdom, it still remains in an appreciable degree. Whether the curves of variation of the so-called fluctuating characters of Vertebrates represent simply or solely the influence of the environment on the organism cannot at present be determined with any degree of certainty; but it appears to me that zoological evidence, confirmed as it is in such a remarkable way by the recent researches of the botanists, points very strongly to the conclusion that the major part of each such curve is, after all, but an expression of the influence of the environment.

In venturing to put before you these considerations, I am quite conscious of the vastness and complexity of the problems involved and of the many omissions and imperfections which a short Address of this kind must contain. Not the least of these omissions is that of any reference to the distinction that might be drawn between continuous and discontinuous variations in the simpler forms of life. This is a matter, however, which involves so many interesting and important questions that I have felt it to be beyond the scope of my Address to-day.

We are still in need of further systematic knowledge of the widely distributed species of Cœlenterates; we want to be able to form a more definite opinion than we can at present upon the value of specific distinctions, and we need still further observations and descriptions of the phenomena of irregular facies, abnormal growths, and meristic variations. But more important still is the need of further researches in the field of experimental morphology.

When we have accumulated further knowledge on these lines in a group of animals such as the Cœlenterata, of relatively simple organisation, we shall be in a better position than we are now to deal with the problems of heredity and variation in the far more complicated groups of Arthropoda and Vertebrates.

NOTES.

THE following committee has been appointed by the Lord President of the Council to make a preliminary inquiry into allegations that have been made concerning the physical deterioration of certain classes of the population:—Mr. Almeric W. FitzRoy, C.V.O. (chairman), Colonel G. M. Fox, C.B., Mr. J. G. Legge, Mr. H. M. Lindsell, Colonel George T. Onslow, C.B., Mr. John Struthers, C.B., Dr. J. F. W. Tatham.

WRITING to the *Times*, the honorary treasurer of the Cancer Research Fund states that Mr. William Waldorf Astor has just sent a cheque for 20,000*l.* to the fund, and that, as a result of the speech delivered on July 30 by Mr. Balfour, several other donations have also been received; he points out, however, that the fund is still more than 25,000*l.* short of the amount required, and appeals for further help. The address of the fund is the Examination Hall, Victoria Embankment, W.C.

THE Paris correspondent of the *Morning Post* states that particulars of a new anti-tuberculosis serum will shortly be communicated to the Academy of Medicine by the discoverer, Dr. Marmorck, of the Pasteur Institute. The new serum is said to have been tried in the Paris hospitals, and to have cured several comparatively advanced cases of tuberculosis.

COMMANDER PEARY has been granted three years' leave of absence by the U.S. Navy Department to enable him to make another attempt to reach the North Pole. According to Reuter he will start by about July 1 next year, in a new steamer, for the Whale Sound region, where he will embark a number of Eskimos and establish a permanent base at Cape Sabine; thence he will force his way to Grant Land, where he hopes to establish his winter quarters on the northern shore. In the following February, with the earliest light, a start will be made due north over the pack ice with a small, lightly equipped party, which will be followed by a larger party. Commander Peary hopes to reach the Pole and return to his winter quarters within little more than 100 days. The distinctive features of the plan are the use of sledges with comparatively light loads drawn by dogs, the adoption of Eskimo methods and customs, and the fullest possible utilisation of the Eskimos themselves.

REUTER'S Agency learns that Major Powell-Cotton, who has been exploring in Africa for the past year, arrived safely at Wadelai, on the Upper Nile, in the middle of July, from Mount Elgon, where he had been studying the cave-dwellers. Major Powell-Cotton had had satisfactory interviews with the Congo officials, and was then preparing to start on an expedition in search of okapi.

A TELEGRAM from Mombasa on Saturday last states that Lieut.-Col. Bruce, who, with Dr. Nabarro, was despatched from London in February last, on behalf of the Government and the Royal Society, to study the sleeping sickness in Uganda, has left for England on the conclusion of his mission. Lieut.-Col. Bruce is reported to have stated that the ravages of the disease are unabated.

ACCORDING to a telegram from New York, through Laffan's Agency, Mr. W. G. Tight, the president of the University of New Mexico, has made the ascent of Mount Orata, in Bolivia. This is the first time the peak has been scaled.

THE members of the Liverpool School of Tropical Medicine trypanosoma expedition to the Congo Free State (Drs. Dutton, Todd, and Christy) started on Friday last from Southampton.

THE next meeting of the International Congress of Hygiene will be held in Berlin in 1907. The congress has been invited to meet in Washington in 1909.

THE fourth general meeting of the American Electrochemical Society begins on Thursday next at Niagara Falls, New York, and will last for three days. The following is a list of the papers which are to be read and discussed:—"A New Type of Electrolytic Cell," P. G. Salom; "Manufacture of Ferro-alloys in the Electric Furnace," Dr. George P. Scholl; "Electrolytic Copper Refining," Dr. W. D. Bancroft; "Electro-metallurgy of Gold," Dr. W. H. Walker; "Some Theoretical Considerations of Resistance Furnaces," F. A. J. FitzGerald; "On the Supposed Electrolysis of Water Vapour," F. Austin Lidbury; "Efficiency of the Nickel Plating Tank," Prof. O. W. Brown; "Electrolysis of Sodium Hydroxide by Alternating Current," Carl Hambuechen; "A Practical Utilisation of the Passive State of Iron," Prof. C. F. Burgess; "The Present Status of the Theory of Electrolytic Dissociation," Dr. E. F. Roeber; "Berthelot's Law of Electrochemical Action," C. J. Reed. There will also be a discussion on the theory of electrolytic dissociation.

THE thirteenth annual convention of the American Electro-Therapeutic Association will take place at Atlantic City, New Jersey, from September 22 to 24. A lengthy programme of interesting papers which are to be read at the gathering has been published.

AN educational exhibition of edible fungi is to be held under the auspices of the Royal Horticultural Society in the Drill Hall, Buckingham Gate, on September 15. A lecture on the subject of the exhibition will be given in the afternoon by Dr. M. C. Cooke. All interested in extending or acquiring the knowledge of the edible species are invited to send specimens, but notice of an intention to exhibit should, if possible, be sent a few days before to the secretary of the Royal Horticultural Society.

AT the International Congress of Hygiene which has just been held in Brussels the following resolution was passed on the motion of Sir Patrick Manson:—"That this congress, recognising the practical importance of the mosquito malaria theory, would urge on all Governments in malarial countries (1) that officials, both civil and military, be required before taking service in such countries to show evidence of practical knowledge of the theory and its application; (2) that educational establishments, whether governmental, missionary, or other, in such countries be requested to include in their curriculum instruction of native students in the mosquito malaria theory and its practical application; (3) that officials ignorant of the theory or systematically ignoring its practical application be considered as unsuitable for service in malarial countries." In addition to the foregoing resolution the first and second sections of the congress sitting together passed the following resolution:—"That human tuberculosis is perfectly transmissible from one person to another. Nevertheless, in the present state of our knowledge, it is necessary to recommend hygienic measures for the prevention of the propagation of animal tuberculosis in the human species."

THE Scottish Sanitary Congress was opened at Stranraer on Thursday last, when the president, Prof. Glaister, of Glasgow University, delivered an address, and various papers dealing with sanitary matters were read and discussed. Prof. Glaister, in the course of his remarks, urged that men of science and local authorities should realise the detrimental effect of atmospheric pollution, and together grapple with the subject. The prejudicial effects of town living could not be better demonstrated than in the depreciated physique of the third and fourth generations of many of those who had proceeded from the country to the towns. One of the significant features of present-day statistics, and one calling for the serious consideration of sanitarians, was the high prevailing rate of infantile mortality in populous centres. If the state of the principal English towns for 1901 be considered, it will be found that the infantile death rate varied from 126 per thousand up to 226 per thousand. These figures exhibited a great wastage of infantile life. He affirmed that it was a preventable wastage, and, therefore, worthy the reflections of sanitarians. Such high rates of infantile mortality were bound in the future to become a serious national concern in view of the diminution of the birth rate which had been progressively taking place for the last few decades.

THE fourteenth annual meeting of the Institution of Mining Engineers was held last week in Nottingham under the presidency of Mr. J. C. Cadman. The Institution appears from the report to be in a satisfactory condition, the membership being at present more numerous than at any former period. The present total is 2601 as compared with 2554 of the previous year.

THE Municipal Exhibition at Dresden has been a great success. In all, 128 German communities, including practically the whole of the large cities, contributed officially to it. The exhibition was of a practical nature, and provided a more or less complete survey of municipal achievement, effort, and ideals. It was divided into eight sections, which again were subdivided. The regulation of traffic, lighting, the police and police-courts, ordinary and model dwelling houses, public art galleries, public health, school accommodation and buildings, public education, the care of the poor and the sick, benevolent institutions and charity schools, the financial administration of municipalities, infectious and common diseases and their prevention and cure, safeguards against fire, parks and open spaces, and the growth of towns were among the numerous features of municipal life illustrated.

SHORTLY before his death, the late Prof. Nocard, of Paris, strongly urged the authorities of the Liverpool School of Tropical Medicine to make the institution available for the instruction of veterinary surgeons. A committee has now been formed for the purpose of giving effect to this suggestion, and the veterinary branch is open for the reception and instruction of students. It is under the direction of Profs. Boyce and Sherrington, with adequate assistance, and a farm has been provided at Runcorn for its requirements.

THE Tramways and Light Railways Association offers an annual prize, consisting of a bronze medal and books, for the best essay on improved means of communication. No essay must exceed 4000 words in length, and the right is reserved by the council to publish the papers in the Association's official journal.

A GRANT of 70,000 r. (7000*l.*) has been made to the Moscow University by the Russian Government for the purpose of technical education; of this sum 30,000 r. is allocated to a

physical institute, 15,000 r. to a chemical laboratory, and the balance to physico-geographical, zoological, and botanical teaching.

A NEW gem, lilac coloured and transparent, has recently been discovered in California by Dr. George F. Kunz, of New York. On the suggestion of Dr. C. Baskerville, of the University of North Carolina, who made an analysis of the mineral at the New York Museum of Natural History, the name of Kunzite has, it is stated, been given to the stone in honour of its discoverer. In the course of the tests made by Dr. Baskerville, the Kunzite crystals were subjected to the action of ultra-violet light without showing any evidence of fluorescence or phosphorescence, and it was not until Röntgen rays of very high penetration were brought to bear upon them that they became at all fluorescent. On their removal to a dark chamber they exhibited a persistent white luminosity never before observed in this class of minerals. A description of the gem, by Dr. Kunz, appears in *Science* of August 28.

THE *Pioneer Mail*, Allahabad, states that the Ceylon Government has given notice that, under the Insect Pest Ordinance, the importation of pepper plants into Ceylon from any part of India is prohibited. The dried seed of the pepper plant imported for commercial use is, however, exempt from the prohibition.

THE daily weather report issued by the Meteorological Office on Friday last, September 4, showed that a barometric depression had passed the Azores and was advancing on an easterly course; the mercury was lowest on the west coast of Ireland, with south-easterly winds, and the air becoming close and thundery. As occasionally happens, a secondary depression was developed to the southward of the primary system, and this subsidiary disturbance caused during the afternoon severe thunderstorms over the southern portion of England, which subsequently extended to the metropolis and eastern coast, accompanied by torrential rain, laying many districts under water. At Ventnor a fall of 1·65 inches was recorded the next morning, at Westbourne 2·4 inches, and at Brixton 1·2 inches. At some places the fall was probably greater, as at Dover the shipment of mails was delayed, and many houses in the low-lying districts of that town were flooded to the depth of several feet.

PROF. LANGLEY has addressed a statement to the American Press with reference to his mechanical flight experiments from which we abstract the following:—"These trials, with some already conducted with steam-driven flying machines, are believed to be the first in the history of invention where bodies far heavier than the air itself have been sustained in the air for more than a few seconds by purely mechanical means. In my previous trials success has only been reached after initial failures, which alone have taught the way to it, and I know no reason why prospective trials should be an exception. . . . The fullest publicity consistent with the national interest (since these recent experiments have for their object the development of a machine for war purposes) will be given to this work when it reaches a stage which warrants publication."

MR. EDISON is reported to have developed his alkaline storage battery into a form fit for commercial use, and already has works equipped capable of turning out per day one complete set of cells suitable for motor-car work; soon he will be able to turn out five sets a day. The results of tests of the practical working of the battery are said to be entirely satisfactory; four sizes are made, capable of running a car 25, 50, 75, and 100 miles respectively on one charge, at an even rate of 25 miles an hour. The possibility of working at more than normal discharge rates without injury to the cells gives cars equipped with this battery good hill-climbing powers. The results of general outside experience of the battery will be eagerly awaited.

MR. MARCONI, who recently went out to America on board the *Lucania*, had special apparatus fitted on the ship to enable him to carry out experiments during the voyage. The main object of the experiments was to determine the power necessary to transmit messages to and from a moving station, such as a ship, with varying distances.

IT is announced that the Metropolitan District Railway will be equipped with trains run on the multiple unit train control, which is in use on the Central London and several American railways. Each train will have three motor-cars all controlled by a single driver; if by any accident the driver is incapacitated, the train is automatically brought to a standstill as soon as he releases his hold on the driving lever. The motor equipment is separated from the public part of the car by a fireproof steel partition. The contract for the equipment (known as the Sprague-Thomson Houston system) has just been placed with the British Thomson Houston Company, of Rugby and London.

THE supervision of the Imperial Department of Agriculture for the West Indies extends to several islands, where the progress that is being made is not placed on record except in the yearly reports. Of these, the report which originates from St. Vincent refers to the eruptions of Mont Soufrière during the period included in the official year 1902–3. The botanic gardens escaped, but the Georgetown experimental plot was almost entirely destroyed; even this catastrophe was turned to account, as experiments were started in order to test the possibility of growing certain plants, such as sugar-canes, cotton, ground-nuts, &c., in the volcanic ash. The experiment station of the British Virginia Islands is situated at Tortola, and the yearly report is presented by Mr. Fishlock, who took up the position of agricultural instructor at the beginning of the year. The station lies low, and is not suited to the cultivation of cacao or coffee, but pines produce excellent crops, and there is every reason to expect that good results will attend the introduction of cotton cultivation.

A PAPER entitled "The Forward Movement in Plant-breeding" was read by Prof. L. H. Bailey before the American Philosophical Society, and is published in its *Proceedings*. The advice which is offered to the scientific breeder is to get thoroughly acquainted with the characteristics and qualities of the plant which it is desired to cultivate, to decide in what direction he can make practical improvements, and after choosing what appears to be a suitable strain, to get all the information possible from his results by means of a careful system of measurement and tabulation.

IN the September issue of the *Irish Naturalist* Messrs. Carpenter and Beresford publish the result of certain experiments as to the relations existing between the wasps respectively known as *Vespa austriaca* and *V. rufa*. The former, which is not uncommon in Ireland, is believed to produce no workers, but to breed as an "inquiline" in the nests of other species. In a nest with an *austriaca* queen kept under observation by the authors, all the workers hatched were of the *rufa* type, while of the drones some were *austriaca*, some *rufa*, and others intermediate between the two. As the two forms are sufficiently distinct to be regarded as species, it seems as if we had here an instance of the origin of species by discontinuous variation. "We

think that we see here a new species arise by the production, through many generations, of an increasing number of individuals (*rufa* forms) among the offspring, that are markedly unlike the parents (*austriaca* forms). We believe that *austriaca* forms give rise to *rufa* forms, but we have no evidence of the reverse process."

AT the conclusion of the second part of his memoir on the development of the molluscan lingual ribbon, or radula, Mr. H. Schnabel, in the *Zeitschrift für wissenschaftliche Zoologie*, vol. lxxiv. part iv., points out an important distinction in this between cephalopods and gastropods. In contrast to the cephalopods, the development of the radula in the gastropods commences, not with the appearance of the single unpaired median row of teeth, but with a number of paired lateral rows. The other contents of the issue include an article on gastrulation in Cucullanus, by E. Martini; an essay on the morphology of the male genital appendages of the Lepidoptera, by E. Zander; and an account of the structure of the bristles in certain chætopods and brachiopods, by A. Schepotieff.

THE alleged occurrence of "aptosochromatism," that is, colour-change in feathers without moulting, in birds, has by no means met with universal acceptation, one at least of the late Mr. F. J. Birtwell's three papers on this subject having been adversely criticised. Shortly before his death Mr. Birtwell entered on a fresh series of observations in the hope of establishing his theory on a basis which would be beyond question. These observations, which were made on two species of buzzard, are now published in the *Bulletin* of the Hadley Laboratory of the University of New Mexico (vol. iii. No. 7).

AN Irish specimen of Dopplerite has been described by Mr. Richard J. Moss (*Sci. Proc.* Royal Dublin Soc., vol. x. No. 6). It was found in peat in Sluggan bog, at Drumsue, near Cookstown Junction, in County Antrim. In its original moist condition it appeared like a stiff jelly of a velvety-black colour, but when dry it became very like jet, breaking with a conchoidal fracture, and exhibiting a vitreous lustre. Dopplerite was originally found in peat in Styria, and has not previously been recorded from Britain. It appears to have been formed from peat by a process of oxidation.

A HANDBOOK to Southport, which should prove of much service to those attending the meeting who are not well acquainted with the town, has been written for the members of the British Association. Southport is considered from a historical and descriptive point of view, and as a health resort. Other chapters are devoted to meteorology, geology, botany, zoology, Martin Mere, archæology, and the life and works of the Rev. Jeremiah Horrocks (spelt in the volume Horrox). The volume is published by Messrs. Fortune and Chant, of Southport, and appears to have been carefully prepared.

THE current issue of the *Illustrated Scientific News* is a double one, and brings to a close our contemporary's first volume. The number contains many interesting articles, among which there are no fewer than three respecting the British Association; one is illustrated by portraits of the president and five of the presidents of sections for this year. Other contributions deal with "Charlottenburg," the "Solar Physics Observatory at Meudon," "Progress with Airships," &c.

THE additions to the Zoological Society's Gardens during the past week include two Black Rats (*Mus rattus*), British, presented by Mr. J. E. Millais; a Ducorps's Cockatoo (*Cacatua ducorpsi*) from the Solomon Islands, presented by Mrs. J. Aarons; a Neumann's Baboon (*Papio neumanni*), a Doguera Baboon (*Papio doguera*) from Abyssinia, a Bell's Cinixys (*Cinixys belliana*) from Tropical Africa, an Adanson's Sternothere (*Sternothoerus adansoni*) from North-east Africa, deposited; three Fat-tailed Desert Mice (*Pachuromys dupresi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SEARCH-EPHEMERIS FOR FAYE'S COMET.—In No. 3896 of the *Astronomische Nachrichten*, Herr E. Strömgren gives a continuation of the search-ephemeris for Faye's comet which appeared in No. 3876 of the same periodical, and was reproduced in these columns. The following is an extract from the later portion:—

Ephemeris 12h. (M.T. Berlin).

1903	α (h. m. s.)	δ (° ′)	log r	log Δ
Sept. 12	8 5 14	+12 13·4	0·2842	0.3864

THE CANALS ON MARS.—In the fifth report of "The Section for the Observation of Mars" (British Astronomical Association *Memoirs*, vol. xi.), several charts of the planet's surface are reproduced, in one of which, Plate viii., the director of the section, M. E. M. Antoniadi, has omitted the reticulated canal systems so familiar to aërographers on the charts published during the last twenty-five years. These have been omitted because recent research has thrown grave doubts on their objective reality.

In the recent experiments carried out by Messrs. Maunder and Lane it was demonstrated that the regular "canaliform" markings may be consistently seen by numerous unbiased individuals on a surface which is free from any such markings, but which has drawn on it features similar to the other markings on Mars. It was also pointed out that, in general, the so-called canals on aërographical maps are drawn either from one projecting feature to another or where half-tone boundaries are seen on the planet, just where one would expect them to be drawn if they were really due to physiological suggestion.

Many so-called "canals" are retained on M. Antoniadi's chart, but these are not of the rigidly geometrical shape shown on the charts published during recent years, and are, probably, objective features of the Martian landscape (the *Observatory*, No. 335).

RADIATION PRESSURE AND COMETARY THEORY.—In No. 5, vol. xvii., of the *Astrophysical Journal*, Messrs. E. F. Nicholls and G. F. Hull describe and illustrate some laboratory experiments they have made at Dartmouth College, Hanover, U.S.A., in order to demonstrate the effect of the solar radiation pressure in the formation of comets' tails.

A glass tube shaped like an hour-glass was partially filled with sand and dried lycopodium powder, and then highly evacuated. On causing the sand and powder to fall from the upper to the lower part of the tube, and directing an intense beam of light against the stream, it was seen that, whilst the sand fell vertically, the powder was diverted in the direction of the beam against the side of the tube opposite to the light source. Unfortunately the light pressure, on particles of the size and density used, had been previously overestimated, and a subsequent calculation showed that the observed deviation may not have been wholly due to the light-pressure, although some of it was.

Another suggestion as to the cause of repulsion in cometary phenomena is that the particles heated from one side evolve gases, and are, therefore, driven in the opposite

direction in a similar manner to the ordinary rocket, and in the experiments performed by Messrs. Nicholls and Hull this "reaction" pressure would be about ten times as great as the "radiation" pressure. This research has experimentally illustrated the repulsion, and has shown that a part of it at least is probably due to the "radiation" pressure; it now remains to determine more definitely the relative effect of each of the possible causes.

A CATALOGUE OF 1520 BRIGHT STARS.—As the "Revised Harvard Photometry," which will contain details of about nine thousand stars of magnitude 6·5 and brighter, is not yet ready, the Harvard College Observatory has published a smaller catalogue, which only contains 1520 stars, and does not give the detailed information which will be contained in the larger volume.

The catalogue gives, in tabular form, the H.P. number, the constellation name, the R.A. and declination, the magnitude and the type of spectrum for each star, and a comprehensive set of "remarks" describes the peculiarities appertaining to various stars included in the list.

A large edition of the catalogue has been prepared, and anyone interested may obtain a copy on applying to the director.

IRON AND STEEL INSTITUTE.

THE autumn meeting of the Iron and Steel Institute was held in the Town Hall, Barrow-in-Furness, on September 1, 2, and 3, with Mr. Andrew Carnegie, the president, in the chair, and was very largely attended. After an eloquent address of welcome from the Mayor, Mr. Carnegie delivered a short presidential address, in which he traced the progress made in the metallurgy of iron and steel since the Institute's last visit to Barrow twenty-nine years ago. After various business announcements had been made by the secretary, Mr. Bennett H. Brough, the reading and discussion of the thirteen papers on the programme began. The first read was that by Mr. R. A. Hadfield on the alloys of iron and tungsten. This formed a monograph of sixty-eight closely printed pages. It contains historical details regarding the ores of tungsten, the metal and its alloys, and a large amount of physical data. It concludes with a carefully compiled bibliography of the subject, showing that a large amount of attention has been devoted to studies of this interesting metal and its employment in the manufacture of steel. Osmond, by his cooling curves, has brought out several peculiar points in the thermal behaviour of this steel, and Barrett has discovered that tungsten affects the conductivity of iron less than any other added element. Though tungsten-iron alloys will have an important future, there is no doubt that their use is not likely to be on the same large scale as some of the other special steels now produced. In the discussion some interesting details were added by Mr. F. W. Harbord and by Mr. J. E. Stead.

This paper was followed by a series of memoirs dealing with the heat treatment of steel. These were discussed together.

The paper read by Mr. J. E. Stead and Mr. Arthur W. Richards on the restoration of dangerously crystalline steel by heat treatment established facts of far-reaching importance. The microscope shows that heating at high temperatures causes a great development in the size of the crystalline grains, and reheating to about 870° restores the original or a better structure. If all structural steels in their normal rolled or forged condition are good, they can be readily deteriorated in quality by heating to a temperature a little above that to which steel is most commonly heated previous to rolling or forging. Steel made brittle by such heating, and dangerously brittle by heating at considerably higher temperatures, can be completely restored to the best possible condition without forging down to a smaller size or by remelting. Not only are the original good qualities of normally rolled steel, after making brittle, restored by the exceedingly simple treatment of heating to about 900° C. for a very short time, but such steel is made considerably better than it was. That brittle "soft steel" can be restored by reheating is well known, but that carbon steels can be actually made much superior to the original properly forged metal by reheating to 870° and cooling in air is a discovery. It is urged that in every large forge and smith's shop Le Chatelier pyrometers should be introduced, together with suitable furnaces for reheating the forgings.

Mr. J. E. Stead and Mr. Arthur W. Richards next read a remarkable paper on sorbitic steel rails. The term sorbitic is used for a transition condition of the carbide intermediate between the states in which it exists in hardened and annealed steels. The chief point of interest in the authors' work is the simple method employed for producing sorbite in steel. The usual custom has been to reheat and oil-harden, or to quench completely in water and reheat to dull redness. They avoid reheating, and quench the heads of the rails, and allow the residual heat in the rails to do the tempering. The results of the later experiments show clearly enough that by partially quenching the heads and allowing the rails to temper themselves, although the elongation is decreased, the contraction of area remains practically the same. A normal rail of 37 tons tenacity when made sorbitic is increased in strength to 45 tons without diminution of the contraction of area. A normal rail with $36\frac{1}{2}$ tons tenacity is increased to 49 tons with a slight increase in the contraction of area. In other cases the tenacity is increased from 43 to 50 tons with a slight diminution in the contraction of the area. Pieces of the rail cut from the area of maximum sorbite on being tested by repeated reversals of strain showed greater toughness and endurance than the normal material. The wear is very greatly in favour of the sorbitic material, as would naturally be expected, and it is believed that, by treating the rails in the simple manner described, their life will be increased from 25 to 50 per cent. The results obtained should lead metallurgists to aim at replacing pearlite by sorbite in all structural steels that have to be subjected to friction, percussion, or vibration when in use.

A paper on the heat treatment of steel rails high in manganese was contributed by Mr. J. S. Lloyd (South Russia). Steels containing more than 1 per cent. of manganese have not hitherto been fully studied, and a research carried out in Russia by the author shows that, at the ordinary normal heat suitable for rolling ingots, steel containing 0·46 per cent. of carbon and 1·33 per cent. of manganese is made exceedingly brittle if it is not further treated, but is allowed to cool on the mill floor. Slowly cooling in the furnace after heating for eighteen hours at 950° makes the material about twice as ductile as it was in the original rail, but the tenacity is considerably reduced. The heating to the rolling temperature causes an enormous development in the size of the crystals, but these are broken up and become about one-eighth of the dimensions by heating to 950° C. and slowly cooling afterwards, and the structure so obtained is twice as fine as it was in the normal rail.

Some further experiments on the diffusion of sulphides through steel were described by Prof. E. D. Campbell, of the University of Michigan. They appear to sustain the conclusions drawn from his work—that iron is permeable by sulphides when heated above 1200° C., and that the sulphur content of the iron is not necessarily increased by the passage of the sulphide through it. In fact, in a slightly oxidising atmosphere the sulphur content of the steel may be even less after the diffusion than it was before. The author is not prepared at present, from the experimental data at hand, to give a positive explanation of the manner in which sulphides permeate or diffuse through iron. The most plausible hypothesis would seem to be that the sulphides originally present in the iron fill more or less completely the interstitial spaces between the crystals of iron; that above 1200° these sulphides are very fluid, and may be drawn out of the steel by capillary action of some absorbent such as asbestos, and their place taken by some other sulphides, provided these latter are sufficiently mobile to find their way into the extremely minute spaces between the steel crystals. If the sulphide replacing the original sulphide contain less sulphur than the latter, or if absorption by the asbestos continued after the sulphides had ceased to enter the iron from within, the diminished percentage of sulphur in the steel at the hot end would be readily accounted for.

The paper by Prof. A. Stansfield on the overheating and burning of steel was a report on work carried out by him

as Carnegie research scholar, its publication having been delayed by his appointment to the chair of metallurgy at Montreal. The memoir covers thirty-six pages. The burnt structure of very much overheated steel is shown to be largely due to the partial melting which results from heating the steel above a given temperature. This melting causes brittleness directly, and indirectly by the admission of oxygen to the steel. According to American metallurgists the latter stage would alone be called burning, but as the effect of partly melting the steel is quite distinct from that of overheating below the zone of partial fusion, the author would prefer to apply one word to the whole of the changes that take place in this zone. If the word burning is still employed, it should be remembered that it is essentially a partial melting of the steel, though often accompanied by oxidation. The following stages have been recognised:—(1) overheating (below the point of incipient fusion); (2) partial melting, called burning; (*a*) merely producing segregation of carbon in the joints; (*b*) accompanied with liquation and producing flaws; (*c*) further liquation and oxidation in the flaws. (1) Steel that has merely been overheated can be completely restored by heating just above its highest recalescence point and allowing to cool. (2) Steel in the stage (*a*) can be restored by suitable annealing; in the stage (*b*) forging would also be needed; and in stage (*c*) it would be restored with great difficulty, if at all.

The paper on the heat treatment of steel submitted by Dr. William Campbell (New York) is a report on research carried out by the author as Carnegie research scholar. It forms a pamphlet of ninety-three pages. The steel used contained 0·50 per cent. of carbon, 0·98 manganese, 0·094 silicon, 0·098 phosphorus, and 0·08 sulphur. The structure of the steel used was found to depend upon the two constituents present, namely, the ferrite and the pearlite. The pearlite will certainly show the finest structure when the steel has been heated to just above Ac_1, or when it has been transformed into martensite. Heating to temperatures above this point will cause a coarsening of the structure. The higher the temperature the coarser the structure. Above Ac_1 the ferrite begins to diminish in size, due to its being dissolved in the martensite. This will continue until the whole of it is dissolved, when the change Ac_{2-3} is complete. Then the finest structure of the whole will be found where these two changes balance. This point is apparently just below the point where Ac_{2-3} is complete. The best finishing temperature is such that the bars leave the rolls as near Ar_{2-3} as possible. The bars would necessarily have to be drawn from the furnace at a higher temperature, which is about 740° C. in this case, allowing for a cooling of, say, 40° C. or more during rolling. In comparing the results obtained with those of pure carbon steel, the effect of the manganese present must be taken into consideration.

An animated discussion followed the reading of these papers on heat treatment, in which Messrs. Westgarth, Ridsdale, Lange, Price-Williams, L. N. Ledingham, and Hadfield took part.

The probability of iron ore lying below the sands of the Duddon Estuary formed the subject of a paper by Mr. J. L. Shaw (Whitehaven). He adduces evidence to show that there is a limestone area probably carrying large bodies of ore, and advocates the putting down of exploratory boreholes. In the discussion Mr. G. J. Snelus gave further particulars of geological interest.

The paper by Mr. W. F. Pettigrew on coal as fuel at Barrow-in-Furness contained much of interest. In that district at the present time coal is obtained from Cumberland, Lancashire, and Yorkshire. As the prices at the pit, the cost of carriage, and the quality of the coal from these districts vary considerably, the author has carried out several experiments to find the relative value of coal obtained from the districts before mentioned, also from various parts of Scotland and South Wales. Experiments carried out with a locomotive showed that the sample of Yorkshire No. 1 gave the best results. This coal has excellent steaming qualities, is very clean, with an open clinker, and low percentage of ash. The Welsh coal was also good when tried, and equal in all respects to the Yorkshire coal, and would no doubt give even better results if properly fired, which was not the case during the trials, the men having had practically no experience with this kind of coal. The Cumberland coal was good, particularly one sample, but this was not found suitable for locomotive purposes. The other sample of Cumberland coal gave fairly good results, but it is a dirty coal, and necessitates the frequent cleaning of fires. The Lancashire samples were in some cases very good steaming coal, with a moderately low consumption, but several samples gave very bad results, and were quite unfit for locomotive purposes. The Scotch coals tested were fairly good, but in most cases a very heavy consumption was recorded. They are quick burning coal and dirty, but with an open clinker, which did not interfere in any way with the steaming. The consumption was from 20 to 40 per cent. higher than the Yorkshire coal.

Mr. C. H. Ridsdale (Middlesbrough) read a lengthy paper on the diseases of steel. In it he collated various types of defects, and traced them to their origin.

Mr. H. Ehrhardt, of Dusseldorf, contributed a paper describing a process for making weldless steel pipes and shells by which rings up to 8 feet in diameter and 10 feet in length are manufactured.

The regulation of the combustion and distribution of the temperature in coke oven practice was dealt with in a paper by Mr. D. A. Louis. Illustrations were given to show the design and character of the Brunck and v. Bauer coke ovens, two ovens of new design.

The influence of silicon on iron was dealt with in a paper by Mr. Thomas Baker. He prepared a series of alloys of silicon and iron with traces only of other elements, and studied the micro-structure and physical properties of each. Although the addition of silicon to iron increases the elastic limit and tenacity of iron, such increase is only obtained by loss of ductility, which loss, provided the material has been well annealed, is very small until the silicon reaches 3 per cent., after which it becomes very great, the ductility almost becoming zero with 4 per cent. silicon. The alloys gradually increase in hardness with the addition of silicon, and after exceeding 5 per cent. silicon require great skill and care in machining in order to avoid fracture of the bar. As the percentage of silicon increases the permeability for low magnetic fields increases, and the coercive force and hysteresis loss decrease. Prof. T. Turner (Birmingham) was the chief speaker in the discussion.

The proceedings concluded with the customary votes of thanks to the reception committee, and an invitation, tendered by Mr. Kirchhoff, of New York, on behalf of the American societies, that the Institute should meet in the United States next autumn was accepted.

In connection with the meeting an elaborate programme of visits and excursions was arranged, including the works of the Barrow Hæmatite Steel Co., the Askham blast furnaces, the Hodbarrow mines and sea-wall, the naval construction works of Vickers, Sons and Maxim, the Furness Railway locomotive works, the North Lonsdale iron works, and to Lake Windermere, Grasmere, and Blackpool. The social functions included a conversazione given by the Mayor, a ball by the reception committee, a garden party by Mr. Victor Cavendish at Holker Hall, and an illuminated *fête* at Furness Abbey.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SATURDAY, October 31, has been fixed for the holding of a convocation of the University of Oxford for the purpose of electing a Chancellor of the University in the place of the late Marquis of Salisbury.

ARRANGEMENTS for next term have been published in connection with the Oxford University School of Geography. Nine lectures a week by different members of the staff will be given in various branches of geographical science, and practical instruction to supplement several of the courses of lectures has been arranged. A geographical scholarship of the value of sixty pounds is to be competed for on October 14, and candidates must have taken honours in one of the final schools of the university. Courses of instruction are now given also in preparation for the university certificate in surveying, and to meet the requirements of students reading for the university diploma in education.

THE report of the Board of Education for 1902–3 shows that during the session 1901–2 the total number of students receiving science and art instruction under the Board was 291,758. The total number of schools in which the teaching was given was 2061. The grants paid during the year amounted to 314,212*l*., of which 143,671*l*. was paid upon attendances. From the same report we learn that great progress has been made with the new buildings for the Royal College of Science. It is hoped the work will be complete in two years' time.

THE University College at Reading continues its useful work in the adjoining counties in connection with field trials and lectures at rural centres, and the work of the agricultural department is of a kind to secure the confidence of practical men. Instruction in dairy farming and dairying is given in cooperation with the British Dairy Institute; the College Poultry Farm at Theale is available for students who desire to obtain a practical acquaintance with poultry-keeping; and there is a college garden for horticultural practice and instruction.

AT the forthcoming opening of the medical schools, the following will deliver addresses:—At the St. George's Hospital medical school on October 1, Dr. W. R. Dakin; at King's College, London, on October 1, Sir John Alexander Cockburn, K.C.M.G., on "Imperial Federation and its Physiological Parallels"; at Guy's Hospital Physical Society, on October 10, Dr. J. F. Goodhart; at the Middlesex Hospital on October 1, Mr. William Hern; at the Medical Faculty of University College, London, on October 5, Prof. E. H. Starling, F.R.S.; at the University of Liverpool on October 1, Sir Dyce Duckworth; and at the University College, Sheffield, on October 15, Sir Michael Foster, K.C.B., F.R.S.

THE report on the work of the Sir John Cass Technical Institute for the session ending last July, and the recently published syllabus of the classes to be held during next winter together show that this young polytechnic is doing excellent work. Many of the students are engaged in technical pursuits during the day. For example, quite half of the students of chemistry are employed in some form of chemical technology, and an examination of the entries of last winter in the metallurgical department shows that one was the head of a firm of bullion refiners, three were managers in metal refining works, five were chemists engaged in metallurgical industries, three were foremen in metallurgical works, and others clerks or samplers in works or trades associated with metals. Among others of a thoroughly practical nature arranged for next session may be noticed a course of practical instruction in glass blowing suited to the requirements of chemists, physicists, teachers, and those engaged in the making of glass apparatus and instruments.

IN his report for the year 1903 on secondary education in Scotland, Sir Henry Craik, K.C.B., says there has again been a gratifying increase in the number of schools presenting candidates in science at the leaving certificate examination, and also in the total number of candidates presented. The examiners report that there is need to repeat once more the warning to teachers against taking up practical work of which the theory is beyond the comprehension of their pupils, or has not been made clear to them. The methods of examination differ in some important points from those regulating the system in regard to other subjects. The examination is chiefly oral and practical, and it is shaped in the case of each school by the curriculum of that school. It is interesting to find that the most satisfactory work appears to be done in the schools the profession of which is comparatively modest. In practical science, as in all educational subjects, the special discipline given is better got from a thorough study of one branch than through a too ambitious attempt to cover a very wide field. The chief examiner is inclined to recommend that, unless the time available during the third year's course is more than four hours a week, the whole of it should be devoted to one subject instead of being divided between two. Another point to which he directs attention is the very limited extent to which "home-made" apparatus is employed in the laboratories.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 31.—M. Bouquet de la Grye in the chair.—A fixing liquid isotonic with sea water, for objects in which it is desired to preserve lime formations, by M. M. C. **Dekhuyzen**. In a previous note a formula has been given for a liquid, isotonic with sea water, for fixing delicate marine organisms. This contains acid, and in fixing the larvæ of sea urchins, which contain extremely delicate chalk formations, it is necessary to employ a liquid free from acidity. The formula of a liquid possessing the required properties is given in the present paper, and in the hands of M. Delage has given perfect results in fixing very delicate larvæ.

GOTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iii. for 1903, contains the following memoirs communicated to the society:—

February 21.—W. **Voigt**: Questions of crystalline physics, i. On the rotatory constants of heat-conduction in apatite and dolomite.

March 7.—W. **Kaufmann**: On the "electromagnetic mass" of the electrons. V. **Cuomo**: Measurements of the electric dispersion in the open air at Capri (October, 1902–February, 1903).

May 16.—W. **Voigt**: On the theory of total reflexion. K. **Schwarzschild**: Contributions to electrodynamics—(1) two forms of the principle of least action in the theory of electrons; (2) the elementary electrodynamic force.

June 13.—F. **Merkel**: Remarks on the fasciæ and veins of the human pelvis.

The "Business Communications," part i. for 1903, contain a report on the Samoa Observatory, and a highly appreciative obituary notice of the late Sir G. G. Stokes, by Prof. W. Voigt.

THE WORTH OF EXPERIMENTAL PSYCHOLOGY.

Experimental Psychology and its Bearing on Culture. By George Malcolm Stratton, M.A., Ph.D. Pp. vi + 331. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 8*s.* 6*d.* net.

THE aim of this well written and interesting book, we are informed, is "to present . . . the character and value of the laboratory psychology, especially as bearing on our moral and philosophical interests. . . . Considerable attention has thus been given to the interpretation of the experimental results—to their more immediate scientific meaning, as well as to what they suggest for life and for speculation." The work, however, contains little that is really relevant to "the bearing of psychology on culture." Such topics as the value and significance of memory, suggestion and illusions, and the relation of psychology to the body and to the soul, ably as they are treated, are hardly synonymous with culture; indeed, from start to finish the object of the book is by no means evident.

It is to be regretted that Prof. Stratton did not confine himself to "the immediate scientific meaning," the range and the worth of psychological laboratory work. Once or twice this task has been already attempted in our language, but it has not yet been satisfactorily performed. The need for such a work has never been greater than now, when the number of psychological laboratories and their workers is multiplying rapidly, while physicists and physiologists are for the most part ignorant of, and hence are prone to ignore and to condemn, the aims and methods of experimental psychology. To this class of readers the present work is not well suited, and will hardly carry conviction. It appeals more to an educated public, which prefers to nibble at the significance of experimental psychology, and to swallow certain inevitable crudities of statement, rather than to digest the subject with proper care. The ground covered by the book is too vast, and departures from purely experimental topics are too often and too far made to allow of a really accurate and critical exposition. For this reason, no doubt, the author has made little attempt to exhibit the various themes of experimental study in their proper perspective. He has been forced to neglect some of the most important advances in purely psychological method, *e.g.* the work of G. E. Müller and his Göttingen school, and the genetic and comparative sides of experimental psychology; while undue space is given to some trivial experiments in æsthetics that have scant meaning or interest, and a few others are made to bear interpretations which are far from being justified in fact.

"Some recent experiments by Dunlap," says the author (pp. 88, 89), "show that lines, so drawn as to produce an illusion of distance [*i.e.*, the angle-forming lines in the well-known illusion of Müller-Lyer], may influence our estimate of space even when these lines are quite imperceptible."

Reference, however, to the statistical results of the original paper and to its writer's own convictions shows that this conclusion is by no means so certain. The author uses these and other considerations in his chapters on the evidence for unconscious ideas. He ends with the statement (p. 92) that

"the results are not in favour of unconscious ideas, but rather of certain unconscious materials out of which conscious ideas arise."

One is tempted to ask how he can be sure, if the "materials" are unconscious, that they *are* "materials" and not "ideas." His psychological treatment of poetical rhythm is not convincing, the subject being too complex to tolerate an acrobatic arithmetic which connects all measures with "the pulse-time of attention." Probably the latter bears about the same relation to our appreciation of rhythm as our range of hearing to the enjoyment of a Beethoven symphony. Nor is it the whole truth, albeit the fashion to say (p. 269) that "what goes on in our minds never is really there until it is expressed," and that "in all manner of mental action there is some physical expression."

The chapters on the general character of psychological experiments, on imitation and suggestion, on illusions, and on the spatial perceptions of the blind, are quite ably and entertainingly written. The author's classification of illusions leads to curious results. He groups the illusion, in which a large box is judged lighter than a smaller box of equal weight, in the same class with the two fundamentally different illusions, in which truly isochronous intervals are subjectively resolved into rhythmic series, and in which a space of time filled with sounds is adjudged of different length from an equal but "empty" space of time. This class of illusions is said to arise "from stress of attention"! We are told also (p. 106) that within this class "the symbols themselves do not seem to be misinterpreted, they have been distorted . . . by our mental states." Elsewhere the author admits that *all* illusions "involve a misinterpretation."

But sufficient has been said to give a general notion of the faults and virtues of this book. In broad principles there is little to which the psychologist can take exception. Its style and language appear to be excellently suited to its readers, and the author has an adequately wide grasp of his subject. If he has failed in his task, the reason is because he has attempted too much. For to treat of the problem, which he has set himself, in three hundred or more pages is as impossible as it is to do justice to his bold endeavour within the compass of this review.

C. S. MYERS.

HYDRAULICS.

Treatise on Hydraulics. By Mansfield Merriman, Professor of Civil Engineering in Lehigh University. Eighth Edition, Rewritten and Enlarged. Pp. viii + 585. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 21*s.* net.

THIS book bears the same title, has practically the same number of pages, and is published by the same firms, as a book by Prof. Bovey, of McGill University, Montreal, which appeared in 1901, and was reviewed in these columns in February last year.

Though, however, the present book, like its predecessor, is intended primarily for students in colleges and technical schools, and secondly for engineers, and one or more problems, intended to be solved by the reader, are appended at the end of each article, relating to the special subject treated of in the article, it deals with the various hydraulic principles and problems successively investigated in a more simple manner than the former book, which is calculated to commend it to the favourable notice of practical engineers, too engrossed in their work to be able to spare the time for fully grasping abstruse mathematical considerations.

The book is divided into sixteen chapters, and is further subdivided into one hundred and ninety-two articles, each numbered, and dealing with a subject under a special heading connected with the general purpose of the chapter which contains it; whilst an appendix at the end, occupying forty-three pages, after pointing out certain analogies between the flow of water in pipes and the passage of the electric current along wires, and adding some miscellaneous problems for solution, furnishes fifty-five useful hydraulic and mathematical tables, the former being given both in English and in metric measures.

The first four chapters treat successively of "Fundamental Data," "Hydrostatics," "Theoretical Hydraulics," and "Instruments and Observations"; whilst the following six chapters are devoted to the consideration of the various kinds of flow, namely, through orifices, over weirs, through tubes, through pipes, in conduits, and the flow of rivers. The remaining six chapters deal with the important practical subjects of "Water-Supply and Water-Power," "Dynamic Pressure of Water," "Water-Wheels," "Turbines," "Naval Hydromechanics," and "Pumps and Pumping." Nearly two hundred figures in the text, mostly in the form of small, simple diagrams, serve still further to elucidate the hydraulic principles so clearly and concisely enunciated; and these diagrams, instead of being numbered consecutively in the usual manner, are given the same number as the articles which they illustrate, adding *a*, *b*, *c*, &c., where more than one occur in a single article; whilst the same system of numbering is adopted for distinguishing the formulas given in the several articles, and the problems appended at the end of them. The advantage of this peculiar method of numbering is not very clear, though possibly it furnishes an excuse for omitting headings from the diagrams, and for dispensing with a list of them. By the above arrangement, however, each article, with its special number and descriptive heading, constitutes a distinct unit, in which the diagrams and formulas are merged; and whereas the chapters in the text are only headed by their special subject, the headings in the table of contents under the main headings consist merely of an enumeration of the headings of the articles in each chapter, preceded by their distinguishing numbers.

The way in which several independent articles are grouped together in the chapters to which their subjects appertain, is well illustrated by the list of articles contained in the chapter on naval hydromechanics, comprising "General Principles," "Frictional Resistance," "Work for Propulsion," "The Jet Propeller," "Paddle-Wheels," "The Screw Propeller," "Stability of a Ship," "Action of the Rudder," and "Tides and Waves." The concise and somewhat cursory manner in which the practical subjects considered in the last six chapters are touched upon, is sufficiently indicated by their taking up less than one-third of the whole contents of the book, and by such important and complex questions as water-supply and water-power being together dealt with in a single chapter of twenty-eight pages. This circumstance, however, must not be regarded as at all detracting from the merits of the book; for evidently the author is mainly concerned in laying down the principles of hydraulics, indicating the means and methods of taking observations, and establishing the laws of the flow of water under various conditions, to which subjects considerably the larger portion of the book is devoted. Then, after the principles and laws of hydraulics have been thoroughly elucidated, the methods of their application to various practical purposes, such, for instance, as water-power, water motors, propulsion, and pumping, are successively indicated, without the slightest intention on the part of the author that the brief treatment of these subjects should furnish substitutes for the standard treatises on them.

In the latter part of the book, indeed, the general features of the subjects introduced, and the action of the hydraulic machines are concisely sketched in suggestive descriptions, leaving a full investigation of the various matters touched upon to be sought elsewhere, according to the special branch on which more detailed information is required. Nevertheless, in spite of the brevity of the treatment, interesting particulars are here and there referred to, as, for example, the present utilisation of the Falls of Niagara in the development of 105,000 electrical horse-power, by means of turbines which are described, and the prospect in the near future of a largely increased use of this natural source of power; whilst it is suggested that the tides and waves afford a source of power which at present is wasted, but which, on the exhaustion of the supplies of coal, wood, and oil, may be utilised for generating power, heat, and light in unlimited quantities.

OUR BOOK SHELF.

Synthesen in der Purin- und Zuckergruppe. By Emil Fischer. Pp. 29. (Braunschweig: Friedrich Vieweg und Sohn, 1903.)

THIS lecture, delivered before the Swedish Academy at Stockholm on December 12 of last year, contains an account of Prof. Emil Fischer's work in organic synthesis, and of the motives that have guided him in attacking successively the problems of the uric acid, sugar, and more recently the albuminoid, groups of organic compounds. The synthetical methods by which the constitution of so many naturally occurring substances have been determined are described in outline only, and in a way that will appeal especially to the non-chemical reader. To the chemist the chief charm of the lecture lies in the frankness with which the lecturer describes the purpose and the ultimate goal of the work to which he has devoted himself.

Incidentally the commercial aspects of the purin syntheses are referred to. The sale of caffein and theobromine for medicinal purposes amounts to a million marks annually; at present this is all extracted from tea and cacao, but theophyllin prepared from uric acid is already on the market, and before long it may be possible to manufacture theobromine and caffein at a price that will render it possible to compete with the natural products. T. M. L.

Report on Field Experiments in Victoria, 1887–1900. By A. N. Pearson. Pp. 124; with illustrations and tables. (Melbourne, 1901.)

A RECORD of experiments on the manuring of the staple farm crops (chiefly wheat) and of fruit conducted with the cooperation of farmers at many different localities in Victoria during the ten years previous to publication. The discussion is popular in nature, and intended for the farmers of the colony. One point is very noticeable, the comparative inutility of nitrogenous manures on the soils tested and the great returns given by phosphatic dressings. A large number of results are reported, and care has been taken to analyse them and reject those vitiated by some of the many irregular factors to which field experiments are liable. The report sadly needs a digest and an index to make it useful to students of agricultural science.

THE BRITISH ASSOCIATION.

THE attendance at the Southport meeting of the British Association, while passing the numbers at Belfast last year, has fallen short of the Southport meeting of 1883 by about 1000. The weather, no doubt, is accountable for a certain diminution of numbers, for given fine weather in the middle part of last week, it is certain the figures would have reached 2000. As it is, they number 1751. Comparing this figure with those of recent meetings, however, it will be seen that a good average has been maintained, the numbers at Southport this year exceeding those at the meetings at Belfast, Dover, Toronto, Ipswich, Nottingham, and Cardiff, and falling only a little way behind the Leeds meeting of 1890. It is only when the meeting is compared with the former one at Southport that the falling off of numbers is noticeable.

On all hands the local arrangements have met with praise, the suite of rooms in the municipal buildings having proved admirably fitting for the purposes for which they were allotted.

Unfortunately, the climatic conditions during the earlier part of the meeting prevented the local arrangements being carried out to their full extent, the Mayor's reception on Thursday night taking place under most depressing conditions of rain and storm, rendering the outdoor portion of the programme an impossibility. The weather, fortunately, cleared for the excursions on Saturday, but the downpour of the previous days prevented many people from taking tickets, and many of the parties had not their full number.

The experiments in kite-flying had to be abandoned owing to various causes, and Mr. Dines has had to be content to exhibit his apparatus without taking it out to sea.

Prof. Pernter's experiments in the firing of vortex rings took place on Monday afternoon before a large number of spectators, the firing taking place from the roof of the boathouse over the North Marine Park.

The International Meteorological Committee has been sitting in the Town Hall during the meeting of the British Association, and the members were formally received by the Mayor of Southport in the Mayor's Parlour prior to the beginning of their deliberations. Opportunities have been afforded the many distinguished foreign men of science present in Southport for visiting some of the laboratories, schools, factories, and dockyards of Manchester and Liverpool.

The lecture to working men on Saturday proved very popular, the Cambridge Hall being crowded. A dinner was given by the Mayor at his residence at Greaves Hall to meet Sir Norman Lockyer and Prof. Mascart (President of the International Meteorological Committee). The guests numbered nearly 100, and included Prof. J. Dewar, A. Hopkinson (Vice-Chancellor of Victoria University), Sir George Pilkington, E. Marshall Hall, K.C., M.P., Charles Scarisbrick (Vice-Presidents), Prof. Carey Foster, Major MacMahon, Dr. Adam Paulsen, M. Teisserenc de Bort, Dr. H. Hildebrandsson, Prof. Pernter, General Rykatcheff, Dr. Hellemann, Dr. Hergesell, Dr. H. Mohn, Prof. Willis Moore, A. L. Rotch, Dr. W. N. Shaw, Dr. Ludwig Boltzmann, Dr. T. P. Lotzy, Prof. O. Lignier, Dr. M. Snellen, Dr. G. G. MacCurdy, Dr. H. C. White, T. H. Yoxall, M.P., Hon. T. E. Fuller, Monsignor Molloy, Monsignor Nugent, Canon Denton Thompson, Dr. J. G. Garson, most of the presidents, vice-presidents, and recorders of Sections, and the local secretaries and treasurer.

At the meeting of the general committee held on Friday last, the names of Profs. Mascart, Simon Newcomb, and Boltzmann were added to the list of vice-presidents of Section A.

The Hon. T. E. Fuller, Agent-General for the Cape Colony, Sir Walter Peace, Agent-General for Natal, and Mr. Fiddes, of the Colonial Office (representing the Transvaal), attended on behalf of their respective Governments for the purpose of formally inviting the Association to South Africa in 1905.

On the proposition of Prof. Dewar, seconded by Prof. H. Marshall Ward, it was decided to hold the 1905 meeting in South Africa.

On the motion of Sir Henry Roscoe, seconded by Prof. Forsyth, the Right Hon. A. J. Balfour was elected President of the meeting to be held next year in Cambridge, the meeting to begin on August 17.

The Lord Lieutenant of Cambridgeshire, the Vice-Chancellor of the University, and the Mayor of Cambridge were elected vice-presidents of the Association.

The following elections for the Cambridge meeting were made:—Local secretaries, Messrs. Ginn, A. C. Seward, G. Skinner, and Mr. A. E. L. Whitehead; local treasurers, Mr. A. E. Shipley and Mr. Parker.

Prof. Carey Foster was re-elected treasurer; Major MacMahon and Prof. Herdman general secretaries; and Dr. Garson assistant general secretary.

At the meeting of the committee of recommendations on Tuesday, the following resolutions were adopted:—

(1) That as urged by the President in his address it is desirable that scientific workers and persons interested in science be so organised that they may exert a permanent influence on public opinion in order more effectively to carry out the third object of this Association originally laid down by the founders, viz.:—"to obtain a more general attention to the objects of science and a removal of any disadvantages of a public kind which impede its progress," and that the council be recommended to take steps to promote such organisation.

(2) That the council be requested to consider the desirability of urging upon the Government by a deputation to the First Lord of the Treasury or other-

wise the importance of increased national provision being made for University education.

A recommendation was received from Section A referring to a suggestion from the International Meteorological Committee. At a meeting of that committee on September 11 it was decided to direct the attention of Section A to the inconveniences which arise from lack of uniformity in the units adopted in meteorological observations, and to ask it to consider if the time has not come for bringing about this uniformity. Acting upon this suggestion, the committee of Section A expressed the opinion "that the introduction of international uniformity in the units adopted for the records of meteorological observations would be of great practical advantage to science." The committee of recommendations was asked to take such steps as it may think fit toward giving effect to the above resolutions. It was decided that the matter should be sent to the council through the general committee.

It was resolved to ask the council to consider whether the form of the daily journal of the Association should not be changed so that a provisional list of arrangements for the reading of papers could be published in the journal at as early a date as possible.

The committee also decided to forward the following recommendation to the council:—

"It is desirable that further steps should be taken to make the reports (as distinguished from papers) communicated to the Association more accessible to the general public by the provision of indices to the published volumes and otherwise."

The following is a synopsis of the grants made at the meeting just concluded:—

Mathematics and Physics.

Rayleigh, Lord—Electrical Standards...Unexpended balance	
Judd, Prof. J. W.—Seismological Observations ...	£40
Shaw, Dr. W. N.—Upper Atmosphere Investigations	50 and unexpended balance
Preece, Sir W. H.—Magnetic Observations	60

Chemistry.

Roscoe, Sir H.—Wave-length Tables of Spectra ...	10
Divers, Prof. E.—Study of Hydroaromatics	25

Geology.

Marr, Mr. J. E.—Erratic Blocks...	10 and balance in hand
Scharff, Dr. R. F.—To Explore Irish Caves	Balance in hand
Watts, Prof. W.—Movements of Underground Waters	Balance in hand
Marr, Mr. J. E.—Life Zones in Carboniferous Rocks...	35
Herdman, Prof.—Fauna and Flora of the Trias ...	10
Lamplugh, Mr. G. W.—To Investigate Fossiliferous Drifts	50

Zoology.

Hickson, Prof. S. J.—Zoological Table at Naples ...	100
Woodward, Dr. H.—Index Animalium	60
Weldon, Prof.—Investigations in Development in the Frog	15
Hickson, Prof. S. J.—Researches on the Higher Crustacea	15

Economic Science and Statistics.

Cannan, Dr. E.—British and Foreign Statistics of International Trade	25

Mechanical Science.

SECTION A.

SUB-SECTION OF ASTRONOMY AND METEOROLOGY.

OPENING ADDRESS BY W. N. SHAW, SC.D., F.R.S., CHAIRMAN OF THE SUB-SECTION.

Methods of Meteorological Investigation.

IN opening the proceedings of the Sub-section devoted to Cosmical Physics, which we may take to be the application of the methods and results of Mathematics and Physics to problems suggested by observations of the earth, the air, or the sky, I desire permission to call your attention to some points of general interest in connection with that department which deals with the air. My justification for doing so is that this is the first occasion upon which a position in any way similar to that which I am now called upon to fill has been occupied by one whose primary obligations are meteorological. That honour I may with confidence attribute to the desire of the Council of the Association to recognise the subject so admirably represented by the distinguished men of science who have come across the seas to deliberate upon those meteorological questions which are the common concern of all nations, and whom we are specially glad to welcome as members of this Sub-section. Their presence and their scientific work are proof, if proof is required, that meteorologists cannot regard meteorological problems as dissociable from Section A; that the prosecution of meteorological research is by the study of the kinematics, the mechanics, the physics, or the mathematics of the data compiled by laborious observation of the earth's atmosphere.

But this is not the first occasion upon which the Address from the Chair of the Sub-section has been devoted to Meteorology. Many of you will recollect the trenchant manner in which a university professor, himself a meteorologist, an astronomer, a physicist, and a mathematician, dealt candidly with the present position of Meteorology. After that Address I am conscious that I have no claim to be called a meteorologist according to the scientific standard of Section A. Prof. Schuster has explained—and I cannot deny it—that the responsible duty of an office from which I cannot dissociate myself is signing weather reports; and I could wish that the duty of making the next Address had been intrusted to one of my colleagues from across the sea. But as Prof. Schuster has set forth the aspect of official meteorology as seen from the academic standpoint with a frankness and candour which I think worthy of imitation, I shall endeavour to put before you the aspect which the relation between Meteorology and academic science wears from the point of view of an official meteorologist whose experience is not long enough to have hardened into that most comfortable of all states of mind, a pessimistic contentment.

Meteorology occupies a peculiar position in this country. From the point of view of Mathematics and Physics, the problems which the subject presents are not devoid of interest, nor are they free from that difficulty which should stimulate scientific effort in academic minds. They afford a most ample field for the display of trained intellect, and even of genius, in devising and applying theoretical and experimental methods. And can we say that the work is unimportant? Look where you will over the countries which the British Association may be supposed to represent, either directly or indirectly, and say where a more

satisfactory knowledge of the laws governing the weather would be unimportant from any point of view. Will you take the British Isles on the eastern shores of the Atlantic, the great meteorological laboratory of the world, with the far-reaching interests of their carrying trade; or India, where the phenomena of the monsoon show most conspicuously the effects of the irregular distribution of land, the second great meteorological cause, and where recurring famines still overstrain the resources of administration. Take the Australasian colonies and the Cape, which, with the Argentine Republic, where Mr. Davis is developing so admirably the methods of the Weather Bureau, constitute the only land projections into the great southern ocean, the region of "planetary meteorology": Australia, with its periods of paralysing drought; the Cape, where the adjustment of crops to climate is a question of the hour; or take Canada, which owns at the same time a granary of enormous dimensions and a large portion of the Arctic Circle; or take the scattered islets of the Atlantic and Pacific or the shipping that goes wherever ships can go. The merest glance will show that we stand to gain more by scientific knowledge, and lose more by unscientific ignorance of the weather, than any other country. The annual loss on account of the weather would work out at no inconsiderable sum per head of the population, and the merest fraction of success in the prevention of what science must regard as preventable loss would compensate for half a century of expenditure on meteorological offices. Or take a less selfish view and consider for a moment our responsibilities to the general community of nations, the advantages we possess as occupying the most important posts of observation. If the meteorology of the world were placed, as perhaps it ought to be, in the hands of an International Commission, it can be no exaggeration to say that a considerable majority of the selected sites for stations of observation would be on British soil or British ships. We cannot help being the most important agency for promoting or for obstructing the extension of meteorological science. I say this bluntly and perhaps crudely because I feel sure that ideas not dissimilar from these must occasionally suggest themselves to every meteorologist, British or foreign; and if they are to be expressed—and I think you will agree with me that they ought to be—a British meteorologist ought to take the responsibility of expressing them.

And how does our academic organisation help us in this matter of more than parochial or even national importance? There was a time when Meteorology was a recognised member of the large physical family and shared the paternal affection of all professors of Physics; but when the poor nestling began to grow up and develop some individuality electricity developed simultaneously with the speed of a young cuckoo. The professors of Physics soon recognised that the nest was not large enough for both, and with a unanimity which is the more remarkable because in some of these academic circles utilitarianism is not a condition of existence, and pure science, not market value, might be the dominant consideration—with singular unanimity the science which bears in its left hand, if not in its right, sources of wealth beyond the dreams of avarice was recognised as a veritable Isaac, and the science wherein the fruits of discovery must be free for all the world, and in which there is not even the most distant prospect of making a fortune—that science was ejected as an Ishmael. Electrical engineering has an abundance of academic representatives; brewing has its professorship and its corps of students, but the specialised physics of the atmosphere has ceased to share the academic hospitality. So far as I know the British universities are unanimous in dissembling their love for Meteorology as a science, and if they do not actually kick it downstairs they are at least content that it has no encouragement to go up. In none is there a professorship, a lectureship, or even a scholarship, to help to form the nucleus of that corps of students which may be regarded as the primary condition of scientific development.

Having cut the knot of their difficulties in this very human but not very humane method, the universities are, I think, disposed to adopt a method of justification which is not unusual in such cases; indications are not wanting which disclose an opinion that Meteorology is, after all, not a science. There are, I am aware, some notable exceptions; but do I exaggerate if I say that when university professors are kind enough to take an interest in the labours of meteorologists, who are doing their best amid many discouragements, it is generally to point out that their work is on the wrong lines; that they had better give it up and do something else? And the interest which the universities display in a general way is a good-humoured jest about the futility of weather prophecy, and the kindly suggestion that the improvement in the prediction of the next twenty-four hours' weather is a natural limit to the orbit of an Ishmaelite's ambition.

In these circumstances such an Address as Prof. Schuster's is very welcome: it recognises at least a scientific brotherhood and points to the responsibility for a scientific standard; it even displays some of the characteristics of the Good Samaritan, for it offers his own beast on which to ride, though it recommends the unfortunate traveller to dispose of what little clothing the stripping has left to provide the two pence for the host.

It is quite possible that the unformulated opinion of the vast majority of people in this country who are only too familiar with the meteorological vagaries of the British Isles is that the weather does just as it pleases; that any day of the year may give you an August storm or a January summer's day; that there are no laws to be discovered, and that the further prosecution of so unsatisfactory a study is not worth the time and money already spent upon it. They forget that there are countries where, to judge by their languages, the weather has so nearly the regularity of "old time" that one word is sufficient to do duty for both ideas. They forget that our interests extend to many climates, and that the characteristics of the eastern shores of the North Atlantic are not appropriate to, say, western Tropical Africa. That may be a sufficient explanation of the attitude of the man in the street, but as regards the British universities dare I offer the difficulty of the subject as a reason for any want of encouragement? Or shall I say that the general ignorance on the part of the public of the scientific aspirations and aims of meteorologists and of the results already obtained is a reason for the universities to keep silence on the subject? With all respect I may say that the aspect which the matter presents to official meteorologists is that the universities are somewhat oblivious of their responsibilities and their opportunities.

I have no doubt that it will at once be said that Meteorology is supported by Government funds, and that alma mater must keep her maternal affection and her exiguous income for subjects that do not enjoy State support. I do not wish just now to discuss the complexities of alma mater's housekeeping. I know she does not adopt the same attitude with regard to astronomy, physics, geology, mineralogy, zoology, or botany, but let that pass. From the point of view of the advancement of science I should like to protest against the idea that the care of certain branches of science by the State and by the universities can be regarded as alternative. The advancement of science demands the co-operation of both in their appropriate ways. As regards Meteorology, in my experience, which I acknowledge is limited, the general attitude towards the department seems to be dictated by the consideration that it must be left severely alone in order to avoid the vicious precedent of doing what is, or perhaps what is thought to be, Government work without getting Government pay, and the result is an almost monastic isolation.

There is too much isolation of scientific agencies in this country. You have recently established a National Physical Laboratory the breath of whose life is its association with the working world of physics and engineering, and you have put it—where? At Cambridge, or anywhere else where young physicists and engineers are being trained? No; but in the peaceful seclusion of a palace in the country, almost equidistant from Cambridge, Oxford, London, and everywhere else. You have established a Meteorological Office, and you have put it in the academic seclusion of Victoria Street. What monastic isolation is good for I do not know. I am perfectly certain it is not good for the scientific progress of Meteorology. How can one hope for effective scientific development without some intimate association with the institutions of the country, which stand for intellectual development and the progress of science?

I could imagine an organisation which by association of

the universities with a central office would enable this country, with its colonies and dependencies, to build up a system of meteorological investigation worthy of its unexampled opportunities. But the co-operation must be real and not one-sided. Meteorology, which depends upon the combination of observations of various kinds from all parts of the world, must be international, and a Government department in some form or other is indispensable. No university could do the work. But whatever form Government service takes it will always have some of those characteristics which, from the point of view of research, may be called bondage. On the other hand, research, to be productive, must be free with an academic freedom, free to succeed or fail, free to be remunerative or unremunerative, without regard to Government audits or House of Commons control. Research looks to the judgment of posterity with a faith which is not unworthy of the Churches, and which is not among those excellent moral qualities embodied in the Controller and Auditor General. *Die academische Freiheit* is not the characteristic of a Government department. The opportunity which gave to the world the "Philosophiæ Naturalis Principia" was not due to the State subvention of the Deputy Mastership of the Mint, but to the modest provision of a professorship by one Henry Lucas, of whose pious benefaction Cambridge has made such wonderful use in her Lucasian professors.

The future of Meteorology lies, I believe, in the association of the universities with a central department. I could imagine that Liverpool or Glasgow might take a special interest in the meteorology of the sea; they might even find the means of maintaining a floating observatory; and when I say that we know practically nothing of the distribution of rainfall over the sea, and we want to know everything about the air above the sea, you will agree with me that there is room for such an enterprise. Edinburgh might, from its association with Ben Nevis, be desirous of developing the investigation of the upper air over our land; in Cambridge might be found the author of a book, on the principles of atmospheric physics, worthy of its Latin predecessor; and for London I can assign no limited possibilities.

If such an association were established I should not need to reply to Prof. Schuster's suggestion for the suppression of observations. The real requirement of the time is not fewer observations, but more men and women to interpret them. I have no doubt that the first expression of such an organisation would be one of recognition and acknowledgment of the patience, the care, the skill, and the public spirit—all of them sound scientific characteristics—which furnish at their own expense those multitudes of observations. The accumulated readings appal by their volume, it is true, but they are, and must be, the foundation upon which the scientific structure will be built.

So far as this country is concerned when one puts what is in comparison with what might be it must be acknowledged that the tendency to pessimistic complaisance is very strong. Yet I ought not to allow the reflections to which my predecessor's Address naturally gave rise to be too depressing. I should remember that, as Dr. Hellmann said some years ago, Meteorology has no frontiers, and each step in its progress is the result of efforts of various kinds in many countries, our own not excluded. In the presence of our guests to-day, some of whom know by practical experience the advantages of the association of academic liberty with official routine, remembering the recent conspicuous successes in the investigation of the upper air in France, Germany, Austria, and the United States, and the prospect of fruitful co-operation of meteorology with other branches of cosmical physics, I may well recall the words of Clough:—

Say not, the struggle nought availeth . . .
And as things have been, things remain.

If hopes were dupes, fears may be liars;
It may be, in yon smoke concealed
Your comrades chase e'en now the fliers,
And, but for you, possess the field.

For while the tired waves, vainly breaking,
Seem here no painful inch to gain,
Far back, through creeks and inlets making,
Comes silent, flooding in, the main.

And not by eastern windows only,
When daylight comes, comes in the light;
In front, the sun climbs slow, how slowly,
But westward, look, the land is bright.

Official meteorologists are not wanting in scientific ambitions and achievements. It is true that Prof. Hann, whose presence here would have been so cordially welcomed, left the public service of Austria to continue his services to the world of science by the compilation of his great handbook, and Snellen is leaving the direction of the weather service of the Netherlands for the more exclusively scientific work of directing an observatory of terrestrial physics; but I am reminded by the presence of Prof. Mascart of those services to meteorological optics and terrestrial magnetism that make his place as President of the International Committee so natural and fitting; and of the solid work of Angot on the diurnal variation of the barometer and the reduction of barometric observations for height that form conspicuous features among the many valuable memoirs of the Central Bureau of Paris.

Of the monumental work of Hildebrandsson in association with Teisserenc de Bort on clouds, which culminated quite recently in a most important addition to the pure kinematics of the atmosphere, I hope the authors will themselves speak. Prof. Willis Moore's presence recalls the advances which Bigelow has made in the kinematics and mechanics of the atmosphere under the auspices of Prof. Moore's office, and reminds us of the debt of gratitude which the English-speaking world owes to Prof. Cleveland Abbé, of the same office, for his treatment of the literature of atmospheric mechanics.

If General Rykatcheff had only the magnificent climatological Atlas of the Russian Empire to his credit he might well rest satisfied. Prof. Mohn's contributions to the mechanics of the atmosphere are examples of Norwegian enterprise in the difficult problems of Meteorology, while Dr. Paulsen maintains for us the right of meteorologists to share in the results of the newest discoveries in physics. Davis's enterprise in the far south does much to bring the southern hemisphere within our reach, while Chaves places the meteorology of the mid-Atlantic at the service of the scientific world. Need I say anything of Billwiller's work upon the special effect of mountains upon meteorological conditions, or of the immense services of the joint editors of the *Meteorologische Zeitschrift*, Prof. Pernter, of Vienna, and Dr. Hellmann, of Berlin; of Palazzo's contributions to terrestrial magnetism? The mention of Eliot's Indian work, or of Russell's organisation of Australian meteorology, will be sufficient to show that the dependencies and colonies are prepared to take a share in scientific enterprise. And if I wished to reassure myself that even the official meteorology of this country is not without its scientific ambitions and achievements, I would refer not only to Scott's many services to science but also to Strachey's papers on Indian and British Meteorology and to the official contributions to Marine Meteorology.

There is another name, well known in the annals of the British Association, that will for ever retain an honoured place among the pioneers of meteorological enterprise—that of James Glaisher, the intrepid explorer of the upper air, the Nestor of meteorologists, who has passed away since the last meeting of the Association.

I should like especially to mention Prof. Hergesell's achievements in the organisation of the international investigation of the upper air by balloons and kites, because it is one of the departments which offers a most promising field for the future, and in which we in this country have a good many arrears to make up. I hope Prof. Hergesell will later on give us some account of the present position of that investigation, and I am glad that Mr. Rotch, to whose enterprise the development of what I may call the scientific kite industry is largely due, is present to take part in the discussion.

Yet with all these achievements it must be confessed that the progress made with the problems of general or dynamical Meteorology in the last thirty years has been disappointing. When we compare the position of the subject with that of other branches of Physics it must be allowed that it still lacks what astronomy found in Newton, sound in Newton and Chladni, light in Young or Fresnel, heat in Joule, Kelvin, Clausius, and Helmholtz, and electricity in Faraday and Maxwell. Above all, it lacks its

Kepler. Let me make this clear. Kepler's contribution to physical astronomy was to formulate laws which no heavenly body actually obeys, but which enabled Newton to deduce the law of gravitation. The first great step in the development of any physical science is to substitute for the indescribably complex reality of nature an ideal system that is an effective equivalent for the purposes of theoretical computation. I cannot refrain from quoting again from Plato's "Republic" a passage which I have quoted elsewhere before. It expresses paradoxically but still clearly the relation of natural philosophy to natural science. In the discussion of the proper means of studying sciences Socrates is made to say "We shall pursue astronomy with the help of problems just as we pursue geometry: but we shall let the heavenly bodies alone if it is our design to become really acquainted with astronomy." What I take to be the same idea is expressed in other words by Rayleigh in the introduction to his "Sound." He there points out as an example that the natural problem of a sounding tuning-fork really comprises the motion of the fork, the air, and the vibrating parts of the ear; and the first step in sound is to simplify the complex system of nature by assuming that the vibrations of the fork, the air, and the ear can be treated independently. Frequently this step is a most difficult one to take. What student of nature, contemplating the infinity of heavenly bodies and unfamiliar with this method of idealism, would imagine that the most remarkable and universal generalisation in physical science was arrived at by reducing the dynamics of the universe to the problem of three bodies? When we look round the sciences each has its own peculiar ideals and its own physical quantities: astronomy has its orbits and its momentum, sound its longitudinal vibration, light its transverse vibration, heat its energy and entropy, electricity its "quantity" and its wave, but meteorology has not yet found a satisfactory ideal problem to substitute for the complexity of nature. I wish to consider the aspect of the science from this point of view and to recall some of the attempts made to arrive at a satisfactory modification of reality. I do not wish to refer to such special applications of physical reasoning as may be involved in the formation of cloud, the thermodynamics of a mixture of air and water vapour, the explanation of optical or electrical phenomena, nor even Helmholtz's application of the theory of gravitational waves to superposed layers of air of different density. These require only conventions which belong already to physics, and though they may furnish suggestions they do not themselves constitute a general meteorological theory.

The most direct efforts to create a general theory of atmospheric circulation are those which attempt to apply Newtonian dynamics, with its more recent developments on the lines of hydrodynamics and thermodynamics. Attempts have been made, mathematical or otherwise, to determine the general circulation of the atmosphere by the application of some form of calculation, assuming only the sun and a rotating earth, with an atmosphere, as the data of the problem. I confess that these attempts, interesting and ingenious as they are, seem to me to be somewhat premature. The "problem" is not sufficiently formulated. When Newton set to work to connect the motions of the heavenly bodies with their causes, he knew what the motions of the heavenly bodies were. Mathematics is an excellent engine for explaining and confirming what you know. It is very rarely a substitute for observation, and before we rely upon it for telling us what the nature of the general circulation of the atmosphere really is, it would be desirable to find out by observation or experiment what dynamical and elastic properties must be attributed to an extremely thin sheet of compressible fluid rotating about an axis with a velocity reaching 1000 miles an hour, and subject to periodic heating and cooling of a very complicated character. It would be more in consonance with the practice of other sciences to find out by observation what the general circulation is before using mathematics to explain it. What strikes one most about the mathematical treatises on the general circulation of the atmosphere is that what is true about the conclusions is what was previously known from observation. It is, I think, clear that that method has not given us the working ideal upon which to base our theory.

Consider next the attempts to regard atmospheric phenomena as periodic. Let me include with this the correlation of groups of atmospheric phenomena with each other or with those of the sun, when the periodicity is not necessarily regular, and the scientific process consists in identifying corresponding changes. This method has given some remarkable results by the comparison of the sequence of changes in the meteorological elements in the hands of Pettersen and Meinardus, and by the comparison of the variation of pressure in different parts of the globe by Sir Norman Lockyer and Dr. W. J. S. Lockyer; as regards the earth and the sun the subject has reached the stage of productive discussion. As a matter of fact, by continuing this Address I am preventing Sir Norman Lockyer from telling you all about it.

For the purpose of dealing with periodicity in any form we substitute for nature an ideal system obtained by using mean values instead of individual values, and leaving out what, from this point of view, are called accidental elements. The simplification is perfectly legitimate. Passing on to the consideration of periodicity in the stricter sense the process which has been so effective in dealing with tides, the motions of the liquid layer, is very attractive as a means of attacking the problems of the atmosphere, because, in accordance with a principle in dynamics, to every periodic cause there must correspond an effect of the same period, although the relation of the magnitude of the effect to the cause is governed by the approximation of the natural period of the body to that of the cause.

There are two forms of the strict periodic method. One is to examine the generalised observations for periodicities of known length, whether it be that of the lunar rotations or of sunspot frequency, or of some longer or shorter period. In this connection let me acknowledge a further obligation to Prof. Schuster for tacking on to his Address of last year a development of his work on the detection of hidden periodicities by giving us a means of estimating numerically what I may call the reality of the periodicity. The other method is by harmonic analysis of a series of observations with the view of finding causes for the several harmonic components. I may say that the Meteorological Office, supported by the strong opinion of Lord Kelvin, has favoured that plan, and on that account has for many years issued the hourly results for its observatories in the form of five-day means as representing the smallest interval for which the harmonic analysis could be satisfactorily employed. Sir Richard Strachey has given some examples of its application, and the capabilities of the method are by no means exhausted, but as regards the general problem of dynamic meteorology harmonic analysis has not as yet led to the disclosure of the required generalisation.

I ought to mention here that Prof. Karl Pearson, with the assistance of Miss Cave, has been making a most vigorous attempt to estimate the numerical value of the relationship, direct or inverse, between the barometric readings at different places on the earth's surface. The attempt is a most interesting one as an entirely new departure in the direction of reducing the complexity of atmospheric phenomena. If it were possible to find coordinates which showed a satisfactory correlation it might be possible to reduce the number of independent variables and refer the atmospheric changes to the variations of definite centres of action in a way that has already been approached by Hildebrandsson from the meteorological side.

Years ago, when Buys Ballot laid down as a first law of atmospheric motion that the direction of the wind was transverse to the barometric gradient and the force largely dependent upon the gradient, and when the examination of synchronous charts showed that the motion of air could be classified into cyclonic and anticyclonic rotation, it appeared that the meteorological Kepler was at hand, and the first step towards the identification of a working meteorological unit had been taken—the phenomena of weather might be accounted for by the motion and action of the cyclonic depression, the position of the ascending current, the barometric minimum. The individual readings over the area of the depression could be represented by a single symbol. By attributing certain weather conditions to certain parts of the cyclonic area and supposing that the depression travelled with more or less unchanged characteristics the vagaries of weather changes can be accounted for. For

thirty years or more the depression has been closely watched, and thousands of successful forecasts have been based upon a knowledge of its habits. But unfortunately the travelling depression cannot be said to preserve its identity in any sense to which quantitative reasoning can be applied. As long as we confine ourselves to a comparatively small region of the earth's surface the travelling depression is a real entity, but when we widen our area it is subject to such variations of path, of speed, of intensity, and of area that its use as a meteorological unit is seriously impaired, and when we attempt to trace it to its source or follow it to its end it eludes us. Its origin, its behaviour, and its end are almost as capricious as the weather itself.

Nor if we examine other cases in which a veritable entity is transmitted can we expect that the simple barometric distribution should be free from inexplicable variations. We are familiar with ordinary motion, or, as I will call it, astronomical motion, wave motion, and vortex motion. Astronomical motion is the motion of matter, wave motion the motion of energy, vortex motion the motion of matter with energy, but the motion of a depression is merely the transmission of the locus of transformation of energy; neither the matter nor the energy need accompany the depression in its motion. If other kinds of motion are subject to the laws of conservation of matter and conservation of energy, the motion of the depression must have regard also to the law of dissipation of energy. An atmospheric disturbance, with the production of rainfall and other thermal phenomena, must comply in some way with the condition of maximum entropy, and we cannot expect to account for its behaviour until we can have proper regard to the variations of entropy. But the conditions are not yet in a form suitable for mathematical calculation, and we have no simple rules to guide us. So far as Meteorology is concerned, Willard Gibbs unfortunately left his work unfinished.

When the cyclonic depression was reluctantly recognised as too unstable a creature to carry the structure of a general theory Mr. Galton's anticyclones, the areas of high pressure and descending currents, claimed consideration as being more permanent. Prof. Köppen and Dr. van Bebber have watched their behaviour with the utmost assiduity and sought to find therein a unit by which the atmospheric changes can be classified; but I am afraid that even Dr. van Bebber must allow that his success is statistical and not dynamical. "High pressures" follow laws on the average, and the quantity we seek is not an average but an individual.

The question arises, whether the knowledge of the sequence of weather changes must elude us altogether, or will yield to further search. Is the man in the street right after all? But consider how limited our real knowledge of the facts of atmospheric phenomena really is. It may very well be that observations on the surface will never tell us enough to establish a meteorological entity that will be subject to mathematical treatment; it may be that we can only acquire a knowledge of the general circulation of the atmosphere by the study of the upper air, and must wait until Prof. Hergesell has carried his international organisation so far that we can form some working idea therefrom of general meteorological processes. But let us consider whether we have even attempted for surface meteorology what the patience of astronomers from Copernicus to Kepler did for astronomy.

Do we yet fully comprehend the kinematics of the travelling depression; and if not, are we in a satisfactory position for dealing with its dynamics? I have lately examined minutely the kinematics of a travelling storm, and the results have certainly surprised me and have made it clear that the travelling depressions are not all of one kinematical type. We are at present hampered by the want of really satisfactory self-recording instruments. I have sometimes thought of appealing to my friends the professors of physics who have laboratories where the reading of the barometer to the thousandth of an inch belongs to the work of the "elementary class," and of asking them to arrange for an occasional orgy of simultaneous readings of the barometer all over the country with corresponding weather observations for twenty-four consecutive hours, so that we might really know the relation between pressure, rainfall, and temperature of the travelling depressions; but I fear the area covered would even then hardly be large enough, and we must improve our self-recording instruments.

Then, again, have we arrived at the extremity of our knowledge of the surface circulation of the atmosphere? We know a great deal about the average monthly distribution, but we know little about the instantaneous distribution. It may be that by taking averages we are hiding the very points which we want to disclose.

Let me remind you again that the thickness of the atmosphere in proportion to the earth's surface is not unsatisfactorily represented by a sheet of paper. Now it is obvious that currents of air in such a thin layer must react upon each other horizontally, and therefore we cannot *a priori* regard one part of the area of the earth's surface as meteorologically independent of any other part. We have daily synoptic charts for various small parts of the globe, and the Weather Bureau extended these over the northern hemisphere for the years 1875 to 1879; but who can say that the meteorology of the northern hemisphere is independent of that of the southern? To settle that primary question we want a synchronous chart for the globe. As long as we are unable to watch the changes in the globe we are to a certain extent groping in the dark. A great part of the world is already mapped every day, and the time has now arrived when it is worth while to consider what contributions we can make towards identifying the distribution of pressure over the globe. We may idealise a little by disregarding the local peculiarities without sacrificing the general application. I have put in the exhibition a series of maps showing what approximation can be made to an isochronous chart of the globe without special effort. We are gradually extending the possibility of acquiring a knowledge of the facts in that as in other directions. With a little additional enterprise a serviceable map could be compiled; and when that has been reached, and when we have added to that what the clouds can tell us, and when the work of the Aëronautical Committee has so far progressed that we can connect the motion of the upper atmosphere with the conditions at the surface, when we know the real kinematics of the vertical and horizontal motion of the various parts of a travelling storm, we shall, if the universities will help us, be able to give some rational explanation of these periodic relations which our solar physics friends are identifying for us, and to classify our phenomena in a way that the inheritors of Kepler's achievements associated with us in this Section may be not unwilling to recognise as scientific.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. W. N. HARTLEY, D.Sc., F.R.S., F.R.S.E., PRESIDENT OF THE SECTION.

THE ofttimes laborious method of investigating the relationship of substances by ascertaining how one form of matter can operate upon another, in other words by chemical reactions, has of late been supplemented by the examination of their physical properties, and has been extended to compounds, both organic and inorganic. In several directions this has led to results of very uncommon interest. Accordingly I propose to offer a brief account of twenty-five years' experimental work in that branch of chemical physics which deals with the emission and absorption of rays of measurable wave-length, and to review its present position chiefly in relation to the theory of chemistry, indicating where it may be usefully and profitably extended.

According to Davy ("Chemical Philosophy," vol. i., 1812, p. 211), Ritter observed chemical action on moist chloride of silver to be different in different parts of the spectrum, slight in the red, greater towards the violet, and entending into a space beyond the violet where there is no sensible light or heat. Wollaston discovered that chemical action was exerted by refracted rays in a region where they were of a higher refrangibility than any rays that were visible. Young showed that the invisible rays are liable to the same affections as visible rays. Hence we have the beginnings of spectrum analysis in its chemical relations to terrestrial matter, in the infra-red, the visible, and the ultra-violet regions.

Everyone is more or less familiar with the subject of spectrum analysis. This was defined by Tait as an optical method of making a diagnosis of the chemical composition of either (*a*) a self-luminous body, or (*b*) an absorbing medium, whether self-luminous or not. It has now become necessary to enlarge this definition, and I would suggest that it is the study of the composition and the constitution of matter by means of radiant energy, and recording in the order of their refrangibilities the rays emitted and absorbed by matter. By this modified statement the infra-red or so-called "invisible heat rays," the visible or "colour rays," and the ultra-violet or "chemical rays" are included.

Spectra are of two kinds, emission and absorption spectra. It will be convenient if the latter are considered first.

ABSORPTION SPECTRA.

The Infra-red Region.

Abney (1880) by the preparation of a particularly sensitive form of collodion emulsion containing silver bromide was successful in obtaining very extraordinary results. Such films as he prepared were so sensitive to invisible radiations of long wave-length as to be capable of forming a representation of even a kettle of boiling water, standing in an absolutely dark room. This picture could not of course be properly referred to as a photograph, though the process by which it was obtained was such as we are accustomed to term a photographic process. It may with greater propriety be termed an actinograph, the result not of light, but of dark rays. The least refrangible of the visible rays lies about wave-length 7800 ten-millionths of a millimetre, or Ångström units; but these rays extend as far as wave-length 12,000, while Becquerel has measured lines in the spectra of metals of as low a refrangibility as wave-length 18,000.

Abney and Festing (1881) investigated the influence of atomic groupings in the molecules of organic substances by measuring their absorption in the infra-red region of the spectrum.

They studied such simply constituted substances as water, hydrochloric acid, chloroform, carbon tetrachloride, and cyanogen, besides many hydrocarbons with their hydroxyl, haloid, and carboxyl derivatives. Characteristic groups of lines or very narrow bands were observed in carbon compounds, but they are absent from carbon compounds containing no hydrogen, and do not all appear in some of the hydrogen compounds. The facts observed led to the conclusion that they belonged to hydrogen, but are subject to some occasional modifications. Oxygen in hydroxyl, for instance, modifies two of the lines, since it obliterates by absorption the rays which lie between them. Oxygen in aldehyde, or when it forms part of the carbon nucleus of some such compound, presents bands which are bounded by well-defined lines, or are inclined to be linear. These appear to be characteristic bands indicating the carbon nucleus of a series of substances. Alkyl radicals, such as ethyl, exhibit absorption bands, and so does the benzene nucleus. It is a remarkable fact that bands appear in the solar spectrum which correspond with those of benzene (1881).

Julius (1893) has investigated the absorption in the infra-red caused by many carbon compounds by means of the bolometer, combined with a prism, and also with a diffraction grating. He showed that the molecules of compound substances absorbed the rays which were emitted at the time of their formation. Thus, to take the simplest case, the emission spectrum of hydrogen burning in air corresponds with the absorption bands of water vapour, that is to say, the absorption spectra of the compounds are the counterpart of the emission spectra of the flames which yield these compounds during combustion. The emission spectrum of carbon dioxide is found in the spectrum of burning carbon monoxide, cyanogen, methane, and carbon disulphide; and that of water-vapour in various hydrocarbons. As early as 1888 Julius, in an Inaugural Dissertation, quoting Tyndall, recognised that the absorption and emission of rays measured with the thermopile were manifestations of the molecular vibrations.

The various absorption spectra examined included those of the alcohols, such as isopentylic, isobutylic, normal butylic, propylic, ethylic, and methylic, as well as hydrocarbons, chloroform, and benzene. The study of the maxima of radiation and the maxima of absorption offers us a means of arriving at a knowledge of a series of new and valuable physical constants, namely, the vibration periods characteristic of the molecules. (Tyndall discussed this subject in his usually luminous style on pp. 391 to 402 of his work "Heat as a Mode of Motion.")

Puccianti (1900) has examined the infra-red absorption spectra of liquids, including aromatic compounds and alkyl derivatives, while Donath has examined in the same region various essential oils. Carbon combined with hydrogen shows a maximum of absorption with a wave-length about (1·71 μ mm.) 17,100 . ngström units.

Benzene and pyridine have two other maxima of absorption in common. The alcohols have very similar maxima of absorption at wave-length 21,000.

The three isomeric xylenes show absorption spectra which are almost identical. At or about wave-length 23,200 another maximum of absorption is shown.

Julius refers to Langley's observation that at a wave-length of 27,000 there is an abrupt termination to the solar spectrum, probably caused by the water vapour in the atmosphere; but a band extends to 273,000, and at no very great elevation above the earth's surface there are rays with a wave-length of 45,700 Ångström units. All radiations of longer wave-length—and Julius has measured down to 149,000 Ångström units—are likely to be absorbed by the carbon dioxide in the atmosphere.

The Visible Rays or Colour Region.

J. L. Schönn (1879) examined the absorption spectra of substances usually considered to be colourless in layers from 1·6 to 3·7 metres in thickness and observed narrow bands in the spectra of methyl, ethyl, and amyl alcohol, lying in the red, orange, and yellow; methyl alcohol showed two bands, ethyl and amyl alcohol each three. Gerard Krüss (1888) calculated the wave-lengths of these bands, and it appears that the higher members of the homologous series have the bands displaced towards the red end of the spectrum. Russell and Lapraik (1879) made similar observations on columns of liquid from two to eight feet in length. All the substances gave well-defined absorption bands lying between wave-lengths 6000 and 7000.

The bands of the different substances differed altogether from the bands of water. Alcohols give a band which is similar in different alcohols, but the higher the alcohol stands in the homologous series, that is to say, the larger the number of carbon atoms it contains, the nearer is the band to the red end of the spectrum (1881).

It was definitely established that for each CH_2 introduced into a molecule of ammonia or benzene there is a shifting of the absorption bands towards the red end of the spectrum.

It will, of course, be understood that the liquids examined were perfectly colourless in the ordinary acceptation of the term; and that they appear so is owing to the bands of absorption being very narrow, so that the percentage of luminous rays withdrawn by absorption is but a very small fraction of the whole spectrum emitted by a source of light when viewed under ordinary conditions.

Numerous observations were made by Melde, Burger, Magnus, H. W. Vogel, and Landauer (1876–78), which showed that changes in the absorption spectra of solutions are partly physical and partly chemical, that is to say, they are caused by changes in the constitution of the solution. Vogel mentions cases where no chemical change was believed to take place, as, for instance, where naphthalene red shows different spectra according to whether it is dissolved in alcohol, water, resin, or is solid or used to colour paper (1878).

This points to some difference in the constitution of the solution. A well-known instance is that of iodine in alcohol, chloroform, or carbon disulphide.

It must be observed that Vogel's work referred merely to phenomena observable in the visible spectrum, to small thicknesses of the absorbing medium, and was not applied quantitatively. Two solutions may give spectra which are apparently identical at one concentration, but spectra quite different when submitted to varying degrees of dilution.

In order to ascertain in what way absorption spectra are

related to the chemical constitution of organic substances, it is necessary to examine a wider range of spectrum than that included in the merely visible region, and this may be done by extending the observations into the ultra-violet.

The Ultra-violet Region.

Stokes in preparing his experiments for a Friday evening discourse at the Royal Institution observed that the spectrum of electric light when a prism and lenses of quartz were used extended no less than six or eight times the length of the visible spectrum. In 1862 he studied the ultra-violet spectra of metals and executed drawings of the lines exhibited by aluminium, zinc, and cadmium. He discovered the fact that certain solutions show light and dark bands in the spectrum of rays transmitted by them, the solutions being colourless; the bands are invisible unless they fall on a fluorescent screen. It was under such conditions that they exhibited light and darkness. The screen used was of plaster of Paris saturated with a fluorescent substance, such as uranium phosphate.

William Allen Miller in 1863, simultaneously with Stokes, described his method of examining the photographic transparency of various saline solutions and organic substances and of depicting metallic spectra. A sensitised photographic plate was used for the reception of the rays of the spectrum, so that they were made to register their own position and intensity. L. Soret invented the fluorescent eye-piece for the purpose of investigating the ultra-violet rays and ascertained the best media for the transmission of rays of high refrangibility. Colourless fluor-spar, a rare mineral, was found to answer best, and quartz lenses were achromatised with this. Iceland spar was found to absorb some of the more refrangible rays, and a pure spectrum was difficult to obtain with quartz prisms owing to double refraction, which caused the lines in metallic spectra to be duplicated. Struck by the fact that Miller had examined many organic substances without obtaining evidence of a connection between their constitution and their absorption spectra—the actual words used by Miller were, "I have not been able to trace any special connection between the chemical complexity of a substance and its diactinic power" (*Journ. Chem. Soc.*, vol. xi. p. 68)—it appeared to me desirable that this point should be systematically reinvestigated. L. Soret had already proceeded with work in this direction, by examining and drawing a great variety of organic substances and diagrams of absorption curves. But it was deemed necessary to make a large number of examinations of substances of a comparatively simple constitution, and according to theory closely related, and afterwards gradually to proceed to the study of substances of greater complexity. For such purposes a photographic method alone appeared a practicable one, particularly when comparisons had to be made between substances observed at different times, for the reason that none but photographic records could be absolutely relied upon and stored away for future reference.[1]

[1] Clerk Maxwell had calculated for Miller the best focal length of lenses of quartz which would give an approximately flat field. His computation made this something over a length of three feet. All Miller's photographs were taken with the plate placed normal to the axis of the lens, but Stokes had shown that the locus of the foci of the different rays formed an arc of a curve or nearly a straight line, lying very obliquely to the axes of the pencils coming through the lens.

It was obvious from Miller's photographs that only one or two rays on each plate were even approximately in focus. To obtain spectra in focus from end to end it was evidently necessary to incline the plate so that the end upon which the red rays would fall, which are of longest wave-length, should be farther off than that upon which the ultra-violet fall, which are of shortest wave-length. It was also found experimentally that lenses of much shorter focal length (ten or twelve inches) could be used, giving perfect definition, and, what is still more important, it was found a positive advantage not to have them corrected by fluor-spar or calcite. The plate carrier was adjusted at an inclination of approximately 22° to the normal; in such a position the rays from the yellow sodium line to the extreme ultra-violet of the spark spectrum of cadmium were simultaneously in focus on a plane surface.

The prism was of quartz cut on Cornu's plan, the method of construction designed to get rid of all double refraction being communicated to me by M. Cornu in a very kindly written letter. The first instrument was constructed in 1878 and the description of it published in 1881. It has been the model for several others. One with two prisms and lenses of 12 inches focus was exhibited by me in the Inventions Exhibition in 1882. At the Jubilee meeting of the British Association at York the spark spectra of iron, cobalt, and nickel, enlarged to twenty-five diameters and printed by the Autotype Company, were exhibited. They are more than 8 feet in length, and have proved very useful for reference. The photographic process is a point of great importance; the then newly invented gelatine bromide films made by Kennet were alone quite suitable.

The plan of the proposed investigation was to photograph the rays transmitted by molecular proportions of hydrocarbons, alcohols, acids, and esters, either alone as vapour or liquid, or dissolved in some neutral and, in comparison with the substances to be examined, an optically non-absorbent solvent.

It was considered that the metameric esters would afford much information if a sufficient number of them were examined and their spectra compared, and if the acids themselves were not responsive the sodium and potassium salts in solution would serve the purpose, since the alkalies did not affect the spectrum. The general deductions (1879) are now well known, but two points not generally taken into account were well established. First, the extraordinary delicacy of the ultra-violet spectrum in detecting traces of impurities. For instance, pyridine, an invariable impurity in commercial ammonia, is present in the proportion of about 1/30000th. It was proved that the absorption spectra of the normal paraffins prepared with the greatest care by Schorlemmer contained traces of impurities which could not be separated. Secondly, some of the normal alcohols could not be rendered pure by the ordinary methods employed, and great care was necessary in their preparation. It may well be asked that, if such were the case, upon what grounds was it concluded that impurities were present? How was it possible to distinguish between a normal and an abnormal absorption spectrum when no standards of comparison existed? It may be of interest if this question be now answered, as no adequate account of it has been made public. All the substances in any one homologous series were shown to vary in the extent to which the rays at the more refrangible end of the spectrum were absorbed, and the different terms of the series differ solely by the number of CH_2 groups in the molecule; and the greater the number of these the greater the absorption. The extent of the absorption should be proportional to the molecular weight of the substance. Accordingly if repeatedly purifying and fractionally distilling a considerable quantity of material failed to give spectra which were constant and identical, but gave instead spectra which were variable, even in a slight degree, it was evident that the absorption due to the molecule of the substance was interfered with by some impurity.

When, however, it became evident that successive quantities of methylic alcohol, for example, prepared in a certain manner yielded spectra which were practically identical under different conditions, such as thickness of liquid, and that they differed but slightly from that of pure water after the type of which the alcohol is constituted, the conclusion was inevitable that we were dealing with a pure preparation. In short, the longest spectrum obtained in all circumstances and under every reasonable condition could not possibly be the result of accident, more particularly if it could be repeatedly obtained from different specimens of the same substance. The same reasoning applies to the acids and their salts in the investigation of which similar difficulties arose.

Soret and Rilliet pointed out that in the rectification and prolonged desiccation of the alcohols there is often slight oxidation which leads to the production of impurities which affect the spectra transmitted by them.

They found that ethyl alcohol is not appreciably less diactinic than methyl alcohol, and both transmitted a spectrum nearly as long as that of water. This was shown by Huntington and me when the usual 25 mm. of thickness of the layer of liquid were tested. By taking columns of liquid 100 mm. in length the differences are greater, and they increase with columns of increased length.

The influence of each additional CH_2 in the molecule causes a shortening of the spectrum. This was shown to be due to the carbon atoms and not to the hydrogen. The acids, containing the same number of carbon atoms as the alcohols, have a much greater absorptive power, which is due to the carboxyl group (C : O · OH). By the examination of a number of various substances, such as polyhydric alcohols, as glycol, glycerol, mannitol, and various sugars, it was found that, no matter what its complexity, no open-chain compound causes selective absorption, *i.e.* absorption bands.

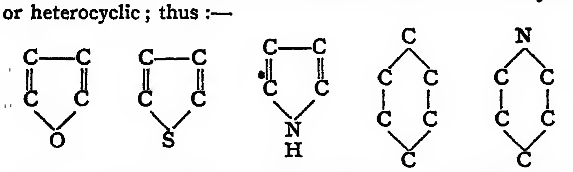
Shortly it may be stated that in the examination of organic substances we have three variations in absorption

spectra: First, those of substances the rays of which are freely transmitted, the absorption being at the more refrangible end of the spectrum, and the spectrum of which is readily increased in length by dilution; secondly, those in which the spectra are of the same kind, but the absorptive power is greater, so that they withstand dilution to a much greater extent; thirdly, those spectra which exhibit selective absorption, and which at the same time exert great absorptive power, or, in other words, can undergo great dilution before the absorption bands are rendered visible, and still further dilution before they are extinguished or obliterated.

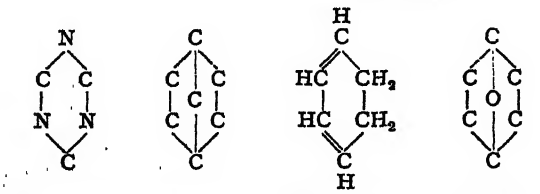
Spectra of the First Variety belong to substances which are constructed on an open chain of carbon atoms, thus: C·C·C·C·C or C=C·C·C·C and C≡C·C·C·C.

The introduction in place of one or more atoms of hydrogen—of hydroxyl, OH, carboxyl, COOH, methoxyl, OCH_3, CO, COH, or NH_3, or of side chains such as CH_3, C_2H_5, &c.—does not affect the character of the spectra, but merely the absorptive power, which is increased when oxygen or an oxygenated radical is introduced.

Spectra of the Second Variety are spectra of substances so constituted that the carbon atoms form a closed chain. It is immaterial whether the closed chains are homocyclic or heterocyclic; thus:—



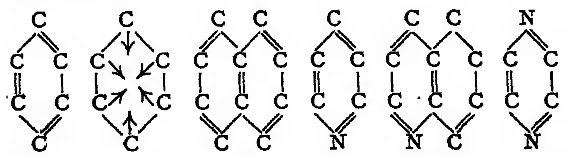
Furfurane Thiophene Pyrrol Diketohexamethylene Hydro-aromatic compounds Piperidine



Cyanuric Acid Camphor Dihydrobenzene Cineol

They possess greater absorptive power than open-chain compounds, but do not exhibit absorption bands. It is manifestly the chain or ring structure of the compounds that gives them greater absorptive power, and not the number of carbon atoms in the molecules.

Spectra of the Third Variety.—These show absorption bands, and the substances yielding them are generally constituted on the type of benzene, naphthalene, anthracene, phenanthrene, &c.; but the rings may be either homocyclic or heterocyclic without the character of the spectra being altered; thus:—



Benzene Benzene Naphthalene Pyridine Quinoline Pyrazine

If we say that the compounds which are homocyclic are constituted of at least three pairs of carbon atoms doubly linked, which are themselves singly linked together, we may make use of the formula of Kekulé for benzene as the simplest expression of their constitution; if we assume that each of the six atoms is linked to at least other two atoms we adopt what is practically the prism formula of Ladenburg, or the same idea expressed in space of two dimensions. It is difficult to express the physical condition by the Armstrong-Baeyer formula or centric arrangement because this does not clearly suggest to one's mind what is manifestly the fact, namely, that the carbon atoms in the nucleus of benzene are much more closely condensed or combined together than those of the hydroaromatic series. This condensed condition of the carbon atoms is evident from the higher molecular refractive energy of aromatic compounds and of the specific refractive energy of the carbon in such combinations.

Side chains such as do not exert selective absorption have no influence on the character of the spectra, but they slightly increase the general absorption.

Heterocyclic compounds possess greater absorptive power, both as regards the general and selective absorption, than those which are homocyclic.

The point which I particularly desire to direct attention to here is, that for the first time Kekulé's remarkable benzene theory was supported by definite physical measurements, and the closed-ring formula represented a veritable actuality.

Of Molecular and Intra-molecular Vibrations.

Johnstone Stoney was the first to show that the cause of the interrupted spectra of gases is to be referred to the motions within the individual molecules, and not to the irregular journeys or encounters of the molecules with each other; and this applies to the absorption as well as to emission spectra. He further advised the use of oscillation frequencies instead of wave-lengths in describing the measurements of spectra. Johnstone Stoney and Emerson Reynolds subsequently examined the extraordinary absorption exhibited by chlorochromic anhydride, the bands in which are evidently harmonically related.

It has already been shown that the hydrocarbons of the aromatic series exert two kinds of absorption, a general and a selective absorption. All the evidence we possess warrants the belief that the general absorption is caused by the motion of the molecules, while the selective absorption is due to the motion within the molecules.

When the molecule of a substance is capable of vibrating synchronously with a radiation, the ray received on this substance is absorbed. The absorption is complete if the direction of the vibration of the molecule and of the ray is the same but the phase opposite, and if the number of molecules in the path of the rays is sufficient to damp all the vibrations.

When the quantity of substance in the path of the rays is reduced, the number of molecules present is not sufficient to damp all the vibrations and some of the rays are transmitted. If, however, certain carbon atoms within the molecule are vibrating synchronously with certain rays, we shall have selective absorption of these rays after the general absorption has been so weakened by dilution or otherwise as to allow them to pass.

It is evident, then, that general absorption exerted by carbon compounds is due to the vibration of the molecules because the absorption increases with the number of carbon atoms in the molecule; or, in other words, in any homologous series the greater the molecular mass the lower the rate of vibration of the molecule.

It has not been found possible to associate any of the absorption bands of the substances examined with any particular carbon atoms; but the bands in benzene are six in number, or the same in number as the carbon atoms. It has, however, been shown that the rapidity of the intramolecular vibrations was dependent upon the rate of vibration of the molecules. From numbers representing approximately the mean wave-lengths of the four chief bands of rays absorbed by benzene, naphthalene, and anthracene, and from the velocity of light, the mean rate of the vibrations within the molecules was calculated (1881), the numbers being as follows:—

	Molecular Vibrations
Benzene	1248^{10}
Naphthalene	1177^{10}
Anthracene	910^{10}

The mean rate of vibration of the rays absorbed by naphthalene is less than that absorbed by benzene, and those of anthracene less than those of naphthalene. It follows from this that the vibrations within the molecules are not independent, but are a consequence, of the fundamental molecular vibrations, like the harmonics of a stretched string or of a bell.

The term absorptive power has generally been used with respect to the extent of rays of the spectrum absorbed, but there is intensity of absorption to be considered. In the case of a vibrating string or tuning-fork greater amplitude

of vibration means a louder note; in the case of molecules greater intensity of absorption may be caused by a greater amplitude of vibration in the molecules of the absorbing medium, the number of molecules being constant. But by greater amplitude it is not to be understood that the rate of vibration is increased.

If this be so then, as the absorption intensity of anthracene and naphthalene is, molecule for molecule, greater than that of benzene, the amplitude of vibration of the molecules of these substances is greater, but the rate of vibration is slower.

From the foregoing it will be observed that where λ is the wave-length $1/\lambda$ is the inverse wave-length, omitting the correction for the refraction of air which is a very small value, it is the oscillation frequency of the ether in a small unit of time, and the most convenient measurement for use in describing spectra. Seven years after the publication of these views Gerard Krüss (1888) dealt with the subject of coloured substances in a similar manner. From the undulatory theory of light, deductions may be drawn regarding the inner molecular movements or inter-atomic movements within the molecules, inasmuch as the vibrations of the ether, which fills the intra-molecular space, are a resultant within that space of the velocity and amplitude of the molecular vibrations.

Thus, if λ be the wave-length of a ray emitted by a substance, and v the velocity of light, the number of vibrations, n, which a molecule sends forth by movements of it as a whole and of its parts can be determined by the equation $n = v/\lambda$.

G. Krüss made a series of calculations for coloured substances similar to those which I had made for colourless substances and for ozone.

Curves of Molecular Vibrations.

Observations on absorption spectra should, whenever it is possible, be made with reference to the quantity of substance which produces a given measurable effect. A molecular weight in milligrams or a milligram-molecule is a convenient quantity which may be dissolved in 20 c.c., 40 c.c., or 100 c.c. of any non-absorbent liquid, and observed through thicknesses of the solution varying from 25 mm. to 1 mm. in thickness. When a series of photographs has been measured a curve is plotted, which shows the general and the selective absorption of the substance. The oscillation frequencies of the absorbed rays are taken as abscissæ, and the proportional thickness in millimetres of the weakest of a series of solutions as ordinates. The curves are as often as possible made continuous, and they are called *curves of molecular vibrations.*

The curves of the molecular vibrations present very striking features: they are valuable physical constants which enable one to classify and identify substances.

Position Isomerism.

Isomerides of the *ortho-*, *meta-*, and *para-*positions in aromatic substances yield spectra with the absorption bands, differing in position, in width, and in intensity. There is no distinguishing character to be observed in the different isomerides. Isomerism in the pyridine, quinoline, and naphthalene derivatives has not yet been completely studied. In such cases as have already passed under review there is nothing that indicates the positions of the substituted hydrogens.

Stereo-isomerism.

Where isomerism is not due to differences in structure, but simply to the distribution of the atoms in space, we have no means of distinguishing isomeric substances from an examination of their spectra; for instance, benz-*syn*-aldoxime and benz-*anti*-aldoxime yield curves of molecular vibrations which are identical.

Tautomerism.

The possibility of an atom of hydrogen occupying alternative positions in a compound

$$(NH \cdot C : O \rightleftarrows N : C \cdot OH)$$

so that it may be united to an atom of nitrogen or of carbon in one instance, or to an atom of oxygen in another, easily gives rise to substances with different characters, the one that of a phenol, the other that of a ketone. One interpretation of the facts observed which has been very commonly received may be stated thus. Certain compounds have in their constitution an atom of hydrogen of a "roving disposition" which at one time will attach itself to an atom of oxygen, or to an atom of nitrogen, and anon it will forsake one of these and unite itself to an atom of carbon. The consequence of this "instability of character" is that when a derivative of the compound is being prepared or sought for by a chemical process, which according to all previous knowledge ought to yield it, the substance brought forth is of a different class, but withal of the same composition; it is, in fact, an isomeride.

According to another theory, the two isomeric derivatives of the parent substance are present in equal proportions in a solution in a state of equilibrium, and upon crystallisation one or other of these assumes the solid form. Taking those cases where a substance has a constitution which it is believed has been correctly ascertained by chemical reactions, and which yields two isomeric alkyl derivatives, it becomes a question as to which of these the parent substance has directly given birth to. The evidence from chemical reactions has in many cases failed to give a satisfactory answer, but the curves of molecular vibrations of such substances afford the desired information concerning the relationship of their constitution to that of their respective derivatives.

Most convincing evidence has been afforded by observations on their spectra, that several of the parent substances are really not what they seem to be.

Thus, isatin and methyl pseudo-isatin yield curves which are almost identical, the sole difference between them being due to the substitution of the alkyl radical for hydrogen, the nature of which difference might have been predicted.

Clearly the parent substance and the pseudo-derivative are of the same nature and constitution.

Carbostyril and methyl-pseudo-carbostyril, *o*-oxycarbanil and its ethyl ether, obtained by boiling with potash and ethyl iodide, are also similarly related, and they possess the ketonic or lactam structure.

On the other hand methylisatin, carbostyril, and the other ether of *o*-oxycarbanil yield curves which are essentially different from the foregoing, and are enolic or of the lactim type. Generally speaking, the ketonic are more stable than the enolic forms. Dibenzoyl-methane is ketonic, and the tautomeric substance oxybenzal-acetophenone is enolic, and in this instance the enolic form is that with the greatest stability. The two substances yield different curves, and the gradual change of the less stable into the more stable form can be traced by photographing the spectra of the solutions at intervals.

The ethyl esters of dibenzoyl succinic acid are of interest in this connection. There are three isomers known out of the thirteen which are possible, and the spectra of these have been studied. Knorr has given three formulæ for what he designates the α, β, and γ esters. Of these there are two, the β and γ forms, which give identical absorption curves: they are of the ketonic type, and structurally identical, but configuratively different, being stereo-isomerides.

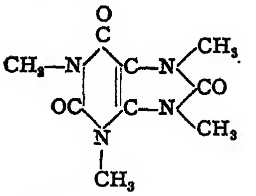
The curve of molecular vibrations of the α ester is quite different from that common to the β and γ compounds. The α compound is of the enolic type, and it changes spontaneously at ordinary temperatures into the ketonic, thus showing that in this case also the latter is the more stable. The transition from the one form into the other was seen to be in progress, and after an interval of only three hours the absorption band of the enolic ester had almost entirely disappeared. In three weeks the transformation had become complete, as was shown by the molecular vibration curve of the α ester being almost exactly coincident with that of the β and γ forms.

Another interesting example is afforded by the study of phloroglucinol, it being a substance with a constitution of a somewhat doubtful character, for owing to the ambiguity of its behaviour towards chemical reagents it is impossible to arrive at a decision from chemical evidence whether the oxygen atoms are present in enolic or ketonic groups. Towards some substances it behaves as a phenol, towards others as a ketone. The doubt also presented itself as to

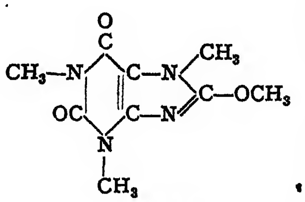
whether phloroglucinol from various sources had the same constitution, and, further, whether there might not be two isomeric forms of the compound present in equal proportions in a solution of the substance. Specimens of phloroglucinol prepared in five different ways from different materials gave curves of molecular vibrations which were identical: this decided the question absolutely; they are one and the same substance. If the constitution of the substance is that of a trihydroxybenzene or phenol, then the trimethyl ether should exhibit an absorption curve differing but slightly in detail from that of the parent substance; and, furthermore, the latter should exhibit a general resemblance to the curves of pyrogallol and phenol. This was found actually to be the case in both particulars.

Finally, with regard to tautomerism, it may be considered as decided that no evidence has been obtained based upon either physical measurements or chemical reactions of, first, the presence of a "wandering" atom of hydrogen as a characteristic of compounds which exhibit tautomerism; secondly, that solutions of tautomeric compounds do not contain equal quantities of the two substances, or enolic and ketonic forms in equilibrium, and that if both are present one so greatly preponderates over the other that no trace of any but the one compound can be detected; thirdly, it has been observed that some substances do change spontaneously from one form to another, and that this change sets in very quickly after the substance has been dissolved; fourthly, that substances change from one form to another under the influence of different reagents, as, for instance, cotarnine, as Dobbie and Lauder (1903) have shown, in presence of methyl alcohol or of caustic soda, and again in presence of potassium cyanide. In fact it appears that under the influence of different reagents one or other of the two compounds is the more stable, and the more stable substance is then formed.

A reaction is recorded in the researches of Emil Fischer where it appears that two tautomeric forms are produced simultaneously from oxycaféine. When the silver salt of this substance is heated with methyl iodide it yields a mixture of tetramethyl uric acid and methoxycaféine, the characteristic groupings in which are $-NH-CO-$ and $-N=COH-$, the hydrogens being methylated. This is a singular reaction which has not yet been studied spectrographically.



Tetramethyluric Acid.



Methoxycaféine.

The Absorption Spectra of Alkaloids.

The interest attached to an examination of the absorption spectra of the alkaloids is not alone the fact that a means of recognising, detecting, and estimating such substances was devised, but still more that we may learn something of their chemical constitution. Many of the poisonous alkaloids give no distinctive chemical reactions, and in certain cases the means of recognising them are restricted to observations on their crystalline form and their physiological action. The physiological action of certain alkaloids of an extremely deadly character is remarkable enough to prove a means of their identification when the effect on the human subject is under observation. The first experimental work on the absorption spectra of the alkaloids arose out of a celebrated trial for murder, which engaged much attention in the year 1882. It was proved that the lethal drug administered was aconitine.

To identify this substance, of which there are several varieties, it was necessary at that time to resort to physiological tests made upon small animals.

Such a course always affords an opportunity for forensic arguments based upon the evidence adduced. To substitute absolute physical measurements for physiological tests seemed to present facilities for securing justice by removing any doubt of the identity of an unknown substance with the nature of one which is known. Alkaloids yield spectra of two kinds, those which do not and those which do exhibit absorption bands, the difference between the two classes of substances being one dependent on the constitution of the nucleus or ultimate radical of the compound. It is possible not only to identify substances, but also to determine the quantity present in a mixture or solution, and this has actually been done.

Alkaloids which are derived from benzenoid hydrocarbons, pyridine, quinoline, or phenanthrene give evidence of their origin by their spectra. It is therefore advantageous to make a careful study of the absorption spectra of the substances themselves and of the various products derived from them when studying their constitution. It was remarked while the work was in progress that the quinine spectrum curve was probably due to the conjugation of four pyridine or two quinoline nuclei. It is known now to be a substance of a complicated structure containing one quinoline nucleus. It differs from cinchonine only by one methoxyl group in the *para*-position. Observations made on simple bases differ from those made on substitution products, such as alkyl derivatives, in this respect, that the bases are the more diactinic, while addition products, such as hydrogenised compounds, and also salts of the alkaloids such as hydrochlorides, are more diactinic than the simple bases. It was shown by the researches of Alder Wright that different preparations of aconitine can yield substances slightly differing in constitution. On examining them it was shown that these preparations yielded different absorption curves the variations in which were due to differences in the constitution of the different preparations. To state a particular case of a well-defined character, the aconitine from *aconitum napellus* and japaconitine from a Japanese aconite prepared by Alder Wright had practically the same absorption spectrum and yielded similar curves; but that of japaconitine was just what might be expected from a substance with a nucleus of a similar constitution, but about twice the molecular weight of aconitine; in other words, a condensation of two molecules of aconitine into one—namely, what was observed in the spectra of morphine and apomorphine, a much greater absorptive intensity with a similar absorption curve.

It was shown that japaconitine has a constitution modified in such a manner; it being, in fact, what was termed by Alder Wright a sesquiapoaconitine; and the formulæ given for these substances are respectively: Aconitine, $C_{34}H_{47}NO_{11}$; japaconitine, $C_{66}H_{88}N_2O_{21}$, which is in agreement with the spectrum observations. It has, however, been supposed by Freund and Beck that the two substances are identical.

Strychnine and brucine are two alkaloids evidently closely related, but little is known about their constitution; both seem to contain a pyridine nucleus united to what is probably a pyrrolic nucleus, the two constituting a conjugated nucleus resembling that of quinoline. The difference between brucine and strychnine is said to be simply that the former contains two methoxyls. The absorption curves show a wider difference than this, and it was predicted that strychnine appears to be a derivative of pyridine, but brucine is more probably a derivative of tetrahydroquinoline, or an addition product of quinoline of the same character, since there is a remarkable similarity between the curves of the two substances. I would suggest that for the future evidence from their spectra be taken into account in studying their constitution.

Stereo-isomerism in the Alkaloids.

Many alkaloids having the same formula are stereoisomerides, and those related in this manner exhibit molecular absorption curves which are identical. The following examples are quoted by Dobbie and Lauder (1903) as the result of their investigations: dextro-corydaline and inactive corydaline; narcotine and gnoscopine; tetrahydroberberine and canadine. Where two compounds are known to have the same formula, and one of these is optically active, the other inactive, it may be inferred, as Dobbie and Lauder have pointed out, that they are not optical isomerides if their absorption curves are different; thus canadine and papaverine have the same formula, but their absorption curves show that they are structurally different.

It is a general rule that substances which agree closely in structure exhibit similar series of absorption spectra, while those which differ essentially in structure show absorption curves which are different; and to this rule neither aromatic compounds, alkaloids, nor dyes and coloured substances form any exceptions. That this is so is easily understood from the theory of absorption spectra. It must, however, be distinctly understood that the essential feature of importance in all such investigations is the quantitative relation of the substance to its spectra, whether these relations are based upon equal weights of material or equimolecular proportions in solutions of given volume and thickness.

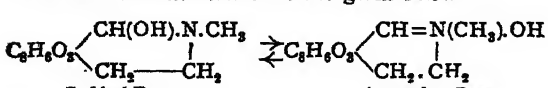
The relationship of morphine, $C_{17}H_{17}NO(OH)_2$, and codeine, or methylmorphine, $C_{17}H_{17}NO.(OH)(OCH_3)$, was shown by their spectra, the latter being a homologue of the former. A similar instance has been investigated recently by Dobbie and Lauder. The resemblance between the spectra of laudanine, $C_{20}H_{25}O_4N$, and laudanosine, $C_{21}H_{27}O_4N$, confirms the view that they are homologous bases. The close agreement of their absorption curves with those of corydaline and tetrahydropapaverine clearly indicates a similarity in structure to that of these alkaloids, but the relationship of laudanosine to corydaline is probably closer than to tetrahydropapaverine, and may be best explained by the formulæ

$$\underset{\text{Corydaline}}{C_{22}H_{27}O_4N} - CH_2 + H_2 = \underset{\text{Laudanosine}}{C_{21}H_{27}O_4N}$$

The removal of a methyl group from such a compound would scarcely cause any appreciable change in the curve of molecular vibrations, and very many cases are known where, when two atoms of hydrogen are introduced into a compound without altering the close linking of the carbon atoms of the ring formation in the compound, the alteration in the spectrum is insignificant.

A particularly interesting example of tautomerism already mentioned has been observed by Dobbie and Lauder in studying the constitution of cotarnine, a substance prepared from narcotine. Three formulæ have been proposed for it: one represents it as an aromatic aldehyde in which one hydrogen is replaced by an open change containing nitrogen; a second gives it the character of a carbinol base; while a third that of an ammonium base. It has been supposed that in solution it is a mixture of two or all three such substances in a state of equilibrium, but as to what is the formula to be assigned to solid cotarnine the data are insufficient to determine. There are, however, two different solutions of the substance obtainable; that in ether or chloroform is quite colourless, like the solid; but a solution in water or alcohol is yellow. From the molecular absorption spectra of these solutions and of certain derivatives with which they are compared there is very distinct evidence that a solution in alcohol or water contains the ammonium base, while under the influence of sodium hydroxide it assumes the condition of the carbinol form. Moreover, the rate of transformation and the conditions which influence this isomeric change have been studied. It suffices here to state that a solution containing entirely the one form may be converted wholly into the other.

The two formulæ referred to are given below:—



Carbinol Form Ammonium Base

EMISSION SPECTRA.

Spark Spectra and their Constitution.

As it became necessary to make accurate measurements of absorption spectra in the ultra-violet, the work of obtaining the wave-lengths of lines in twenty metallic spectra was undertaken. They were for the most part in a region which, except in the case of two or three elements, had not been previously explored. A small Rutherford grating was employed, combined with quartz lenses with a focal length of three feet. Experience has shown that it was advisable in describing these spectra to give measurements in hundredths of an inch of the positions of the lines on the published photographs of the prismatic spectra in the *Journal* of the Chemical Society (March, 1882), and to follow Lecocq de Boisbaudran by giving a description of the character of each of the lines. In this way they are easily identified, and the value of the measurements for practical purposes is greatly enhanced. Prior to the publication of the work (1882), in the prosecution of which Dr. Adeney was associated with me, Liveing and Dewar, who had been engaged on a similar investigation, but operating in a different manner, published an account of the spectra of the metals of the alkalies and alkaline earths, and subsequently the lines of iron, nickel, and cobalt. They showed a rhythmic grouping of the lines to be characteristic of the spectra of the alkali metals.

In connection with the prismatic spectra which were photographed some remarkable facts were noticed; for instance, the character of the lines belonging to different groups of elements was a noticeable feature, as well also their disposition or arrangement, more particularly in the ultra-violet. Similarities in the visible spectra of zinc and cadmium, of calcium, strontium, and barium, and in those of the alkali metals had been observed by Mitscherlich, by Lecocq de Boisbaudran, and also by Ciamician. As to the grouping of the lines as observed on the photographs, it appeared that the spectra of well-defined groups of elements had characteristics in common which were different from those of other groups. For instance, the alkali metals differed from the alkali earth metals which appeared to form a group by themselves. Then in marked contrast to these simple spectra were those of iron, nickel, and cobalt, which though very complicated were seen to be much alike. Nearest to these but differing from them in certain respects were the palladium, gold, and platinum spectra.

It was observed how these elements with certain chemical and physical properties in common could be recognised as being relations owing to their family likeness when their spectra were photographed. Then it was remarked that the spectra of magnesium, zinc, and cadmium, had distinctive characters in common; for instance, the individual lines in these spectra were marked by similar characteristics, such as a great extension of the strong lines above and below the points of the electrodes. This extension was increased with the atomic mass of the metal, and with the greater atomic mass in this group the volatility of the metal is also greater. An arrangement of the lines in pairs and triplets was noticed, the triplets being repeated, but less distinctly than in the first instance, and again repeated sharply but less strongly, so that there were three different sets of triplets in each spectrum. The point of greatest interest and importance was the connection traced between the atomic mass and the numerical differences observed in the intervals between the lines of different groups when measured by their oscillation frequencies.

These differences were not in the spectrum of one element, but were in the lines of each metal of the group, and were clearly associated with the atomic mass and chemical properties in each case.

The arrangement of the lines, which was common to all the metals in the magnesium, zinc, cadmium group, may shortly be described as follows:—Three isolated lines and one pair of lines in magnesium, with four sets of triplets; one isolated line and one pair of lines in zinc, with three sets of triplets; one isolated line and one pair of lines in cadmium, with three sets of triplets.

Besides the arrangement of these lines there were in the spectrum of each element two groups of the most refrangible lines, consisting one of a quadruple group and the other of a quintuple group, the groups and the lines composing them being similarly disposed in each spectrum. It was, however, not distinctly proved that these particular groups were strictly homologous, the most refrangible lines in the zinc spectrum being very difficult to photograph even on specially prepared plates, though the lines are strong. It was furthermore observed that with an increase in the atomic mass the distances between the lines both in pairs and triplets were greater. The same was the case with the quadruple and quintuple groups. In the magnesium spectrum, if we compare the first with the second group of triplets, we find the intervals extending from the first line in the first group to the first line in the second group, and from the second line in the first group to the second line

in the second group, and from the third line in the first group to the third line in the second group, when measured in terms of oscillation frequencies to be 677·1, 677·0, and 677·4. Similarly taking the second and third groups it is 391·2, 391·1, and 391·1. Between the third and fourth groups in like manner it is 230 9, 233, and 233; so that the intervals diminish with increase of refrangibility of the lines.

In the zinc spectrum the intervals between the lines in the first and second groups are 910, 910, and 910; in the second and third groups 582, 581, and 583.

In the cadmium spectrum the corresponding intervals are 801·5, 800, and 800; in the second and third groups 588, 589, and 587. The more accurately the lines are measured the more exactly do these differences correspond. It is scarcely necessary to point out that the differences in the atomic masses of the elements are in round numbers where H=1, Mg 24, Zn 65, and Cd 112.

The *Law of Constant Differences* rendered it evident that the spectra of the elements were subject to a law of homology, which was closely connected with the atomic mass and with their chemical and physical properties.

It was, in fact, found, in accordance with the periodic law, that the spectra of definite groups were spectra similarly constituted, from which it was deduced that they are produced by similarly constituted molecules. It is evident that there is periodicity in their spectra. The metals studied being all monatomic in their molecular condition, the conclusion was inevitable that the atoms were of complex constitution, and that not only was the complex nature of these atoms disclosed, but it was also shown that groups of elements with similar chemical and physical properties, the atomic weights of which differed by fixed definite values, were composed of the same kind of matter, but the matter of the different elements was in different states of condensation, as we know it to be in different members of the same homologous series of organic compounds. If this were not the case, the mass or quantity of matter in the atom would not affect in the same manner its rate of vibration—which the facts observed lead us to conclude that it does—and the chemical properties of the substances would differ more widely from one another, and the differences between them would not be gradational, which in fact they are. It was thus impossible to believe that the atoms were the ultimate particles of matter, though so far as chemical investigations had proceeded they were parts which had not been divided. Here the conviction was forced upon one that matter might exist in a state which had hitherto been unrecognised by those who accepted the atomic theory without searching beneath it. All that the atomic theory enabled the chemist to take account of were the laws of combination and decomposition of the forms of matter that are ponderable and of sufficient mass to be weighable on the finest balances, which after all are but crude and imperfect instruments for the study of matter, since they are capable only of determining differences between masses of tangible size. It became conceivable that matter in the state of gas or vapour might become so attenuated that repulsion of the molecules would be greater than the attraction; that they would then no longer form aggregates, and in consequence would cease to be weighable. In such a condition they may be imagined to constitute the ether, and in view of this conception there may be recognised four physical conditions of material substances, namely, solid, liquid, gas, and ether.

It is more than twenty years ago since the study of homology in spectra led me to the conviction that the chemical atoms are not the ultimate particles of matter, and that they have a complex constitution.

That the atoms of definite groups of chemically related elements are composed of the same kind of matter in different states of condensation is not a dream or a view of a visionary character, for it is based upon definite observations controlled by exact physical measurements, and is therefore in the nature of a theory rather than an hypothesis. Batchinski (1903) regards the atoms as being in a state of vibration, and the periods of vibration of related elements appear to stand in a simple relation to their properties. The mass of an atom is proportional to the square of its period of vibration, and conversely the vibration period of the atom may be calculated from the square root of the atomic weight. These values have been calculated and arranged according to Mendeléeff's classification, whereby it is shown that there is a decided tendency to form harmonic series in the vertical columns. The deviations are probably capable of explanation, as the author believes, on the ground that the atom is not to be regarded as a material point, but as a material system. It is well to remember that the precursor of the Periodic Law was Newland's Law of Octaves.

I have always experienced great difficulty in accepting the view that because the spectrum of an element contained a line or lines in it which were coincident with a line or lines in another element it was evidence of the dissociation of the elements into simpler forms of matter. In my opinion, evidence of the compound nature of the elements has never been obtained from the coincidence of a line or lines exclusively belonging to the spectrum of one element with a line or lines in the spectrum exclusively belonging to another element. This view is based upon the following grounds:—First, because the coincidences have generally been shown to be only apparent, and have never been proved to be real; secondly, because the great difficulty of obtaining one kind of matter entirely free from every other kind of matter is so great that where coincident lines occur in the spectra of what have been believed to be elementary substances they have been shown from time to time to be caused by traces of foreign matter, such as by chemists are commonly termed impurities; thirdly, no instance has ever been recorded of any homologous group of lines belonging to one element occurring in the spectrum of another, except and alone where the one has been shown to constitute an impurity in the other; as, for instance, where the triplet of zinc is found in cadmium and the triplet of cadmium in zinc; the three strongest lines in the quintuple group of magnesium in graphite, and so on. The latest elucidation of the cause of coincidences of this kind arises out of a tabulated record from the wave-length measurements of about three thousand lines in the spectra of sixteen elements made by Adeney and myself. The instances where lines appeared to coincide were extremely rare; but there was one remarkable case of a group of lines in the spectrum of copper which appeared to be common to tellurium; also lines in indium, tin, antimony, and bismuth which seemed to have an origin in common with those of tellurium.

It is difficult to separate tellurium from copper, and copper from tellurium, by ordinary chemical processes. Dr. Köthner, of Charlottenburg, has succeeded in obtaining very pure tellurium from the spectrum of which these lines and also several others have been almost entirely eliminated, which shows that they are foreign to the element, and that his specimen of tellurium is probably purer than any previously obtained. For determining the atomic weight of tellurium it is of course necessary to obtain it in the greatest possible state of purity; and it may be mentioned that the material which Staudenmaier employed for this purpose was found, from Köthner's photograph of its spectrum, to be a very pure specimen.

The prosecution of researches in connection with the constitution of spectra was initiated by Johnstone Stoney, by Balmer with respect to hydrogen, and continued by Rydberg, Deslandres, Ames, and, above all, by Kayser and Runge, who by an elaborate and exhaustive investigation of the arc spectra of the elements have given us formulæ by which the wave-lengths of lines in the spectra of different elements in certain definite groups may be calculated. They also showed the spectra to be constituted of three series of lines, the principal series and two subordinate series, one sharp and the other diffuse.

Ramage, however, has given us a simpler formula, depending on the atomic weight, which applies to several groups, and he has co-ordinated the spectra of several of the elements with the squares of their atomic masses, and also their atomic masses with other of their physical properties.

It may here be remarked that the homology of the spark spectra in the magnesium, zinc, and cadmium series was at first called in question by Ames, though he proved the arc spectra of zinc and cadmium to be strictly homologous.

Preston decided the question by demonstrating by means of beautiful photographs that corresponding lines such as the pairs, triplets, and the quadruple groups in the spark spectra of the three metals when under the influence of a

very powerful magnetic field underwent the same kind of change; for instance, each quadruple group changed to sextuple, the second and fourth lines in each group becoming double. Lines in spectra which have not the same constitution behave differently. Recently Runge and Paschen have arrived at the same conclusion; and, furthermore, have established homology in the spectra of sodium, copper, and silver; also between aluminium and thallium. Indium is almost certainly homologous with aluminium and thallium, but it was probably not investigated on account of its rarity. Marshall Watts has pointed out that a relationship exists between the lines in the spectra of some elements and the squares of their atomic weights, from which it is possible to calculate the atomic weight of an element if that of another in the same homologous series is known, and the oscillation frequencies of corresponding lines are known.

The knowledge of spectra we now possess enables the determination of atomic weights to be controlled with quite as much efficiency and certainty in many instances as by specific heat or vapour-density determinations.

The first application of the observed homology in spectra was directed towards the question of the atomic mass of beryllium, for which purpose the lines in the ultra-violet spark spectrum of this element were first photographed and measured. The nature of the evidence on the subject adduced at the time was in outline as follows:—

"If, as Nilson and Petterson suggest, the position of beryllium is at the head of a series of triad rare earth metals, the element scandium (at. wt. 44) and yttrium (at. wt. 89) must be members of the same group. If this be the case the spectra of the three elements must have certain characters in common, for the series of which aluminium and indium are the first and third terms yield strictly homologous spectra. As a matter of fact no two spectra could be more dissimilar than those of beryllium and scandium."

Having compared the photographs and wave-length measurements of a large number of spectra of the elements, I felt justified in making the following remarks:—

"The spectrum of beryllium exhibits no marked analogy with the calcium, the magnesium, or the aluminium spectra, all of which are members of well-defined homologous series. There is nothing similar in it to the boron, silicon, or carbon spectra, nor to those of the scandium, yttrium, or cerium. The spectrum of lithium is most closely analogous to that of beryllium in the number, relative positions, and intensities of the lines. This leads to the conclusion that beryllium is the first member of a dyad series of metals, to which in all probability calcium, strontium, and barium, as a sub-group, are homologous, its atomic mass being 9·2, its place is above magnesium." Subsequently Nilson, and also Humpidge, by chemical evidence and from vapour-density determinations of certain compounds, substantiated the conclusion previously arrived at by Emerson Reynolds, that the atomic mass of beryllium was not 13·8 but 9·2.

The next practical application of the spark spectra was to the analysis of rhabdophane, a mineral found many years ago in Cornwall and described by Heuland in 1837 as a zinc blende of a peculiar character.

This mineral I found to contain neither zinc nor sulphur, and therefore it is not a blende. It is, in fact, a phosphate of the formula $R_2O_3.P_2O_5.2H_2O$, in which the oxides of cerium, didymium, lanthanum, and yttrium may wholly or in part replace each other. The didymium absorption spectrum is well seen both by reflection from the surface and transmission through thin sections of the mineral. The spark spectrum of the yttrium chloride obtained from rhabdophane was compared with that observed by Thalén and ascribed to yttrium. Of the fifty-one lines in the spectrum of yttrium thirty-eight were absent from the yttrium obtained from rhabdophane, and it was concluded that the purest yttrium was that which yielded the simplest spectrum. This was the first occasion of the finding of yttrium in any British mineral. Quite recently a confirmation of this view has been obtained by comparing this spectrum with lists of the arc lines of yttrium and ytterbium which have just been published by Kayser (1903).

Penfield analysed a mineral found in the United States which he named scovellite: it proved to be identical in species with rhabdophane.

Flame Spectra at High Temperatures.

What are commonly known in the chemical laboratory as flame spectra are chiefly those of the metals of the alkalies and alkaline earths; also of gallium, indium, and thallium. The researches of Mitscherlich and Lecocq de Boisbaudran first showed that copper, manganese, and gold gave flame spectra. Lockyer, Gouy, and Marshall Watts also investigated flame spectra.

In 1887 I used iridium wires one millimetre thick, twisted into loops upon which fragments of minerals were heated in the oxygen blowpipe flame. Natural silicates yielded spectra not only of alkalies but of the alkaline earths, and also distinct manganese spectra. Baryta, strontia, and lime gave spectra when insoluble compounds such as the sulphates were thus examined at high temperatures. Iron, cobalt, and nickel gave spectra even when compounds such as the oxides were heated strongly. But iridium, though infusible, is somewhat volatile, and contributes a line spectrum to the flame. In 1890 thin slips of the mineral kyanite and even pieces of tobacco pipe were used instead. Experience with this method of working went to show how the flame spectra of oxides of calcium, strontium, and barium could be separated from those of lithium, sodium, potassium, rubidium, and cæsium, as observed in the Bunsen flame. Furthermore, that even the most volatile of these substances could be made to yield a continuous coloration from a single bead of salt for a period exceeding fifteen minutes, and extending to one or two hours, so that measurements of the lines might be made with some degree of certainty.

In order to study the flames emitted from furnaces during metallurgical operations, and particularly from the mouth of Bessemer vessels, it became necessary to ascertain what really were the lines of the elements observed under different conditions at a high temperature, and accordingly systematic methods of study were developed from the previous somewhat tentative experiments.

In all the flame spectra obtained by the oxyhydrogen blowpipe the ultra-violet line spectrum emitted by water vapour which had been discovered by Huggins and by Liveing and Dewar was visible on the photographs by reason of the combustion of the hydrogen in the hydrocarbon, or the hydrogen gas itself, when burnt along with oxygen. The flame spectra are always shorter than those obtained from the arc or from condensed sparks. After an extended examination of spectra produced by the oxyhydrogen blowpipe from solid substances, the knowledge obtained was applied to the examination of the flames coming from the Bessemer vessel during the "blow" during all periods from the commencement to the termination. These observations were made at the London and North-Western Railway Steel Works at Crewe; and at Dowlais, in South Wales. In collaboration with Mr. Ramage, a large number of these complicated spectra were photographed at the North-Eastern Steel Works, where the Thomas-Gilchrist process is carried out. The spectra were fully described and measured, with the result that every one of the lines and bands was accounted for. A new line belonging to potassium was discovered to have peculiar properties. Gallium was proved to be present in the Cleveland ore from Yorkshire, in the finished metal, in clays and in all aluminous minerals, even in corundum. Also, by very accurate determinations of the wave-lengths of its principal lines, gallium was proved to be a constituent of the sun. Moreover it was found in several meteorites. Pure gallium oxide was separated, by analytical methods, from iron ores and other materials; and the proportion of the metal in the steel rails made by the North-Eastern Steel Company, of Middlesbrough, was determined and found to be one part in thirty thousand. This Yorkshire steel is richer in gallium than any other substance from which it has been extracted; for instance, the Bensburg blende, supposed hitherto to be the richest ore, contains only one part in fifty thousand.

By observations on the spectra, the thermo-chemistry of the Bessemer process of steel manufacture was studied, and the temperatures attained under varying conditions were estimated. The demonstration of the great volatility of most metals, and of many metallic oxides in an undecomposed condition, at the temperature of the oxyhydrogen blowpipe and of the Bessemer flame was of special interest.

The metals chiefly referred to are copper, silver, lead, tin, manganese, chromium, iron, cobalt, nickel, palladium, gold, and iridium. Several of these, such as silver and gold, have lately been distilled *in vacuo* by Krafft.

Banded Flame Spectra.

Well-defined groups of elements yield banded flame spectra which have a similar constitution; thus magnesium, zinc, and cadmium yield bands composed of fine lines, degraded towards the violet, while fluted band spectra of beryllium, aluminium, and indium were found to be degraded towards the red. Thallium also yields a fluted spectrum; gallium gives a line spectrum; lanthanum gives bands degraded towards the red; palladium gives bands in the nature of flutings composed of fine lines; germanium gave very faint indications of bands; rhodium and iridium both lines and bands. It became manifest that elements belonging to the same group in the periodic system of classification exhibited banded spectra which are similarly constituted, and hence similarly constituted molecules of the elements have similar modes of vibration, whether at the lower temperature of the flame or at the higher temperature of the arc or spark. Banded spectra are thus shown to be connected with the periodic law.

A great advantage is to be derived from an investigation of banded spectra from a theoretical point of view, as well as from the application of this method to the analysis of terrestrial matter. While the spectra are easily obtained, they can be applied in a very simple manner to the chemical analysis of minute quantities of material, and may readily be made quantitative.

M. Armand de Gramont has described a method of obtaining spectra of metals and metalloids by means of a spark, and has given the analysis of eighty-six mineral species. The novelty and importance of his work lies in the method of obtaining spectra of such constituent substances as chlorine, bromine and iodine, sulphur, selenium and tellurium; also phosphorus and carbon when in a state of combination, as sulphates, phosphates, carbonates, &c.

There is a possibility of utilising this method for the quantitative determination of carbon, sulphur, and phosphorus in iron and steel during the process of manufacture.

Definition of an Element.

In a discussion on the question of the elementary character of argon in 1895 it was pointed out by me that argon gave a distinct spark spectrum by the action of condensed sparks, and therefore, on this evidence alone, it must be regarded as an element. The fact that it gave two spectra under different conditions was not opposed to, nor did it invalidate, this evidence, because such an element as nitrogen not only emits two spark spectra, but the two spectra can be readily photographed simultaneously from the same spark discharge.

It was proposed by M. de Gramont at the International Congress in Paris in 1900, and agreed, that no new substance should be described as an element until its spark spectrum had been measured and shown to be different from that of every other known form of matter.

This appears to me to have been one of the most important transactions of the Congress. The first application of this rule has resulted in the recognition of radium as a new element: it is characterised by a special spark spectrum of fifteen lines which have been fully studied and measured by Demarçay. It shows no lines of any other element.

Another application of this rule has recently been made by Exner and Haschek with preparations of the oxide of an element obtained by Demarçay, and named europium. It exhibits 1193 spark lines and 257 arc lines.

I have already mentioned that one feature strikingly shown in the spectra of chemically related elements was the wider separation of the lines in pairs, triplets, or other groups; was in some way related to the atomic mass, since the separation was greater in those elements the atomic weights of which were greater. Kayser and Runge, and also Rydberg, have shown that in the series of alkali metals the differences between the oscillation frequencies of the lines are very nearly proportional to the squares of the atomic weights. Runge and Precht have recently shown that in every group of elements that are chemically related the atomic weight is proportional to some power of the distance separating the two lines of the pairs of which the spectrum is constituted. In other words, if the logarithms of the atomic weight and distance between the lines be taken as coordinates the corresponding points of a group of elements which are chemically related will lie on a straight line. Applying this law to the determination of the atomic weight of radium they find that the strongest lines of the new element are exactly analogous to the strongest barium lines, and to those of the closely related elements magnesium, calcium, and strontium. The intervals between the two lines of each pair in the principal series, and in the first and second subordinate series, if measured on the scale of oscillation frequencies, are equal for each element, and the same law holds good for the spectrum of radium. From this the value 257·8 was found for the atomic mass of the element. This does not quite accord with the number obtained by Madame Curie, who found it to be 225. It will be interesting to see which number will eventually be proved to be the more correct.

It is now many years since I first pointed out that the absolute wave-lengths of the lines of emission spectra of the elements are physical constants of quite as great importance in theoretical chemistry as the atomic weights; in the light of recent discoveries this statement may be said to be now fully justified.

Radio-active Elements.

From the study of rays of measurable wave-lengths we have lately sailed under the guidance of M. Henri Becquerel into another region where it is doubtful whether all the rays conform to the undulatory theory. In fact some of the rays are believed to be charged particles of matter, charged, that is to say, with electricity. Beyond doubt they are possessed of very extraordinary properties, inasmuch as they are able to penetrate the clothing, celluloid, gutta percha, glass, and various metals. They are, moreover, endowed with a no less remarkable physiological action, producing blisters and ulcerations in the flesh which are difficult to heal. It is an established fact that such effects have been caused by only a few centigrams of a radium compound contained in a glass tube enclosed in a thin metallic box carried in the pocket.

From this we can quite understand that there is no exaggeration in the statement attributed to the discoverer, Prof. Curie, by Mr. W. J. Hanmer, of the American Institute of Electrical Engineers, that he would not care to trust himself in a room with a kilogram of pure radium, because it would doubtless destroy his eyesight, burn all the skin off his body, and probably kill him.

It remains for me to express regret that without an undue extension of the time devoted to this Address it would have been scarcely possible to afford adequate treatment to the absorption spectra of inorganic compounds, particularly those of the rare earths, and such also as afford evidence of the chemical constitution of saline solutions; or of organic compounds closely related to coloured substances and dyes, the investigation of which leads to the elucidation of the origin of colour, and serves to indicate the nature of the chemical reactions by which coloured substances may be evolved from those which are colourless.

Chemistry is popularly known as a science of far-reaching importance to specific arts, industries, and manufactures; but it occupies a peculiar position in this respect, that it is at one and the same time an abstract science, and one with an ever-increasing number of practical applications. To draw a line between the two and say where the one ends and the other begins is impossible, because the theoretical problem of to-day may reappear upon the morrow as the foundation of a valuable invention.

SECTION C.

GEOLOGY.

Opening Address by Prof. W. W. Watts, M.A., M.Sc., President of the Section.

There are two circumstances which invest the fact of my presidency of the Section this year with peculiar pleasure to myself. The first public lecture I ever gave was in the Town Hall at Birkdale in 1882, and the first of the fifteen meetings of the British Association which I have attended was that held in Southport in 1883.

There is still a third reason, that this meeting is in many respects a geological meeting. A palæobotanist is presiding over Section K, and the Council has invited, for the first time for many years, one geologist to deliver an evening discourse and another to give the address to artisans. I need hardly say that we are all looking forward to the lectures of Dr. Rowe and Dr. Flett with keen anticipation. To the one for his successful use of new methods of developing fossils and his scientific employment of the material thus prepared in stratigraphic research; to the other for his prompt, daring, and businesslike expedition to the scene of recent volcanic activity in the West Indies, during which he and his colleague, Dr. Tempest Anderson, collected so many important facts and brought away so much new knowledge of the mechanism of that disastrous and exceptional volcanic outbreak.

The Functions of Geology in Education and in Practical Life.

At the meeting in 1890, at Leeds, my old friend Prof. A. H. Green delivered an address to the Section which has generally been regarded as expressing an opinion adverse to the use of the Science of Geology as an educational agent. Some of the expressions used by him, if taken alone, certainly seem to bear out this interpretation. For instance, he says: "Geologists are in danger of becoming loose reasoners"; further he says: "I cannot shut my eyes to the fact that when Geology is to be used as a means of education there are certain attendant risks that need to be carefully and watchfully guarded against." Then he adds: "Inferences based on such incomplete and shaky foundations must necessarily be largely hypothetical."

Such expressions, falling from an accomplished mathematician and one who was such an eminent field geologist as Prof. Green, the author of some of the most trustworthy and most useful of the Geological Survey Memoirs, and above all one of the clearest of our teachers and the writer of the best and most eminently practical text-book on Physical Geology in this or any other language, naturally exercised great influence on contemporary thought. And I should be as unwise as I am certainly rash in endeavouring to controvert them but for the fact that I think he only half believed his own words. He remarks that "to be forewarned is a proverbial safeguard, and those who are alive to a danger will cast about for a means of guarding against it. And there are many ways of neutralising whatever there may be potentially harmful in the use of Geology for educational ends."

After thus himself answering what is in reality his main indictment, Prof. Green proceeds with the rest of an address crammed full of such valuable hints as could only fall from an experienced and practical teacher, showing how much could be done if the science were only properly taught. And then he concludes by asking for "that kindly and genial criticism with which the brotherhood of the hammer are wont to welcome attempts to strengthen the cornerstones and widen the domain of the science we love so well."

I think the time has now come to speak with greater confidence, and, although the distance signal stands at danger, to forge ahead slowly but surely, keeping our eyes open for all the risks of the road, with one hand on the brakes and the other on the driving gear, secure at least in the confidence that Nature, unlike man, never switches a down train on to the up track.

Those of us who have been teaching our science for any considerable time have come to realise that there are many reasons why Geology should be more widely taught than at present; that there are many types of mind to whom this science appeals as no other one does; and that there are abundant places and frequent circumstances which allow of the teaching of it when other sciences are unsuitable.

To begin with, there is no science in which the materials for elementary teaching are so common, so cheap, and everywhere so accessible. Nor is there any science which touches so quickly the earliest and most elementary interests. It was for this reason that Huxley built his new science of Physiography on a geological basis. Hills, plains, valleys, crags, quarries, cuttings, are attractive to every boy and girl, and always rouse intelligent curiosity and frequent inquiry; and although the questions asked are difficult to answer in full, a keen teacher can soon set his children to hunt for fossils or structures which will give them part of the information they seek. Of course the teaching cannot go very far without simple laboratory and museum accommodation, and without a small expenditure on maps and sections; but the former of these requirements can soon be supplied from the chemical laboratory and by the collection of the students themselves, while the latter are every day becoming cheaper and more accessible and useful. The bicycle and the camera, too, are providing new teaching material and methods, while at the same time they are giving new interests. The bicycle has already begun to create a generation to whom relief maps are not an altogether sealed book, and for whom the laws which govern the relief of a country are rapidly finding practical utility; and the camera, at the same time that it quickens the appreciation of natural beauty, must give new interest to each scrap of knowledge as to the causes, whether botanical or geological, to which that beauty is due. And it is this new knowledge which in turn develops the æsthetic sense. *Mente, manu, et malleo* sums up most of what is required in the early stages of learning; but to round off the motto we still require words to express the camera and bicycle.

Another reason is the open-airness of the practice of the science. The delight of the open country comes with intense relief after the classroom, the laboratory, or the workshop. In education generally, and especially in geological education, we have reached the end of the period when

> "all roads lead to Rome
> Or books—the refuge of the destitute."

Of course I realise fully the vital necessity of laboratory and museum work in the stages of both learning and investigation, and quite freely admit that there is an immense amount of useful work being done and to be done in these institutions alone. But what I think I do right to insist upon is that all work in the laboratory and museum must be mainly preparatory to the field-work which is to follow; every type of geological student must be sent into the field sooner or later, and in most cases the sooner the better. I have generally found that students in the early stages have a great repugnance to the grind of working through countless varieties of minerals, rocks, and fossils; but once they have gone into the field, collected with their own hands, and seen the importance of these things, and the inferences to be drawn from them, for themselves—once indeed they have got keen—they come back willingly, even eagerly, to any amount of hard indoor work.

But it is when they leave ordinary excursion work and start upon regular field training that one really feels them spurt forward. As soon as they begin to realise that surface-features are only the reflex of rock-structure and can be utilised for mapping, that to check their lines and initiate new ones they must search for and find new exposures, and that each observation while settling perhaps one disputed point may originate a host of new ones, when above all they can be trusted with a certain amount of individual responsibility and given a definite point to settle for themselves, it is then that their progress is most rapid, and is bounded only by their powers of endurance.

I have often watched my students through the various stages of their field training with the deepest interest as a study of the development of character. At first they look upon it merely as a relief from the tedium of the classroom and laboratory, and as a pleasant country excursion. But gradually the fascination of research comes over them, and as they feel their capacity increasing and their grip and insight into the structure of the country deepening, one can see them growing up under one's eyes. They come into the field a rabble of larky boys; they begin to develop into men before they leave it.

And what is true of students is more than ever true of the working geologist. I hold that every geologist, whatever his special branch may be, should spend a portion of every year in the field. Though a petrologist may have specimens sent to him from every variety, even the common ones, in a rock mass, and have their relations and proportions properly explained to him, it is quite impossible for

him to feel and appreciate these proportions and relationships so well as if he had studied and collected in the field and gained a personal interest in them. Besides this the conclusions drawn in the field are the crystalline and washed residuum, so to speak, left on the mind after the handling of dozens of specimens, weathered and unweathered, and the seeing them in a host of different lights and aspects. The rock is hammered and puzzled over and its relations studied until some conclusion is arrived at which bears the test of application to all the facts observed in the field.

Again, once a palæontologist is divorced from the field he loses the significance of minute time variations, the proportion of aberrant to normal forms, and the value of naked-eye characteristics which can be "spotted" in the field. Huxley once asked for a palæontologist who was no geologist; I venture to think we have now had enough of them. What we want above all at the present time is the recognition of such characters as have enabled our field palæontologists to zone by means of the graptolites, the ammonites, and the echinids, so that every rock system we possess may be subdivided with the same minuteness and trustworthiness as the Ordovician, Silurian, and Jurassic systems, and the Chalk.

If this is once done the biological results will take care of themselves, and we may feel perfect confidence that new laws of biological succession and evolution will result from such work, as indeed they are now doing—laws which could never be reached from first principles, but could only come out in the hands of those to whom time and place were the factors by which they were most impressed. It is only by field work that we shall ever get rid of the confusion which has been inevitable from the supposed existence of such so-called species as *Orthis caligramma, Atrypa reticularis*, and *Productus giganteus*.

As for the geological results, it is only necessary to read the excellent and workmanlike Address delivered to this Section at Liverpool in 1896 by Mr. Marr to realise how many problems of succession and structure, of distribution and causation, of ancient geography and modern landscape, are still awaiting solution by the application of minute and exact zonal researches.

On the other hand it goes without saying that the more a field geologist knows of his rocks and fossils the better will his stratigraphical work become; but this is too obvious to require more than stating.

Geology, again, is of value as a recreative science, one which can be enjoyed when cycling, walking, or climbing, even when sailing or travelling by rail. Indeed it is difficult to find a place in which to treat the confirmed geologist if you wish to make him a "total abstainer." There are others than those who must make use of their science in their professions, those in need of a hobby, those interested in natural scenery, veterans who have seen much and now have leisure and means to see more, and those fortunate ones who have not to earn their bread by the sweat of their brain or brow. Many of these have done and are doing good work for us, and many more would find real pleasure in doing so if only they had been inoculated in those early days when impressions sink deep. Mr. A. S. Reid, who has had much and fruitful experience in teaching, tells me that he has often seen seed planted in barren ground at school spring up and grow and blossom as a country-holiday recreation after schooldays, or bear the good fruit of solid research after lying dormant for many years.

We may next look upon Geology as an educational medium from quite a different point of view. If more than half the work of the man of science is the collection of fact, and of actual fact as opposed to the result of the personal equation, Geology is perhaps the very best training-ground. There are such hosts of facts to be still recorded, so many erroneous observations to be corrected, and so much hope of extending observations on already recorded facts, that there is plenty of work even for the man who can snatch but limited leisure from other pursuits and the one who is a collector of fact and nothing else, as well as those

"under whose command
Is earth and earth's, and in their hand
Is Nature like an open book."

But in the collection of facts a wise and careful selection is constantly necessary in order to pick out from the multitude those which are of exceptional value and importance in the construction of hypotheses. Nature, it is true, cannot lie; she is a perfectly honest but expert witness, and it takes an astonishing amount of acute cross-examination to elicit the truth, the whole truth, and nothing but the truth.

There is no science which needs such a variety of observations as Field Geology. When we remember that Sedgwick and Darwin visited Cwm Glas and carried away no recollection of the features which now shout "glaciation" to everyone who enters the Cwm, it is easy to see how alert must be the eyes and how agile the mind of the man who has to carry a dozen problems in his mind at once, and must be on the look-out for evidence with regard to all of them if he would work out the structure of a difficult country; and who is not only looking out for facts to test his own hypothesis, but wishes to observe so accurately that if his hypothesis gives way even at the eleventh hour his facts are ready to suggest and test its successor. There is no class of men so well up in what may be called observational natural history generally as the practised field geologist, because he never knows at what moment some chance observation—a mound, a spring, a flower, a feature, even a rabbit-hole or a shadow—may be of service to him. Not only should he know his country in its every feature and every aspect, but he must have, and in most cases soon acquires, that remarkable instinct, which can only be denoted as an "eye for a country," with which generally goes a naturalist's knowledge of its plants and of its birds, beasts, and fishes.

At the present time many educationists are in favour of teaching only the experimental sciences to the exclusion of those which collect their facts by observation. This attitude may do some good to Geology in compelling us to pay more attention to that side of our science which has been better cultivated hitherto in France than in our own country. But whether we think of education as the equipping of a scientific man for his future career or as the training of the mind to encounter the problems of life, we must admit that it would be as wrong to ignore one of the two ways only of collecting fact as it would be to teach deductive reasoning to the exclusion of that by induction. Indeed this is understating the case, for in the vast majority of the problems which confront us in everyday life the solution can only be reached if an accurate grasp of the facts can be obtained from observation. The training of the mind solely by means of experiments carefully designed to eliminate all confusing and collateral elements savours too much of "milk for babes" and too little of "strong meat for men."

Mr. Teall in his masterly Address to the Geological Society in 1901 pointed out "that the state of advancement of a science must be measured, not by the number of facts collected, but by the number of facts *coordinated*." Theory, consistent, comprehensive, tested, verified, is the life-blood of our science as of any other. It is what history is to politics, what morals are to manners, and what faith is to religion.

It is almost impossible to collect facts at all without carrying a working hypothesis to string them on. It is easy to follow Darwin's advice and speculate freely; the speculation may be right, and if wrong it will be weeded out by new facts and criticism, while the speculative instinct will suggest others. In hypothesis there will always be an ultimate survival of the fittest.

And it is not only easy but absolutely necessary, because in Geology, more perhaps than in any other science, hypotheses are like steps in a staircase: each one must be mounted before the next one can be reached; and if you have no intention of coming back again that way, it does not matter if you destroy each step when you have made use of it. Every new hypothesis has something fresh to teach, and nearly all have some element of untruth to be ultimately eliminated. But each one is a stage, and a necessary stage, in progress.

In physics and in chemistry the chief difficulties are those which surround the making of experiments. When these

have been successfully overcome the right theory follows naturally, and verification is not usually a very lengthy process. In Geology, on the other hand, theory is more quickly arrived at from the numerous facts; but the price is paid in the patience required for testing and the ruthless refusal to strain fact to fit theory. Every hypothesis leads back to facts again and again for verification, extension, and improvement.

Many of the leading conclusions of our science have not yet become part of the common stock of the knowledge of the world; indeed they are not even fully realised by many men eminent in their own sciences. The momentum given by Werner and Playfair, Phillips and Jukes, Sedgwick and Lyell, and other pioneers of the fighting science, has died down, and in the interval of hard work, detailed observation, minute subdivision, involved classification, and pedantic nomenclature which has followed, and which I believe to be only the prelude to an epoch of more important generalisation in the immediate future, it has been difficult for an outsider to see the wood for the trees. He has hardly yet realised that facts as vital to the social and economic well-being of the people at large, and conclusions of as great importance in the progress of the science and of as far-reaching consequence in the allied sciences, are being wrung from Nature now as in the past.

"The unimaginable touch of Time," the antiquity of the globe as the abode of life, the absolute proof of the evolution of life given by fossils, the proofs of change and evolution in geography and climate, the antiquity of man, the nature of the earth's interior, the tremendous cumulative effect of small causes, the definite position of deposits of economic value, the *rôle* played by denudation and earth-movement in the development of landscape, the view of the earth as a living organism with the heyday of its youth, its maturity, and its future old age and death, to mention but a few of our great principles, furnish us with conceptions which cannot fail to quicken the attention and inspire the thought of students of history, geography, and other sciences.

Now that these things are capable of definite proof, that they are of real significance in the cognate sciences, and of actual economic value, above all now that the nineteenth century, the geological century, has closed, that the heroic age is over, that we have passed the stages of scepticism and religious intolerance and reached the stage "when everybody knew it before," it might be expected that a fairly accurate knowledge and appreciation of these principles should form part of the common stock of knowledge, and be a starting-point in the teaching of allied sciences.

Another feature which adds to the attractiveness of geological observations is their immediate usefulness from many points of view. The relief and outline of any area are as closely related to its rocky framework as the form of a human being is related to his skeleton and muscles. The geological surveyor recognises how every rise and fall is the direct reflex of some corresponding difference in the underlying rocks; he seeks to observe and explain the ordinary as well as anomalous ground-features, every one of which conveys some meaning to him.

A geological basis for the classification and grouping of surface-features is the only one which is likely to be satisfactory in the end, because it is the only one founded on a definite natural principle, the relation of cause to effect. It is not without good reason that the topographic and geological surveys of the United States are combined under one management, and nowhere else are the topographic results more accurate and satisfactory. Landscape is traced back to its ultimate source, and consequently sketched in with more feeling for the country and greater accuracy of knowledge than would otherwise be possible. Geologists were among the first to cry out for increasing accuracy and detail in our Government maps, and they have consistently made the utmost use of the best of these maps as fast as they appeared. With the publication of each type of map, hachured, contoured, six-inch, twenty-five inch, the value and accuracy of geological mapping have advanced step by step. Wherever the topography is better delineated than usual, the facilities are greater for accurate geological work, and the best geological maps, and those in greatest demand, are always those based on the most minute and detailed topographic work. On the other hand geologists are training up a class of men who can read and interpret the inner meaning of these maps, and make the fullest use of the splendid facilities given by the minute accuracy of the ordnance work.

Lord Roberts has recently complained that the cadets at Woolwich are unable to read and interpret maps, and he "strongly advised them to set about improving themselves in this respect, or they would find themselves heavily handicapped in the future." I believe that the only training in this subject before entering the Royal Military Academy and the Royal Military College has been that given to those candidates who have taken up Geology for their entrance examination. By encouraging these students to study and draw maps and sections of their own districts, and to explain and draw sections across geological maps generally, thus accounting for surface-features, the examiners have compelled this small group of candidates to see deeper into a map than ordinary people. If only this training had been encouraged and advanced and made use of later, the Commander-in-Chief would have had no cause of complaint with regard to these particular men. Looking at a map is one thing; working at it, seeing into it, and getting out of it what is wanted from the vast mass of information crammed into it, is quite another; and Geology is the very best and perhaps the only means of compelling such a close study of maps as to enable students to seize upon the salient features of a country from a map as quickly and accurately as if the country itself were spread out before them. The geologist is compelled to work out and classify for himself the features he observes on his maps, such as scarps and terraces, crags and waterfalls, streams and gorges, passes and ridges, the run of the roads, canals, and railways, the nature and accessibility of the coast, and all those features which make the difference between easy-going and a difficult country. When he has worked his way over a map in this fashion that map becomes to him a real and telling picture of the country itself.

Experience, bitter experience, in South Africa has shown the necessity not only for good maps and map-reading, but for that which is the most priceless possession alike of the best field geologists and of the best strategists, a good "eye for a country." It has been said that the Boer war was a geographical war; but it was even more, and, especially in its later stages, a topographic war. Again and again the Boers aroused our astonishment and admiration by the way in which their topographic knowledge and instinct enabled them to fight, to defend themselves, and to secure their retreat by the most consummate ability in utilising the natural features of their country. This was due to two things. In the first place they took care to have with them in each part of the country the men who knew that particular district best in every detail and in every aspect. But in the second place there can be no doubt that they made the utmost use of that hunter-craft by which the majority of them could take in at a glance the character of a country, even a new one, as a whole, guided by certain unconscious principles which each man absorbed as part of his country life and hunter's training. They possessed, and had of necessity cultivated to a very high degree, an "eye for a country."

Now the study of the geology of any district, and especially the geological mapping of it, goes a long way towards giving and educating the very kind of eye for a country which is required, partly by reason of the practice in observation and interpretation which it is continuously giving, and partly because it deliberately supplies the very kinds of classification and the principles of form which a hunter-people have unconsciously built up from their outdoor experience.

Any geologist who thinks of the Weald, the wolds and downs of Eastern England, the scarps and terraces of the Pennine, the buried mountain structure of the Midlands, even the complicated mountain types of Lakeland and Wales, will remember how often his general knowledge of the rock-structure of the region has helped him as a guide to the topography; and as his geological knowledge of the area has increased he will recall how easy it has become to carry the most complicated topography in his mind, or to revive his recollection of it from a glance at the map,

because the geological structure, the anatomy, is present in his mind throughout, and the outside form is the inevitable consequence of that structure. Indeed the reading of a good geological map to the geologist is like the reading of score by a musician.

Surely it would be most unwise if the Committee on Military Education were to cut out of their curriculum the one subject which has exercised and educated this faculty, and one which is at the same time doing a great deal to counteract that degeneration of observing faculties inseparable from a town life. Some cadets at least ought to be chosen from amongst those men who have been trained by this method to see quickly and accurately into the topographic character and possibilities of a country, and provision should be made for educating their faculties further until they become of genuine strategic value.

Then I believe it would be correct to say that no class of men get to know their own country with anything like the minuteness and accuracy of the geological surveyor. The mere topographer simply transfers his impressions on the spot as quickly as may be to paper, and has no further concern with them. The geologist must keep them stored in his mind, watching the variation and development of each feature from point to point for his own purposes. He must traverse every inch of his ground, he must know where he can climb each mountain and ford every brook, where there are quarries or roads, springs or flats; what can be seen from every point of view, how the habitability or habitations vary from point to point; in short, he must become a veritable walking map of his own district. Why not scatter such men in every quarter of the globe, particularly where any trouble is likely to arise? They are cheap enough, they will waste no time, and they will be so glad of the chance for research that they will not be hard to satisfy in the matter of pay and equipment. Thus you will acquire a corps of guides, ready wherever and whenever they are wanted; and when trouble arises they may do a great deal by means of their minute knowledge of topography to save millions of money and thousands of lives, and to prevent the irritating recurrence of the kind of disaster with which we have become sadly familiar within the last five years.

In dealing with the relationship of Geology to Geography geologists are frequently charged with claiming too much. On this point at least, however, there can be no difference of opinion, that the majority of geological surveyors and unofficial investigators have kept their eyes open to this relationship, and have often contributed new explanations to old problems. They have been compelled to observe, and often to explain, surface-features before making use of them in their own mapping, and in doing so have often hit upon new principles. It is hardly needful to mention such examples as Ramsay's great conception of plains of marine denudation, Whitaker's convincing memoir on subaërial denudation, Jukes's explanation of the laws of river adjustment, Gilbert's scientific essay on erosion, Heim's demonstration of the share taken by earth-movement in the modelling of landscape features, and the exceedingly valuable proofs of the relation of human settlement and movement to underground structure, worked out with such skill and diligence by Topley in his masterly memoir on the Weald—the jumping-off place, if I may so term it, of the new geography.

No one is more pleased than geologists that geographers have ceased to draw their knowledge of causation solely from history, and that they have turned their attention to the dependence and reaction of mankind on nature as well. But while hoping that geographers will continue to study, so far as they logically can, the relationship of plants, animals, and mankind to the solid framework of the globe on which they live, we must draw the line at the invention of new geological hypotheses to explain geographic difficulties on no better evidence than that furnished by the difficulties themselves; on the other hand, we must insist that each new geological principle must take its place amongst geographic explanations as soon as it is freely admitted to be based on a sound substratum of fact.

I must confine myself to a few instances of what I mean. Mr. Marr's geological work on the origin of lake-basins has led to some remarkable and unexpected conclusions with regard to the history and origin of the drainage of the Lake district. Some of the very difficult questions raised by the physical geography of the North Riding of Yorkshire have received a new explanation from the researches of Prof. Kendall and Mr. Dwerryhouse, an explanation which is the outcome of purely geological methods of observation of geological materials. Again, the simple geological interpretation of a well-known unconformity between Archæan and Triassic rocks has made it extremely probable that many of the present landscapes, not only in the Midlands but elsewhere, may be really fossil landscapes, of great antiquity and due to causes quite different from those in operation there at the present day. In mountain regions, too, it can only be by geological observation that we shall ever determine what has been the precise direct share of earth-movement in the production of surface relief. Such examples seem to indicate that many of the principles must be of geological origin but of geographic application.

While Geology has been of direct scientific utility in topography and geography there is another domain, that of Economic Geology, which is entirely its own. The application of Geology extends to every industry and occupation which has to do with our connection with the earth on which we live. Agriculture, engineering, the obtaining of the useful and precious metals, chemical substances, building materials, and road metals, sanitary science, the winning and working of coal, iron, oil, gas, and water, all these and many more pursuits are carried on the better if founded on a knowledge of the structure of the earth's crust. Indeed a geological map of this country, showing rocks, solid and superficial, of which no economic use could be made, would be nearly blank. Yet so much has this side of the science been neglected of recent years that our only comprehensive text-books on it are altogether out of date.

But in teaching Geology as a technical science, or rather as one with technological applications, one of the greatest difficulties before us is to steer between two opposing schools, the so-called theoretical school and the practical school.

There are those who say that there is but one geology, the theoretical, and that a thorough knowledge of this must be obtained by all those who intend to apply the science. Others think that this is too much to ask—that the time available is not sufficient—and that it is only necessary to teach so much of the subject as is obviously germane to the question in hand.

The best course appears to me to be the middle one between the two extremes. If the engineer or miner, the water-finder or quarryman, has no knowledge of principles, but only of such facts as appear to be required in the present position of his profession, he will be incapable of making any improvement in his methods so far as they depend upon geology. If, on the other hand, he is a purely theoretical man without a detailed practical and working acquaintance with the facts which specially concern him, he will be put down by his colleagues as unpractical; he will have to learn the facts as quickly as he can and buy his experience in the dearest market.

It seems to me that there is certain common ground which must be acquired by all types of professional men. The general petrographic character of the common rocks, enough of their mode of origin to aid the memory, the principle of order and age in the stratified rocks, the use of fossils and superposition as tests of age, the nature of unconformities, the relation of structure to the form of the ground, the occurrence of folds and faults, and above all the reading of maps and sections, and sufficient field work to give confidence in the representation of facts on maps—these things are required by everybody who makes any use of geology in his daily life.

But when so much has been acquired it should be possible to separate out the students for more special treatment. The coal-miner will require especially a full knowledge of the coal-bearing systems, not in our own islands merely, but all over the world; a special acquaintance with the effects of folds and faults, and an advanced training in the maps and sections of coal-bearing areas. The vein-miner should be well up in faulting and all the geometrical problems associated with it, and he should have an exhaustive acquaintance with the vein and metalliferous minerals.

The water engineer needs to know especially well the porous and impervious rock types, the texture and composition of these rocks, the nature of their cements and joints, and the distribution of water levels in them. Further, he must know what there is to be known on the problems of permeability and absorption, the relation of rain to supply, the changes undergone by water and the paths taken by it on its route underground, and the varying nature of rocks in depth. He must also realise the effects of folds and faults on drainage areas and on underground watercourses, the special qualities of water-yielding rocks, of those forming the foundation of reservoir sites, and those suitable for the construction of dams.

The sanitary engineer will need to be acquainted with the same range of special knowledge as the water engineer, but will naturally be more interested in getting rid of surface water without contaminating it more than he can help than in obtaining it; he will also need a more detailed acquaintance with superficial deposits than any other class of professional men.

The quarryman and architect ought to know the rocks both macroscopically and microscopically, in their chemical and mineralogical character, their grains and their cements. But he ought to be well acquainted with the laws of bedding, jointing, and cleavage, with questions of outcrop and underground extent, and all those other characters which make the difference between good and bad stone, or between one desirable and undesirable in the particular circumstances in which a building is to be erected. Further, he should make a particular study of the action of weight and weather on the rocks which he employs.

The road engineer and surveyor, now that it has been discovered that it is cheaper and better to use the best and most lasting road-metal instead of any that happens to be at hand, requires to have an extensive acquaintance with our igneous and other durable rocks. He needs, however, not only petrographic and chemical knowledge, but also a type of information not at present accessible in England, the relative value of these rocks in resisting the wear and tear of traffic, the cementing power of the worn material, and the surface characters of roads made from them, in order that he may in each case select the stone which in his particular circumstances gives the best value for money. It would surely pay the county councils to follow, with modifications, the example of the French and Americans, and carry out a deliberate and well-planned series of experiments on all the material accessible to them in their respective districts.

The teaching of the application of Geology should therefore take some such form as the following:—First, the principles should be thoroughly taught with the use for the most part of examples drawn from the economic side; thus cementing might be illustrated on the side of water percolation, jointing from the making of mine roads and from quarry sites, faulting from effects on coal outcrops and veins, unconformity from its significance to the coal-miner; while in teaching the sequence of stratified rocks the systems and stages could be mainly individualised by their economic characters. When this is done the class must be divided into groups, each paying special attention to the points which are of essential importance to them.

The teaching at all stages should be practical and, so far as can be, experimental, and in all cases where possible a certain amount of field work should be attempted. For the field after all is the laboratory of the geologist, where he can observe experiments being made on a gigantic scale under his eyes.

The aim of the teaching should be to give to students the equipment necessary to deal with the chief geological problems that they will meet with in their varied professions; it should show them where to go for maps, memoirs, or descriptions of the areas with which they are dealing; and in cases of great difficulty should enable them to see where further geological assistance is required, and to weigh and balance the expert evidence given them against the economic and other factors of the problem before them.

From men educated thus Geology has the right to expect a valuable return. There is a vast amount of knowledge on economic subjects in existence but not readily accessible. It has been obtained by experts, and after being used is locked up or lost. And yet it is the very kind of knowledge which is wanted to extend our principles further into the economic side of the subject. So well is this recognised that many geologists are attracted to economic work mainly because of the wide range of new facts that they can only thus become acquainted with. It is possible to make use of many of these facts for scientific induction without in any way betraying confidence or revealing the source from which they are obtained; and even if they cannot be used directly they are often of great service in giving moral support, or the contrary, to working hypotheses founded on other evidence.

The knowledge of our mineral resources is of such vital consequence to ourselves and to our present and future welfare as a nation, and yet it is a matter of so much popular misconception, that I feel bound to dwell on this subject a little longer. To anyone who studies the growth and distribution of population in any important modern State the facts and reasons become as clear as day.

It is easy to construct maps showing at a glance the density of population in any country. Perhaps the most effective way to do so is to draw a series of isodemic lines and to gradually increase the depth of tint within them as the number of people per square mile increases until absolute blackness represents, say, more than 2000 people per square mile. Such maps are the best means of displaying the geography of the available sources of energy in a country at any particular period. Population maps of England and Wales in the early part of the eighteenth century would be pale in tint with a few rather darker patches, and would show a distribution dependent solely upon food as a source of energy working through the medium of mankind and animals. Such maps would be purely agricultural and maricultural, dependent upon the harvests of the land and sea. Maps made at a later period would show a new concentration round other sources of energy, particularly wind and water, but would not be perceptibly darker in tint as a whole; for although we are apt to think that we have in this country too much wind and water, they are not in such a form that we can extract any appreciable supply of energy directly from them.

But maps representing the present population, while still mainly energy maps, at once bring out the fact that our leading source of energy is now *coal* and no longer food, wind, or water. The new concentrations, marked now by patches and bands of deepest black, have shifted away from the agricultural regions and settled upon and around the coalfields. The map has now become geological.

The difference between the old and the new map is, however, not only in kind; it is even more remarkable in degree. The population is everywhere much denser. Not only are the mining and manufacturing areas on the new map more than eight times as densely populated as any areas on the older map, not only is the average population five times greater throughout the country, but the lightest spot in the new map is nearly as dark as the darkest spot on the old one. The sparsest population at the present day is as thick on the ground as it was in the densest spots indicated on the older map, while at the same time the standards of wages, living, and comfort, instead of decreasing, have increased.

The discovery of this new source of energy, coal, immediately gave employment to a much larger number of people; it paid for their food and provided the means of transporting it from the uttermost parts of the earth. Under agricultural conditions the map shows that the population attained a given maximum density, and no further increase was possible, the density being regulated by the food supply raised on the surface of the land. Our dwelling-house was but one story high. Under industrial conditions our mineral resources can support five times the number. Our dwelling-house is of five stories—one above ground and four below it.

At the same time the type of distribution is altered. The agricultural areas are now covered by a relatively scanty population, and the dense areas are situated on or near to the coal and iron fields, the regions yielding other metals, those suitable for industries which consume large supplies of fuel, and a host of new distributing centres, nodal points on the new lines of traffic, either inside the country or on

its margins where the great routes of ocean transport converge, or where the sea penetrates far in towards the industrial regions.

It has been the good fortune of this country to be the first to realise, and with characteristic energy to take advantage of, the new possibilities for development opened up by the discovery and utilisation of its mineral wealth. We were exceedingly fortunate in having so much of this wealth at hand, easy to get and work from geological considerations, cheap to transport and export from geographical considerations. So we were able to pay cash for the products of the whole world, to handle, manufacture, and transport them, and thus to become the traders and carriers of the world.

But other nations are waking up. We have no monopoly of underground wealth, and day by day we are feeling the competition of their awakening strength. Can we carry on the struggle and maintain the lead we have gained?

In answering this question there are three great considerations to keep in mind. First, our own mineral wealth is unexhausted; secondly, that of our colonies is as yet almost untouched; and thirdly, there are still many uncolonised areas left in the world.

The very plenty of our coal and iron, and the ease of extracting it, has been an economic danger. There has been waste in exploration because of ignorance of the structure and position of the coal-yielding rocks; waste in extraction because of defective appliances, of the working only of the best-paying seams and areas, of the water difficulty, and the want of well-kept plans and records of areas worked and unworked; waste in employment because of the low efficiency of the machinery which turns this energy into work. With all this waste our coalfields have hardly yielded a miserable *one* per cent. of the energy which the coal actually possesses when *in situ*.

Engineers and miners are trying to diminish two of these sources of waste, and Geology has done something to reduce that of exploration. This has been done by detailed mapping and study, so that we now know the areas covered by the coal-seams, their varying thickness, the "wants," folds, and faults by which they are traversed, and all that great group of characters designated as the geological structure of the coalfields. It could not have been accomplished unless unproductive as well as productive areas had been studied, the margins of the fields mapped as well as their interiors, and unless the geological principles wrested from all sorts of rocks and regions had been available for application to the coal districts in question. We no longer imagine every grey shale to be an index of coal; we are not frightened by every roll or fault we meet with underground; nor do we, as in the past, throw away vast sums of money in sinking for coal in Cambrian or Silurian rocks.

We cannot afford, hard bitten as we are in the rough school of experience and with our increased knowledge, to make all the old mistakes over again, and yet we are on the very eve of doing it. Up to the present it is our visible coalfields that we have been working, and we have got to know their extent and character fairly well. But so much coal has now been raised, so much wasted in extraction, and so many areas rendered dangerous or impossible to work, that we cannot shut our eyes to the grave fact that these visible fields are rapidly approaching exhaustion. The Government have done well to take stock again of our coal supply and to make a really serious attempt by means of a Royal Commission to gauge its extent and duration; and we all look forward to that Commission to direct attention to this serious waste and to the possibility of better economy which will result from the fuller application of scientific method to exploration, working and employment.

But we still have an area of concealed coalfields left, possibly at least as large and productive as those already explored and as full of hope for increased industrial development. It is to these we must now turn attention with a view of obtaining from them the maximum amount possible of the energy that they contain. The same problems which beset the earlier explorers of the visible coalfields will again be present with us in our new task, and there will be in addition a host of new ones, even more difficult and costly, to solve. In spite of this the task will have to be undertaken, and we must not rest until we have as good a knowledge of the concealed coalfields as we have of those at the surface. This knowledge will have to be obtained in the old way by geological surveying and mapping and by the coordination of all the observations available in the productive rocks themselves and in those associated with them, whether made in the course of geological study or in mining and exploration. But now the work will have to be done at a depth of thousands instead of hundreds of feet, and under a thick cover of newer strata resting unconformably on those we wish to pierce and work. When we get under the unconformable cover we meet the same geology and the same laws of stratigraphy and structure as in more superficial deposits, but accurate induction is rendered increasingly difficult by the paucity of exposures and the small number of facts available owing to the great expense of deep boring. How precious, then, becomes every scrap of information obtained from sinkings and borings, not only where success is met with, but where it is not; and how little short of criminal is it that there should be the probability that much of this information is being and will be irretrievably lost!

Mr. Harmer pointed out in a paper to this Section in 1895 that under present conditions there was an automatic check on all explorations of this kind. The only person who can carry it out is the landowner. If he fails he loses his money and does not even secure the sympathy of his neighbours. If he succeeds his neighbours stand to gain as much as he does without sharing in the expense. The successful explorer naturally conceals the information he has acquired because he has had to pay so heavily for it that he cannot afford to put his neighbours in as good a position as himself and make them his rivals as well; while the unsuccessful man is only too glad to forget as soon as possible all about his unfortunate venture. And yet in work of this kind failure is second only to success in the value of the information it gives as to the underground structure which it is so necessary to have if deep mining is to become a real addition to the resources of the country.

Systematic and detailed exploration, guided by scientific principles, and advancing from the known to the unknown, ought to be our next move forward: a method of exploration which shall benefit the nation as well as the individual, a careful record of everything done, a body of men who shall interpret and map the facts as they are acquired and draw conclusions with regard to structure and position from them—in short a Geological Survey which shall do as much for Hypogean Geology as existing surveys have done for Epigean Geology, is now our crying need. Unless something of this sort is done, and done in a systematic and masterful manner, we run a great risk of frittering away the most important of our national resources left to us, of destroying confidence, of wasting time and money at a most precious and critical period of our history, and of slipping downhill at a time when our equipment and resources are ready to enable us to stride forward.

We do not want to be in the position of a certain town council which kept a list of its old workmen and entered opposite one, formerly sewerage inspector, that he possessed "an extensive memory which is at the disposal of the corporation."

Even supposing the scheme outlined by Mr. Harmer cannot be carried out in its complete form, a great deal will be done if mining engineers can receive a sufficient geological training to enable them to realise the significance of these underground problems, so that they can recognise when any exploration they are carrying out inside their own area is likely to be of far-reaching geological and economic significance outside the immediate district in which they are personally and immediately concerned.

Turning to our colonies it is true that in many of them much is being done by competent surveys to attain a knowledge of mineral resources, but this work should be pushed forward more rapidly, with greater strength and larger staffs, and above all it should not be limited to areas that happen to be of known economic value just at the present moment. It is almost a truism that the scientific principle of to-day is the economic instrument of to-morrow, and it will be a good investment to enlarge the bounds of geological theory, trusting to the inevitable result that every

new principle and fact discovered will soon find its economic application. Further, it is necessary that we should obtain as soon as possible a better knowledge of the mineral resources of the smaller and thinly inhabited colonies, protectorates, and spheres of influence. This is one of the things which would conduce to the more rapid, effective occupation of these areas.

With regard to areas not at present British colonies, it seems to me that no great harm would be done by obtaining, not in any obtrusive way, some general knowledge of the mineral resources of likely areas. This at least seems to be what other nations find it worth their while to do, and then, when the opportunity of selection arises, they are able to choose such regions as will most rapidly fill up and soonest yield a return for the private or public capital invested in them.

To sum up, I consider that the time has come when geologists should make a firm and consistent stand for the teaching of their science in schools, technical colleges, and universities. Such an extension of teaching will of course need the expenditure of time and money; but England is at last beginning to wake up to the belief, now an axiom in Germany and America, that one of the best investments of money that can be made by the pious benefactor or by the State is that laid up at compound interest, "where neither rust nor moth doth corrupt," in the brains of its young men.

This knowledge has been an asset of monetary value to hosts of individuals who have made their great wealth by the utilisation of our mineral resources, and to our country, which owes its high position among the nations to the power and importance given to it by its coal and iron. It is surely good advice to individuals and to the State to ask them to reinvest some of their savings in the business which has already given such excellent returns, so that they and we may not be losers through our lack of knowledge of those sources of energy which have made us what we are, and are capable of keeping for many years the position they have won for us.

And in our present revival of education it would be well that its rightful position should be given to a science which is useful in training and exercising the faculty of observation and the power of reasoning, which conduces to the open-air life and to the appreciation of the beautiful in nature, which places its services at the disposal of the allied sciences of topography and geography, which is the handmaid of many of the useful arts, and which brings about a better knowledge and appreciation of the life and growth of that planet which we inhabit for a while, and wish to hand on to our descendants as little impaired in vitality and energy as is consistent with the economic use of our own life-interest in it.

NOTES.

THE following have been elected Fellows of the Reale Accademia dei Lincei:—As Ordinary Fellows ("Soci nazionali"), Messrs. J. Dalla Vedova for geography, A. Naccari for physics, C. de Stefani for geology, A. Borzi, J. Fano, A. Maffucci for zoology, pathology, &c. As Corresponding Fellows ("Corrispondenti"), Messrs. P. Pizzetti for mechanics, A. Angeli for chemistry, R. Fusari and A. Stefani for zoology and physiology. As Foreign Fellows, Messrs. D. Hilbert and J. D. van der Waals for mathematics and mechanics, J. Thomson and H. Becquerel for physics, R. Lydekker for geology and palæontology, E. B. Wilson, T. Schlösing, P. Sorauer and F. Marchand for zoology, agronomy and pathology.

THE prizes offered by the Reale Accademia dei Lincei for the present year have been allotted as follows:—Royal prizes have been awarded to Prof. Artini for mineralogy and geology, to Prof. Ghino Valenti for social and economic science, and to the late Prof. Contardo Ferrini for jurisprudence and political science. Of the prizes offered by the Minister of Public Instruction, awards have been made for physical and chemical science to Profs. Cicconetti and Pierpaoli (jointly), and to Prof. Baggio Lera, and for philology to Profs. Toldo, G. Tàmbara and V. Ussani. The Carpi prize for botany has been conferred on Dr. Biagio Longo, of Rome. The award of the Royal prize for mathematics has been deferred.

WE have received a copy of the programme of prizes to be awarded in 1904 by the Société Industrielle de Mulhouse. The present publication takes the place of all previous issues, and copies of the programme, in which certain changes have been made, can be obtained on application to the secretary of the society. There are no fewer than fifty-six competitions concerned with chemical technology, more than twenty dealing with the mechanical arts, and twelve with natural history and agriculture. Several prizes are offered with the object of improving and stimulating local industries. The programme also contains full particulars of several large prizes of five thousand francs, which are awarded for scientific work at intervals of in some cases ten, and in others five years.

THE death is announced, at the age of eighty-one years, of the Rev. Maxwell Henry Close, treasurer of the Royal Irish Academy, and author of numerous contributions to the *Proceedings* of the Royal Irish Academy.

VIOLENT earthquake shocks of seventeen seconds' duration are reported by Reuter to have been experienced in Bucharest, Roumania, at 10 a.m. on Sunday last.

AN earthquake is stated in the *Globe* to have taken place in Lisbon at 1.34 p.m. on Monday last. It was of three seconds' duration.

DR. W. H. ALLCHIN is to deliver the Harveian oration at the Royal College of Physicians of London on Monday, October 19. The Bradshaw lecture (the subject of which will be "Some Observations on Tuberculosis of the Nervous System") will be delivered at the college by Dr. E. F. Trevelyan on Thursday, November 5.

A COURSE of lectures on bacteriology for medical men, veterinary surgeons, agriculturists, brewers, farmers, sanitary inspectors, teachers and others is to be given by Dr. F. Bushnell at Plymouth under the direction of the education authority for that town. The lectures will be illustrated by lantern slides, cultures and demonstrations, and it is hoped to make arrangements for a class of practical bacteriology in the future.

AN International Exhibition of Inventions is to be held at Brighton in November next. The object of the exhibition is to afford inventors and patentees an opportunity of bringing their inventions before the notice of capitalists, manufacturers, and users. Awards of gold, silver, and bronze medals will be made for inventions possessing the greatest merit combined with commercial utility.

IT has been decided to start a school of colonial medicine at Marseilles, and Surgeon-Major Martine, of the colonial military service, has just been appointed by the French Minister of War to confer with the municipality of Marseilles relative to its establishment.

THE U.S. Consul-General at Frankfort is reported by the *Chemist and Druggist* to have stated that "the city of Düsseldorf will soon have the first academy for practical medicine in Germany, and it will be in connection with the new hospital to be erected." Prof. Witzel, of the University of Bonn, is proposed as director of the academy. The establishment of other similar academies is under consideration.

An exposition is to be held in Baltimore under the auspices of the Maryland Public Health Association and the Tuberculosis Commission appointed by the Governor of that State, the object of which is to arouse public and professional interest in the subject of tuberculosis. The basis for the exposition will, says the *Lancet*, be the investigations of the Tuberculosis Commission into the cause, the prevalence, and the distribution of human tuberculosis in that State, its influence on the public welfare, and the best methods of restricting and controlling the disease. The medical questions involved, the importance of habits, occupation, and housing conditions will receive consideration. The ultimate purpose of the exposition is to determine the proper legislation, municipal, State, and national, to be recommended, some definite line of prophylaxis, as well as measures relating to the care and cure of both advanced and incipient cases of pulmonary tuberculosis.

It is stated in the *British Medical Journal* that a number of consumptive patients have been taken by Dr. Kuss, of Paris, to the Vallot Observatory, near the summit of Mont Blanc, for the purpose of ascertaining the effect of rarefied air on their lungs. The patients remain in the open for the greater part of the twenty-four hours in every kind of weather.

The next meeting of the International Congress of Ophthalmology is to take place at Lucerne from September 19 to 21 of next year, under the presidency of Prof. Dufour. According to the official circular which has recently been distributed, no papers are to be read, but such, if written in English, French, German, or Italian, and sent with the admittance fee before May 1 next to Prof. Mellinger, of Basle, will be printed and grouped according to their subjects, and this printed report will be sent to each member with his admission card at least two weeks before the date appointed for the opening of the congress. At the meetings the authors of the papers will have the opportunity of stating the conclusion of their respective papers in a few words, and the discussion will then commence. Members present who are interested in the subject of the paper will, of course, have had the opportunity of reading the paper before the opening of the congress. The discussions will be printed and published at the close of the congress, and possibly papers received too late to be printed before the opening of the congress will also be discussed and printed with the discussions. The afternoons of the congress will be devoted to practical demonstrations.

The Paris Society of Pharmacy is to celebrate its centenary on October 17, and in connection with it an historical account of the Society has been prepared and will be read by Prof. E. M. Bourquelot, the general secretary, at a public meeting. This history, together with other original matter that may be supplied by members of the Society, will, says the *Chemist and Druggist*, form the material of a book which will be published later. The work will also contain the portraits and biographies of leading pharmacists and chemists who have been connected with the Society, such as Nicolas Houël, the founder, the "Citizen" Trusson, one of the last directors of the Free Society of Pharmacists, Parmentier, Vauquelin, Bouillon-Lagrange, and others.

A meeting was recently held in America, under the chairmanship of Dr. D. C. Gilman, to promote a proposed memorial to the late Major Reed, M.D., well known for his work in connection with the discovery of the mode by which yellow fever has been spread, and the suppression of the disease. According to *Science* the meeting decided that an effort should be made to raise a memorial fund of 25,000 dollars or more, the income to be given to the widow and daughter of Dr. Reed, and that after their decease the principal shall be appropriated either to the promotion of researches in Dr. Reed's special field, or to the erection of a memorial in his honour at Washington.

Particulars, according to the *Lancet*, have been received of the medical results of the expedition of investigation to the Bahamas which was sent out some time ago by the Johns Hopkins University and the Baltimore Geographical Society, from which we glean the following. Skin diseases, and especially leprosy, were found to be very prevalent. No effort is made to prevent the spread of leprosy, and many instances were noted where persons suffering from that disease were engaged in the sale of provisions, in piloting vessels, and in other pursuits. No cases of yellow fever were discovered, and but two cases of malaria were recognised. Many species of mosquito were secured for subsequent study. A special feature of the work of the medical department was the study of the degenerates of Abaco, descendants of the Torys, who closely intermarry.

According to the *Times* a prehistoric British barrow has just been opened at Martinstown, Dorset. The barrow contained worked flints, a quantity of pottery, and a large British urn inverted on a slab of stone, covering some cremated remains which had been wrapped in a rough material of cloth or rushes, the texture of the weaving of which was still traceable. In another barrow close by have been found a vase and a bronze knife with a portion of a willow handle.

On this day week, September 10, a storm of unusual violence advanced over the central portion of the British Islands, causing enormous damage in its passage over sea and land. The *Daily Weather Report* issued by the Meteorological Office for 8h. a.m. of that day showed that a depression lay to the westward of the Irish coasts; by 6h. p.m. the disturbance reached the Irish Sea, and had advanced at the rate of about fifty miles an hour, while by the evening it had spread over nearly the whole country. So rapid was its rate of progression that the *Daily Weather Report* of the morning of September 11 showed that the centre of the storm had reached the north of Holland. The destruction was so general that it seems somewhat invidious to refer to individual instances. We merely quote two cases to illustrate its violence—the demolition of the solid breakwater at Dover, and the uprooting of trees in the vicinity of London that had withstood the storms of a hundred years. During the passage of the gale the barometer fell at the unusual rate of more than 0·1 inch an hour. The velocity of the wind to the southward of the centre of the storm was much greater than to the northward; near the mouth of the Channel on the evening of September 10 it reached nearly 70 miles an hour. The rainfall measured in the twenty-four hours ending on Friday exceeded an inch and a half in the north-west, and an inch and a quarter in the east of England.

The September issue of the Meteorological Office pilot chart contains, in addition to the twelve maps showing the tidal streams round the British Isles, a reproduction of Dr. Hermann Berghaus's chart of cotidal lines round our own and the North Sea coasts, with explanatory remarks by Prof. G. H. Darwin. To render the information more complete to the mariner, there is a table giving the times of high water at Dover throughout the month. Another addition deals with a proposal to alter the steamship route between the Bristol Channel and Jamaica. A comparison has been

instituted to show the merits and demerits of the Great Circle track, 3524 miles; the Rhumb track, 3603 miles; and the suggested route *viâ* the Azores and the Mona passage, 3722 miles. The conclusion arrived at is that, "taking into consideration the wind direction, the wind force, and the sea-surface currents, it seems safe to assume that the Azores routes will be covered by a vessel at her usual speed in an interval of time certainly not greater than that occupied by the same ship in following either the Great Circle route or the Rhumb track, and probably in less."

The report of the Meteorological Commission of Cape Colony for the year 1901 shows a considerable falling off as regards the number of stations, compared with that of the previous year, owing to the difficulties of observation and communication under the operation of Martial Law within the colony. Nevertheless, the commission has been able to publish rainfall statistics from 436 stations, excluding those connected with the Kenilworth Observatory, and a large amount of valuable general meteorological observations. Many of the stations destroyed or discontinued were situated in the more sparsely populated districts, and it is estimated that it will take years to recover the lost ground. The commission reports, however, that there is an awakening sense of the importance of meteorology among the governing bodies of the other British South African territories, and that, in spite of the troublous times recently passed through, the prospects of the development of meteorological observations are much brighter now than ever they have been. We wish the commission success in the continuation of its very useful operations.

Particulars are given in the *Scientific American* of an ingenious invention which has been brought out to notify automatically the outbreak of fire, and to indicate to the fire stations the name and position of the building which is in danger. Of the device, which is the invention of M. Emile Guarini, the essential feature is a thermometer which is so arranged that it is capable of releasing a toothed wheel which serves to transmit the requisite information. When the heat reaches the thermometer and the mercury rises in the tube until it reaches the mark indicated by 42° on the Réaumur scale it touches a small platinum wire inserted in the upper end of the tube, and thereby closes an electric circuit including an electro-magnet. Thus excited the magnet attracts and holds its armature. This motion releases a toothed wheel of peculiar construction, which, by means of a weight or spring, is made to revolve, and produces during each revolution a series of makes and breaks upon a contact piece placed in its path. A connected induction coil describes the exact location of the endangered property to the neighbouring fire station, where the message is registered by a Morse apparatus, and the attention of the attendants is directed by an electric gong to the signal received. An incandescent lamp also glows when the alarm is sounded.

It will not be owing to want of help from the Imperial Department of Agriculture if West Indian planters fail to get profitable returns from their land. In the last number of the *West Indian Bulletin* the value of ground nuts, Eucalyptus trees, and the bay tree is brought to notice. Mr. W. G. Freeman has collected much practical information on the subject of ground nuts, known also as monkey nuts and pea nuts. Besides furnishing oils of which the best grades are nearly equal to olive oil, the ground nut, *Arachis hypogaea*, offers another source of profit, since it may be manufactured into oil-cake, for which there is evident demand, as at the present time large quantities are imported. For the manufacture of bay oil and bay rum the tree *Pimenta acris* has a considerable value; it is indigenous to many of the islands, but must be distinguished from the tree known as "bois d'Inde citron" in Dominica, the product from which is inferior.

Judging from a circular which has been received from the Forestry Bureau of the U.S. Department of Agriculture the lumbermen of the United States of America do not yet thoroughly recognise that their interests coincide with those of the forester. Of the three papers included in the circular, the first is an address delivered by President Roosevelt in which he states that "the forest problem is in many ways the most vital internal problem in the United States." Chief-forester Pinchot discusses the mutual position of the lumberman and the forester.

We have received a chart of fossil shells found in connection with the seams of coal and ironstone in north Staffordshire, drawn up by Dr. Wheelton Hind and Mr. J. T. Stobbs. There are columns showing the strata met with in the Potteries and Cheadle coal-fields, but the information relates chiefly to the former and more important district. The species figured are chiefly Mollusca, and they are arranged alongside the divisions which they characterise. The chart is published by the North Staffordshire Institute of Mining and Mechanical Engineers, and it should prove of practical use to mining students and to those engaged in sinking for coal.

Dr. J. F. Whiteaves has described some additional fossils from the Cretaceous rocks of Vancouver, and has given a revised list of the species therefrom, in the fifth and concluding part of his first volume on Mesozoic fossils (Geol. Survey of Canada, August). A number of Crustacea, of Cephalopoda and other Mollusca, and Brachiopoda are figured. Echinoderms are represented only by fragments, and corals and Polyzoa by two or three specimens. A few fish-remains occur, including *Lamna appendiculata*, which extends through the Upper Cretaceous strata, and ranges from northern Europe to New Jersey and Queensland.

Dr. Ernest W. Skeats contributes an essay on the chemical composition of limestones from upraised coral islands, with notes on their microscopic structure (*Bull.* Museum Comp. Zool., Harvard Coll., vol. xlii.). The rocks consist of true coral reefs and of fragmental strata made up of organic débris. The author, after describing the materials, briefly discusses the relation of the distribution of magnesium carbonate in the limestones to the question of the origin of dolomite. It seems probable that the introduction of magnesium into the rocks takes place from the waters of lagoons under certain favourable conditions.

In addition to his presidential address on the distribution of life in the Antarctic, Dr. H. Woodward contributes a paper on East Anglian geology to the *Transactions* of the Norfolk and Norwich Naturalists' Society for 1902–1903.

We have received two parts of the *Bulletin International* (Rospravy Ceske Ak. Praze) for 1903. Among their contents, reference may be made to an important article, by Dr. O. Völker, on the development of the pancreas in the amniote vertebrates, and to a second, by Prof. J. Janošík, on that of the blood corpuscles in the same great group.

A lengthy illustrated account of the "Bathymetrical Survey of the Fresh-water Lochs of Scotland" appears in the current *Geographical Journal*, the introductory portion of which gives the history of the origin of the survey; this is followed by particulars of some six of the lochs. The *Geographical Journal* is to publish the bathymetrical maps

and the other observations of the survey staff, and the series of articles will, it is hoped, when completed, form a worthy memorial of the late Mr. F. P. Pullar.

THE September issue of the *American Journal of Science* contains, as frontispiece, a process portrait of Prof. J. Willard Gibbs, and an obituary notice of Prof. Gibbs by Prof. H. A. Bumstead. The number also contains an article by Mr. J. Stanley Gardiner, of Cambridge, on "The Origin of Coral Reefs as shown by the Maldives."

THE September issue of the *Popular Science Monthly* (New York) is full of interesting matter, and contains, among other contributions, articles on "Palm and Sole Impressions and their use for Purposes of Personal Identification," by Prof. H. H. Wilder; "Theories of Sleep," by Dr. P. G. Stiles; "Mosquitoes and Suggestions for their Extermination," by W. L. Underwood; and part iv. of a series of articles by Prof. J. A. Fleming, F.R.S., on "Hertzian Wave Wireless Telegraphy."

MESSRS. WATTS AND CO. have issued, for the Rationalist Press Association, a reprint, at sixpence, of the first edition of "The Origin of Species." It will be remembered that an edition of the final form of this great classic was brought out not long ago by Mr. Murray in paper covers at one shilling.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mr. C. Pells; two Masai Ostriches (*Struthio camelus*, var. *massaicus*) from East Africa, presented by Mr. A. Marsden; two Grey-breasted Parrakeets (*Myopsittacus monachus*) from Monte Video, presented by Mr. C. Martin; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, two Mozambique Monkeys (*Cercopithecus pygerythrus*) from East Africa, a Black-striped Wallaby (*Macropus dorsalis*), a Black-tailed Wallaby (*Macropus walabates*), a Rufous Hare Wallaby (*Lagorchestes hirsutus*) from New South Wales, two Black-headed Caiques (*Caia melanocephala*) from Demerara, an Australian Barn Owl (*Strix delicatula*), a Winking Owl (*Ninox connivens*), a Burton's Lizard (*Lialis burtoni*), a Limbless Lizard (*Pygopus lepidopus*) from Australia, a Javan Loris (*Nycticebus javanicus*) from Java, two Grey Monitors (*Varanus griseus*) from North Africa, two Muricated Lizards (*Amphibolurus muricatus*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

SEARCH-EPHEMERIS FOR COMET 1896 v. (GIACOBINI).—Herr M. Ebell contributes to No. 3898 of the *Astronomische Nachrichten* a second portion of the ephemeris for comet 1896 v. which he commenced in No. 3881 of the same journal. This ephemeris takes as the time of perihelion June 22·5, 1903, but Herr Ebell also gives ephemerides in which the time of perihelion passage is taken as June 6·5 and July 8·5 respectively.

Ephemeris 12h. M.T. (Berlin). T=June 22·5 1903.

INTENSITY OF SPECTRAL LINES.—*Circular* No. 72 of the Harvard College Observatory is devoted to the explanation of a scheme, proposed by Prof. Pickering, for the formation of a uniform universal method of recording the absolute intensities of spectral lines.

Comparative intensities are easily determined, in the case of bright lines by the bolometric method, in the case of dark lines by using the bright background as the standard unity intensity. Absolute values, however, are much more difficult to determine, and two methods offered themselves to Prof. Pickering's choice. First, the determination once for all of the intensities of certain well-known lines; secondly, the construction of an artificial standard with which all lines might be directly compared; he decided to use the second method.

A standard scale was constructed in which each line was 1·26 times as wide as the one next below it, so that the logarithms of their widths differed by 0·1, and the scale was then reduced rather more than twenty times and printed on sensitised paper, the haziness, which is characteristic of real spectral lines, being produced by inserting various thicknesses of white paper between the negative and the sensitive paper.

To standardise this prepared scale the line E of the Fraunhofer spectrum on Higgs's charts was used, and the intensities of thirty-six lines between λ 5261·8 and λ 5276·2 were measured, on the scale, on five different charts, and the five independent scale readings, their mean, the residuals from the mean and the width of each line in Ångström units, are given in the table accompanying Prof. Pickering's paper.

A PROVISIONAL CATALOGUE OF VARIABLE STARS.—No. 3 vol. xlviii. of the Harvard College Observatory *Annals* is devoted to a provisional catalogue of variable stars in which reference is made to some 1227 different variables. The catalogue has been prepared from a card-index of variable stars, commenced by Prof. W. M. Reed in 1888, and carried forward by Miss A. J. Cannon since 1900, which now contains about 34,000 cards referring to observations of variables.

A new notation has been adopted after grave consideration in this catalogue. Each star is designated by a number containing six figures, which are printed in ordinary type if the star is in the northern hemisphere and in italics if it is in the southern. The first two figures give the hours and the second two the minutes in the R.A., whilst the last two give the degrees in the declination; thus the designation of the first star in the catalogue (V. Sculptoris) is *000339* which, when translated, gives the approximate position of the star as R.A.=0h. 3m., Dec.=−39°.

The catalogue also gives the Chandler number, the name of the star or its constellation, the D.M. number, the exact position for 1900, the chief particulars of the elements, the class of the variable and of its spectrum, and the date of discovery, with the name of the discoverer, for each variable.

MASS OF MERCURY.—In No. 3897 of the *Astronomische Nachrichten*, Prof. T. J. J. See, of Washington, gives the results of his recomputation of the mass of Mercury, and points out, *en passant*, the importance to workers in celestial mechanics of obtaining the truest possible value of this constant.

The latest measurements of the planet's diameter have slightly increased the former values, and Prof. See adopts 6″·00 as the most probable value of the diameter at unit distance; this gives an absolute diameter of 4351±72km. and a resulting mass of $m=1:14868548\pm743427$, which Prof. See adopts as the definite value. The mean specific gravity of the planet, with this mass, is 3·09, and this conforms very well with the other densities obtaining in the solar system.

CORRECTIONS TO EXISTING STAR CATALOGUES.—Since the publication of the "Catalogue of Reference Stars in the Zone +46° to +55°," by the Royal Observatory of Catania, Signor G. Boccardi has discovered a number of errors in various existing catalogues. These are set forth and their corrections given in a paper communicated by him to No. 3898 of the *Astronomische Nachrichten*; they include errata in the coordinates and in the precessional corrections.

Twelve catalogues are dealt with, including, among others, "The Radcliffe Catalogue of 6317 Stars (1845·0),"

"The Brussels Catalogue of 10,792 Stars (1865·0)," "The Harvard College Catalogue of 8627 Stars, A.G. Zone +50° to +55°" (Leipzig, 1892), and "The Bonn Catalogue of 18,457 Stars (1875·0), A.G. Zone +40° to +50°," published at Leipzig in 1894.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—An examination for a geographical scholarship of the value of 60*l.* will be held on Wednesday, October 14. Candidates, who must have taken honours in one of the final schools of the university, should send in their names to the reader in geography not later than Thursday, October 1. The scholar elected will be required to attend the full course of instruction at the School of Geography during the academic year 1903–4, and to enter for the university diploma in geography in June, 1904.

DR. F. H. NEWMAN, principal of the Carlisle Technical School and director of higher education in that city, has been appointed principal of the Norwich Technical Institute and organiser of higher education.

IT is stated in *Science* that a gift of ten thousand dollars has been made to Washington and Lee University by Mrs. Cyrus H. McCormick and her three sons, of Chicago, the interest of which sum is to be devoted to the development of the department of physics. A new laboratory of engineering and physics, the gift of an anonymous donor, is expected to be ready for occupation in the summer of next year.

THE evening continuation schools in connection with the School Board for London reopened on September 14. As the School Board will cease to exist after the end of April next the present session will be the last under the Board. Among the numerous classes arranged we notice that doctors and nurses will teach first aid and home nursing in upwards of two hundred schools. There will also be facilities for women and girls to learn practical cookery, dress-cutting and making, and laundrywork, and for men and boys to receive instruction in woodwork. The lantern will, in many cases, be used to illustrate the lessons in geography. The Board has arranged for medical men to give simple lectures on health in twenty schools; the subjects will include the air and ventilation, the house, prevention of consumption, the care of the skin, personal hygiene, how to prevent the spread of infectious disease, the care of infancy and childhood, ill-health in women, &c.; all the lectures will be illustrated by diagrams, and many simple experiments will be shown by the lecturers.

THE Board of Education, South Kensington, has issued the following list of candidates successful in the 1903 competition for the Whitworth scholarships and exhibitions:—Scholarships, 125*l.* a year each (tenable for three years), John S. Nicholson, Alford, Aberdeenshire; Leonard Southerns, Retford, Notts.; Alec J. Simpson, Edinburgh; Alexander Gray, Edinburgh. Exhibitions, 50*l.* (tenable for one year), Frederick G. Turner, Southsea; James Cunningham, Banbury; William Welch, London; Edmund W. Spalding, Lincoln; William E. Hogg, London; Alfred R. Stamford, Plumstead, Kent; Joseph Lloyd, Pembroke Dock; John A. Davenport, Liverpool; Stewart S. Spears, Sheerness-on-Sea; James Lees, Southsea; William H. Powell, London; Edwin C. Trew, Landport, Portsmouth; Frederick W. B. Sellers, Sutton, Surrey; John E. Lister, Doncaster; Richard W. Bailey, Manor Park, Essex; Laurence H. Pomeroy, London; Christopher J. Lees, London; Fred Newell, Plumstead, Kent; Edmund G. Nicholls, Swansea; Maurice K. Pedlar, East Stonehouse, Devon; George F. Sutherland, Aberdeen, N.B.; Charles I. Sutton, Plumstead, Kent; Robert H. Barr, Barrow-in-Furness; William H. Hemer, Devonport; James Nicol, Barrhead, N.B.; Frederick E. Pollard, Eastwood, Notts.; Arnold Sykes, Huddersfield; Wilfred C. Kimber, London; Henry F. Elliott, Plumstead, Kent; David Richardson, Crewe.

THE following list of successful candidates for royal exhibitions, national scholarships, and free studentships (science), 1903, has been issued by the Board of Education, South Kensington:—Frederick G. Turner, Southsea; James M. Mackintosh, Inverness, N.B.; Samuel Lees, Broughton, Manchester; John H. Hugon, Eccles, Manchester; Arthur A. Rowse, Southsea; William E. Hogg, London; William L. Perry, Plymouth, royal exhibitions; Archibald Ward, Sheffield; Alexander Gray, Edinburgh; Edwin S. Crump, Wolverhampton; Leslie G. Milner, New Brompton, Kent; Archibald R. Richardson, London; Francis G. Steed, Devonport, national scholarships for mechanics (group A); Harold H. Broughton, Huddersfield; George F. Sutherland, Aberdeen, N.B., free studentships for mechanics (group A); William H. L. Patterson, Chiswick; Arthur E. Hall, Swindon; William F. G. Swann, Brighton; James Hoggarth, Bath; John Watson, Sunderland, national scholarships for physics (group B); Charles I. Robinson, London, free studentship for physics (group B); Frederick Dewhurst, Middleton Junction, Manchester; William Godden, Canterbury; George S. Whitby, Hull; John F. Stansfield, Morley, Leeds; Henry Holmes, Middlesbrough; Thomas Jackson, Middlesbrough, national scholarships for chemistry (group C); Frederic W. Caton, Hove, Sussex; John Keegan, Burnley, free studentships for chemistry (group C); Edward Hindle, East Bierley, Bradford; Ethel Mellor, Burnley, national scholarships for biology (group D); Ellis L. Jones, Blaenau Festiniog, free studentship for biology (group D); Winifred M. Clune, Bristol; Fred Thistlethwaite, Burnley; Diogo F. de Souza, London, national scholarships for geology (group E).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 7.—M. Albert Gaudry in the chair.—Parthenogenesis of the larvæ of Asteriæ by the action of carbonic acid, by M. Yves **Delage**. By modifying the conditions, the larvæ develop to the stage when all the essential organs are well marked.—On the production of glycogen in fungi cultivated in weak sugar solutions, by M. Émile **Laurent**. The production of reserve carbohydrates is related both in fungi and in vascular plants to a food supply containing an abundance of sugar or analogous substances. The author has discovered an interesting exception to this rule, four species of moulds, *Mucor racemosus, Sclerotinia Libertiana, Botrytis cinerea,* and *Saccharomyces cerevisiae*, all giving considerable quantities of glycogen when grown in very dilute organic solutions.—Observations of the planet MA (August 24, 1903) made at the Observatory of Besançon, by M. P. **Chofardet**.—On a bacterial disease of tobacco, "chancre" or "anthracnose," by M. G. **Delacroix**. This disease is due to a bacillus, not previously described, and to which the name of *Bacillus oeruginosus* is given, on account of the coloration it develops in certain culture media.

PLANT PHYSIOLOGY.

A Text-book of Plant Physiology. By George James Peirce, Ph.D. Pp. iv + 285. (New York: Henry Holt and Co., 1903.)

THE author's object is to present "the main facts of plant physiology and the saner hypotheses regarding them, striving to express safe views rather than to echo the most recent . . . and everywhere trying to avoid giving the impression that the science, or any part of it, has reached ultimate knowledge and final conclusions." The standard adopted is to treat the subject "less exhaustively than Pfeffer's 'Handbuch,' and more fully than Noll's section of the Bonn text-book."

This, though doubtless an admirable object, is one not easy to attain, and the result, it must be confessed, is a book of unequal merit. As an instance of the author at his best may be mentioned the section (p. 72) on "Root-tubercle Plants." The six pages devoted to the matter give a clear and readable account which should suffice for the needs of the moderately elementary student. On the other hand, the final section of the same chapter—that on the ash constituents—is unsatisfactory. The student gets from it neither a clear conception of what is meant by the essential constituents of the mineral food-supply nor a knowledge of the more interesting details. For instance, the reader is not even directed by references to Schimper's work on oxalates in reference to the assimilation of nitrates. It is possible that the author does not consider this to be one of the "saner hypotheses," but in that case it might have been discussed with a caution.

When the author deals with photosynthesis the result is better, and there is much to interest the reader. The chief fault in his presentment of the subject is that he does not fully face the relation between the photosynthetic activity of different parts of the spectrum and the absorption bands of the chlorophyll spectrum. This is a fundamental point, and should be discussed in a treatise such as the present.

Dr. Peirce's style might here and there be mended. Take, for instance, the following sentence (p. 43), with which photosynthesis is introduced:—

"The source of carbon for all organisms except the nitrogen bacteria and plants containing chlorophyll or its apparent equivalent physiologically, bacteriopurpurin, is, directly or indirectly, these colour-containing plants."

The chapter (p. 103) on the "absorption and movement of water, &c.," is not uniformly good. The student will learn from it if he has the gift of picking out what is best, but we fear that he will not get to the root of the matter. This part suffers especially from the author's plan of not in general describing methods of research. It seems to us impossible to give a clear or interesting view of the problem of water-transport without a more direct appeal to experiment. Thus, in the section on "the means of transfer of nutrient solutions" (pp. 116–124), we miss an account of the fundamental fact that a cut branch in a glass of water is a self-regulating mechanism, in which absorption is practically equal to loss by transpiration. It is only at p. 141 that we get the idea briefly stated without proof.

Chapters v., vi. and vii. are respectively devoted to growth, irritability, and reproduction. It is doubtless a difficult matter to give an adequate account of irritability in such a book as the text-book before us, but when full allowance has been made for such difficulty, there remains a good deal to which exception must be taken.

We miss a general statement of the widely accepted view according to which a plant (like an animal) is guided by certain definite irritabilities strictly comparable to the senses of animals.[1] It seems to us clear that Dr. Peirce's views do not harmonise with the modern conception of irritability. Thus, in speaking (p. 213) of heliotropic curvatures, he asserts that the bending of a stem towards the light is the mechanical result of the increased growth-rate on the shady side of the stem. He thus ignores the well-known fact that the growth-rate of apheliotropic organs is also increased by darkness, a result fatal to his point of view. It is depressing to find this way of looking at heliotropism (which we had hoped was dead and buried) once more to the fore.

In some matters of fact we cannot agree with the author's statements. Thus at p. 214 we read:—

"So much more does gravity influence the direction of growth of roots that the influence of light is scarcely apparent until all parts are uniformly subjected to gravitation by means of the clinostat."

The student who has grown mustard seedlings in a glass of water and exposed them to one-sided illumination will read the above statement with surprise. Elsewhere the author's treatment of the action of light and gravitation is singularly confused, if not downright wrong. Thus (p. 214) we read that the direction of growth of leaves is a resultant of two forces, gravity and light, in illustration of which he describes leaves assuming a normal light position while slowly rotated on the clinostat, the whole point of the experiment being in reality to prove that the normal light position may be assumed in response to light alone, and not as a compromise between sensitiveness to light and gravitation.

On the whole, we think the part on irritability suffers from the attempt to crowd too much into the available space. The student would gain if less detail were attempted, and a simpler, broader treatment adopted.

What we have said of one section may be perhaps applied to the book as a whole. A reader with a power of selection will be able to make use of it, and he will find much that is not to be obtained from ordinary English text-books.

F. D.

[1] Brief and partial statements occur at pp. 206 and 207.

THE MINERAL RESOURCES OF THE FRENCH COLONIES.

Les Produits Coloniaux d'Origine Minérale. By Prof. Laurent. Pp. viii + 352. (Paris: Baillière, 1903.) Price 5 francs.

THIS little work forms one volume of the "Colonial Library," which is a small series of four-shilling books dealing with the animal, vegetable, and mineral products of the French colonies, as well as with the question of hygiene. It is divided into two chapters; the first briefly describes the geology of each colony and enumerates its various mineral products; in the second, each useful mineral is taken in its turn, and the sources of supply in each colony are discussed.

The book would have been improved by a summary, giving at a glance a general idea of the mineral wealth of the French possessions. This I have endeavoured to supply so far as official information is available.

Mineral Output of the French Colonies and Protectorates, 1901.

[1] Estimated.

The total value of all the minerals produced by the French colonies is about 2 millions sterling, of which Algeria claims more than one-third. The mineral wealth of this colony is derived mainly from its iron ore and phosphate of lime; French Guiana is the largest gold producer; New Caledonia is famous for its nickel ore; and Tunisia is coming into notice on account of its phosphatic deposits.

The growing importance of the phosphate industry of northern Africa is worthy of notice, indeed, this mineral comes second in order of value in the table. The author gives some interesting details concerning the phosphatic beds at Gafsa, from which nearly all the phosphate of Tunisia is obtained. The mineral was not discovered at Gafsa until 1885, and the concession for working it was not obtained until 1896. Since that date the French have constructed a railway 156 miles long, from the port of Sfax to the centre of the mining district, and it is expected that the output for 1903 will be about 300,000 tons. The phosphatic beds occur in rocks of Lower Eocene age; the principal seam now being worked at Gafsa is 11 ft. 6 ins. thick, and contains 60 per cent. of tribasic phosphate of lime.

In spite of being full of valuable information, Prof. Laurent's book is unsatisfactory, because he has introduced much matter which is entirely out of place under the title chosen for the volume. But in his preface he tells us that the book is a *résumé* of his lectures to young men who propose to go to the colonies, and that he wishes them to know something of the modes of occurrence and methods of treatment of minerals in other countries, so that they may be able to take advantage of the possible resources of new districts. He consequently enters into details which make parts of the book into a jumble of geology, mineralogy, prospecting, mining, quarrying, dressing, smelting, salt-making, &c. There is no royal road to learning, and the attempt to teach in one course of lectures what in reality requires at least four separate courses should certainly be discouraged. And there are other grounds for complaint; the figure of a sulphur-still is very antiquated, and, if my memory serves me aright, it appeared in my French lesson books half a century ago. I doubt very much whether this old form is ever used now; at all events, it is very different from the "doppioni" which were employed for treating the sulphur rock in the Romagna in the early 'seventies. The picture of the modern kiln does not give the proportions of an ordinary Sicilian "calcarone." Other second-hand figures have been picked up and inserted here and there with little advantage to the reader. Nothing could well be worse than the figure of a blast-furnace, and a student unacquainted with Blake's stone-breaker would fail to understand its action by

reference to the illustration. It is true this is well lettered, but no explanation is furnished as to what each letter denotes. Many of the figures prepared specially for the book from photographs are of little use.

In a word, the book would have been more acceptable if the author had confined his attention to the matters really included in the title, and had supplied better illustrations.

EXPERIMENTAL SCIENCE FOR BEGINNERS.

Practical Chemistry. By Walter Harris, M.A., Ph.D. Vol. i. Measurement. Vol. ii. Exercises and Problems. Vol. iii. Qualitative and Quantitative Analysis. Pp. x+91; ix+172; vii+146. (London: Whittaker and Co., 1903.)

THERE are probably few teachers, who, with half-a-dozen pupils and plenty of time to devote to them, would not prefer the oral to the book process of imparting the elements of experimental science. Yet when the number in a class is large, and laboratory work is limited to one or two hours a week—the usual order of things in schools—the demonstrator must be relieved by the aid of some form of printed instructions.

In compiling a book of this kind, the chief difficulty which presents itself is to know how much to tell about the processes, and how much to leave to the pupil's intelligence and initiative.

Given the budding philosopher and plenty of time, very little book direction is necessary, and he may safely be left to worry out details for himself. The everyday youth is not a philosopher, and if, in addition, he has only one hour a week in the laboratory, he must be helped to his results in a very substantial manner, to enable him not only to absorb a variety of facts in the time at his disposal, but (and this is equally important) to avoid the discouraging consequences of repeated experimental failures. These points have been recognised in the three little volumes which together make up Dr. Harris's "Practical Chemistry." Vol. i. deals really with elementary physics, and contains exercises in measurement of length and volume, mass and density. Vol. ii. contains easy qualitative and quantitative experiments in chemistry. The third volume contains the elements of qualitative and quantitative analysis, in reference to which the author laconically remarks that "for those who do not require this section for examination purposes, it should be omitted." The experiments in the first two volumes are numerous, simple, and suggestive, and well adapted for a school laboratory, and there are many things which will be found of value to the teacher as well as to the student.

One feels compelled to differ from the author on the subject of illustrations. The author says: "The omission of all illustrations of apparatus is a new departure." Is it a good one? We must remember that the beginner does not recognise by name even "the permanent apparatus commonly seen in laboratories," and although it is very desirable that "the student should be encouraged to devise his own apparatus," it is a process which is certain to result in failure and loss of time. Those who have attempted with all the knowledge of laboratory resources to reduce an apparatus to a simple form, will recognise how troublesome the process is. Moreover, the author gives no directions for working glass; which, one would suppose, would be the first step in fitting up glass apparatus.

May one further suggestion be offered? Experiment 1, in section ii., on homogeneous and heterogeneous substances, is not a single experiment at all, but a very condensed account of the separation of solids and liquids, in which filtration, sublimation, levigation, and fractional distillation are discussed in turn. This and some other chapters would be improved by dividing them up and by giving, in addition to general principles, a description of specific instances, from which the teacher might make his own selection.

There is no doubt that these volumes will form a useful addition to the modern literature on science teaching. J. B. C.

OUR BOOK SHELF.

Untersuchungen über Amylose und Amyloseartige Körper. By O. Bütschli. (Heidelberg: Carl Winter, 1903.)

THIS pamphlet of about 100 pages is a reprint from the *Proceedings* of the Heidelberg Association for Natural History and Medicine (vol. vii. part iii.), which is one of the best known of the German scientific societies. It illustrates a tendency, not infrequently seen in Germany, to utilise the pages of a journal for the issue of what is practically a book. The author, Prof. Bütschli, is well known to students of biology for his work on protoplasm, and distant as the subject of starch may at first appear from zoological studies, the present research is a direct outcome of the former. The microscopic investigation of various colloids occurring in nature which led Bütschli to his well-known hypothesis of the foam-like structure of protoplasm caused him later to direct his attention to the formation of starch grains, cellulose membranes and the like in the vegetable world. Some years ago he published his view that starch grains are of the nature of sphæro-crystals. From this he passed on to attempt to prepare starch grains artificially from starch solutions, and he was rewarded by the discovery that, under certain conditions, especially on evaporating a solution containing also 5 per cent. of gelatin, particles differing but slightly from natural starch grains are deposited. These results were criticised by Arthur Meyer, who expressed the opinion that these particles consisted not of starch, but of amylodextrin. The present pamphlet is a reply to these criticisms, and on the ground of various chemical reactions the conclusion is finally reached that Meyer was wrong, and the author right in his original contention.

This is the gist of the monograph, and its length is due to the fact that it became necessary for the author to make a chemical investigation of various starches, dextrins, and allied carbohydrates in order to justify his main conclusions.

From the purely chemical standpoint very little real progress is contributed to our knowledge of the carbohydrates. The sugars, thanks to Fischer and others, we now know something about, but concerning the

molecular size and constitution of the heavy carbohydrates, like starch and glycogen, and the family of dextrins intermediate between these and the sugars, we have at present little more than guesses to go upon. To give, as the present author does, long lists of reactions with iodine and other reagents, and on the strength of differences in these to describe as separate substances amylose, amylosan, amylodextrin, and other forms of dextrin, and to add to the list amyloporphyrin and amylorubin, does not really advance matters much. Bütschli apologises at the start for his lack of chemical knowledge, and in the end admits that several of his preparations are mere mixtures; we therefore fear that, from the chemists, his work will meet with but scant courtesy. He has nevertheless succeeded in producing a very readable little brochure, and if his main contention is accepted, his labours will not have been useless.

Lessons on Country Life. By H. B. M. Buchanan and R. R. C. Gregory. Pp. xi+330. (London: Macmillan and Co., Ltd., 1903.) Price 3*s.* 6*d.*

ONE of the authors of the above book, Mr. H. B. M. Buchanan, produced a little time ago two small "Country Readers," most excellent books for the children of a rural elementary school, in which our common domestic animals were discussed from a full knowledge in an easy, pleasant style. We are sorry we cannot give the same praise to the "Lessons" before us; the educational value of the former book has disappeared, and the authors have allowed a craving for completeness to swamp their judgment, so that the result is a miniature and scrappy encyclopædia instead of a book.

Country life is a vast subject, so vast that no child can learn during his school life even a fraction of the information it may be desirable he should possess in his after life; the teacher, then, must abandon the attempt to impart information, but devote his energies to instilling into his pupils the right way of looking at things, the method which they can employ themselves when going about the world. The method consists in a training in observation and experiment. Here instead we have first a sort of abbreviated text-book on live stock, hints on breeding and feeding, twelve breeds of cattle described at lengths varying from a page down to two lines, horses, sheep and pigs to correspond, analyses of milk, rules for making butter and cheddar cheese; with such a programme what chance is there of observation or experiment for school children?

The latter portion of the book deals with common birds and mammals in a much better spirit; strike out the unnecessary Latin names for orders, families and species, and it forms a fair reading book. The last section, on insects, is again spoiled by a wholly unnecessary passion for classification; classification is only grammar, and the parts of τυπτω are just as good in this way as "Coleoptera, Euplexoptera, Orthoptera, Thysanoptera, &c." We know by sad experience how easy the schoolmaster finds it to write these things on the blackboard and make his class copy them with due attention to neatness and spelling; observation and experiment require both labour and thought. We grieve to speak unkindly of Mr. Buchanan, who has done such excellent work before; there are good things in the book, *e.g.* the section on poultry and the illustrations, but, like the curate's egg, it is only good "in parts." If the new teaching on country life is to succeed in our schools, it will be in virtue of the spirit, and not of the information which the teacher imparts to his pupil, and we consider that this book fatally misses the spirit.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Radio-activity and the Age of the Sun.

IN the Appendix E of Thomson and Tait's "Natural Philosophy," Lord Kelvin has computed the energy lost in the concentration of the sun from a condition of infinite dispersion, and argues thence that it seems "on the whole probable that the sun has not illuminated the earth for 100,000,000 years, and almost certain that he has not done so for 500,000,000 years. As for the future, we may say, with equal certainty, that inhabitants of the earth cannot continue to enjoy the light and heat essential to their life for many million years longer, unless sources now unknown to us are prepared in the great storehouse of creation."

The object of the present note is to point out that we have recently learnt the existence of another source of energy, and that the amount of energy available is so great as to render it impossible to say how long the sun's heat has already existed, or how long it will last in the future.

The lost energy of concentration of the sun, supposed to be a homogeneous sphere of mass M and radius a, is $\frac{3}{5}\mu M^2/a$, where μ is the constant of gravitation. On introducing numerical values for the symbols in this formula I find the lost energy to be $2{\cdot}7\times 10^7$ M calories, where M is expressed in grammes. If we adopt Langley's value of the solar constant this heat suffices to give a supply for 12 million years. Lord Kelvin used Pouillet's value for that constant, but if he had been able to use Langley's his 100 million would have been reduced to 60 million. The discrepancy between my result of 12 million and his of 60 million is explained by a conjectural augmentation of the lost energy to allow for the concentration of the solar mass towards its central parts. I should have thought the augmentation somewhat too liberal, but for the present argument it is immaterial whether it is so or not.

Now Prof. Rutherford has recently shown that a gramme of radium is capable of giving forth 10^9 calories. If, then, the sun were made of such a radio-active material it would be capable of emitting 10^9 M calories without reference to gravitation. This energy is nearly forty times as much as the gravitational lost energy of the homogeneous sun, and eight times as much as Lord Kelvin's conjecturally concentrated sun.

Knowing, as we now do, that an atom of matter is capable of containing an enormous store of energy in itself, I think we have no right to assume that the sun is incapable of liberating atomic energy to a degree at least comparable with that which it would do if made of radium. Accordingly, I see no reason for doubting the possibility of augmenting the estimate of solar heat as derived from the theory of gravitation by some such factor as ten or twenty.

In an address to Section A of the British Association in 1886 I discussed the various estimates which have been made of geological time, and I said, "Although speculations as to the future course of science are usually of little avail, yet it seems as likely that meteorology and geology will pass the word of command to cosmical physics as the converse." I think the recent extraordinary discoveries show that this forecast was reasonable.

It is probable that the bearing of radio-activity on the cosmical time-scale has occurred to others, but I do not happen to have seen any such statement.

Cambridge, September 20. G. H. DARWIN.

The Principle of Radium.

WOULD some of your readers inform me whether the case of the radium phenomena is quite unique? When a small magnet in my drawer has been ready to act on a compass at any time during the last twenty years, and has not

altered its appearance in any appreciable way, I ask whence comes the continuous magnetic supply?

Again, when a lady has had for a great many years a cedar work-box which has never failed in its characteristic odour, it is a natural question to ask, whence comes the smell? The statement in books, both of physics and physiology, is that something material is given off from the wood which alights on the olfactory membrane of the nose. This is purely gratuitous, as the statement is without a shadow of proof, the box being to all appearances in no way diminished in size or otherwise altered. If the hypothesis, for it is nothing more, fails, how does the case differ in principle from that of radium? S. W.

Normally Unequal Growth as a Possible Cause of Death.

I HAVE found from a good many years' experience that it is frequently difficult to assign any definite cause of death to the lower Vertebrata which die in the Zoological Society's Gardens from time to time. The examination of a large example of the Japanese salamander (*Megalobatrachus japonicus*), which lived for a good many (nineteen) years here, and measured some three feet in length, has suggested to me a rather curious and truly "natural" cause of death—if my inferences be correct. The animal showed no obvious signs of disease in any organ. Judging from its length it must have been old, for a specimen three feet long is asserted to have been at least fifty-two years old (*vide* Gadow, Cambridge Natural History, "Amphibia and Reptiles," p. 99). Comparing this specimen with one some twenty inches in length I found that the size of the heart, as of the other organs, was, as might be expected, actually larger, but that all the subdivisions of the heart were of the same proportions in the two animals. But in the course of a dissection of the heart it was plain that the two series of valves, which lie respectively at the anterior and at the posterior end of the pylangium, were so small, relatively speaking, that, when forced backwards by the pressure of blood in the entire conus arteriosus, they would not meet in the middle line. On the other hand, in the smaller salamander the three valves in question were in the first place situated closer together than in the large animal, being nearly in actual contact, and in the second place their size was so great in relation to the diameter of the pylangium that they would—or, I should rather say, could—meet after the systole of the ventricle. The fact is that these valves do not appear to grow *pari passu* with the general increase in size of the heart and the conus arteriosus. My own observations as to the small size of the valves in the large example are quite in accord with those of Hyrtl (*Cryptobranchus japonicus*, Vindobonae, 1865), who dissected an animal two and a half feet in length, and figures the valves, incorrectly as I believe in some particulars, but correctly in representing them to be of small relative size. It might be suggested, therefore, that the imperfection of the circulatory mechanism necessarily caused by the condition of the valves would lead to serious disturbances, and perhaps to death. If so the animal has a term put to its life by the mere fact that, while the heart grows with the increase in bodily size, the semilunar valves of the conus arteriosus do not.

Zoological Society's Gardens, London, N.W.

Can Carrier-pigeons Cross the Atlantic?

COULD any of your readers give me an answer to this query? It is stated in the London *Standard* (April 20, *circâ*) that this feat was accomplished in 1886, when three out of nine American carrier-pigeons set free in London returned to their home-huts. I have hitherto been unsuccessful in getting the authority for this particular experiment. From the points of view of bird migration and of seed dispersal, it is a query of considerable importance.

21 Henleaze Gardens, Westbury, Bristol, September 21.

A TECHNICAL SCHOOL FOR THE HIGHLANDS OF SCOTLAND.

THE difficult problem of catering for the educational needs of remote and isolated rural districts has been dealt with practically in this country by such enlightened benefactors as the Countess of Warwick in her school at Bigods, near Dunmow, in Essex, which has been carrying on its useful work for some five years, and which is now about to be made still more strictly into a school of agriculture, so as to bring it into harmony with the requirements of the district and of the counties which it serves. Lady Warwick's sister, the Duchess of Sutherland, has faced the still more difficult problem of providing a technical school for the Highlands of Scotland, and a preliminary account of the first scheme was given in these columns at the time of its inception (NATURE, vol. lxv. p. 106, December 5, 1901). The work thus set going by Her Grace was formally inaugurated on September 8 by Lord Balfour of Burleigh, Secretary for Scotland, at a public ceremony held for the purpose of laying the memorial stone. The building, the design of which is by Mr. Dick Peddie, of Edinburgh, is already several feet above its foundations, and is situated on the picturesque slope of a hill overlooking the little town of Golspie, on the shore of Dornoch Firth, and within two miles of the beautiful grounds of Dunrobin Castle, the Scottish home of the Sutherlands. The main features of the educational scheme, as set forth in the statement published in our first notice, have been adhered to, but the details of a curriculum suitable for requirements of such a very diverse nature as have to be met in this remote Highland district can only be worked out by actual experience—it will be a case, as Lord Balfour said at the meeting, of *solvitur ambulando*. How diverse these conditions are will be realised when it is pointed out that the industries which have to be catered for are agriculture, almost entirely of the "crofting" type, textiles and dyeing, small mechanical trades and handicrafts, and fishing.

The ceremony on September 8, rendered picturesque by the surroundings and by the great gathering of some 2000 people from the neighbourhood and from all the towns and villages served by the Highland Railway from Inverness northwards, was opened by the singing of the Hundredth Psalm, and by a prayer for the success of the undertaking by Archdeacon Sinclair. The gathering was in itself a memorable one, the Duke of Sutherland, who presided, being supported by the Duchess and their family, by the Duke and Duchess of Portland, Mr. Andrew Carnegie and his partner Mr. Henry Phipps, Mr. R. B. Haldane, K.C., M.P., Prof. Meldola, by representatives of nearly all the leading Scottish families, by Members of Parliament, Provosts and Sheriffs, the Principals of the Scotch universities, the chairman of the governors of the Glasgow and West of Scotland Technical College, the conveners of the county councils, and by educationists of every class, including professors and inspectors of schools. Mr. James Macdonald, W.S. of Edinburgh, the hon. secretary of the school committee, had made himself responsible for the organisation of the meeting, which was in every way successful. After the laying of the stone, Lord Balfour said in the course of his speech:—

"This is to be a school for Sutherland and these other counties (Caithness, Ross and Cromarty). It is not only to be accessible to Sutherland and these other counties, as any other school might be, but it is a school expressly designed for the needs and wants of the district in which we are met. Its curriculum will be based on a careful study of the condition of things as they now exist, and will have, as the promoters

clearly indicate, a direct reference to the special wants and wishes of those in the district around it. I think I am not wrong in claiming for this departure on the part of its promoters that it is to be a new fact in the educational history of our country . . . this school is not merely a copy—still less is it intended to be a rival of other educational agencies and institutions, whether they be of an elementary or of a higher or secondary type . . . it is an intelligent effort and a new attempt to solve a difficult problem, and one which never was more difficult than it is to-day, as to whether you can, in regard to any given population, living under certain given conditions, which perhaps cannot in the district be much altered, give education and ameliorate for them those conditions, and if so, what kind of education will best do it . . . in this matter the promoters have set themselves not to consider codes or grants or examination successes."

In view of the fact that the Sutherland Technical School is entirely due to private enterprise, and is therefore in the same position as regards support from public sources as Lady Warwick's school in Essex, it will be of importance to those interested in this phase of recent educational development to give another extract from Lord Balfour's speech:—

"This school is an experiment, a highly desirable and promising experiment, but not one on which any local authority could itself venture. Nor could the Education Department do it, much as we approve of the proposal. It is work for private initiative, for private enterprise, and for individual enthusiasm. May I just say in passing that if we remodel our educational system, as I for one sincerely hope we shall do, that we bring it up to date, and that we make it more complete than it is at present, let us leave some place for free individual action. Boards, committees and departments are all very well in their way, but they are apt to be regulative rather than initiative, critical rather than constructive. Many advances in education must start outside the established system. Do not let us keep private institutions out of that system. Widen your local powers if you like. Let them take advantage of and help those institutions outside their own system which are well managed. In the present instance, as I understand, the local authority—the technical committee of the county—has promised a considerable measure of support, and under the freer conditions of State recognition that have obtained in recent years, we do not anticipate there will be any difficulty in our helping them. What the exact measure of that support may be, and on what conditions it is given, it is difficult to say until the plan of the school work becomes more defined; but I can give you this assurance with every intention of seeing it carried out, that the progress of the school will be watched with interest and sympathy by the officials of my department, and that as large a measure of support will be accorded it as the conditions laid down by Parliament for supporting education will allow."

In moving a vote of thanks to Lord Balfour, the Duchess of Sutherland, in the course of an admirable speech, made some remarks so thoroughly in harmony with the views of the advocates of the newer education that they may appropriately be transferred to these columns:—

"It has been suggested that in Scotland the old system of what is called classical education is sufficient to meet all requirements; that the secondary departments of the primary schools are fairly equipped, and that if a boy wishes to pursue so-called technical studies he might be awarded a sum of money to enable him to go into large cities and there pursue them. It has even been suggested that essentially a rural agricultural school must in its aims be opposed to mental culture. Such ideas are fallacies. I am afraid that the studies of the immortal wonders of the classics and of what are so strangely called the deal languages have too often proved a dead study to the student. A mere mechanical acquisition of knowledge leads us nowhere. How would Aristophanes, author of the "Birds" and the "Clouds," how would Hesiod, the poet of the husbandman, how would Theocritus and Virgil, singers of pastoral delights, turn in their graves if they could know that only their dog-eared books spoke their music to our children, and that the chords from which that music sprang were unassayed, unloved, even unnoticed by the scholars of to-day. Not, indeed, that the children will not notice, and that they cannot love, but the present time education has, until very recently, driven them away from the region of growth to the region of the cut and dried. They live in this inspiring country at an age when the swelling of the grain on the hillside, the habits of the birds, the marvellous nature of a handful of earth, might rouse a passionate interest and quicken every faculty of observation. In a school such as this we would draw culture from its source until the youth, who for himself has seen and understood, should turn away from the intoxication of his own experiments to the books of those who long ago saw and understood, and there find a background for his own ideas and an echo to his conclusions. I deny . . . that there is any divorce between these imaginations and the practical conditions of to-day. . . . This is a scientific age; that is why we need the scientific schools. Every hour fresh marvels of the mysterious nature which surrounds us are being by science revealed."

The Duke of Portland, in seconding the vote of thanks, dwelt forcibly upon the point that the new school would not in any way compete with or overlap the work of existing institutions. A vote of thanks to the donors of the building fund, the Duke of Sutherland and Mr. Andrew Carnegie, was proposed by Mr. R. B. Haldane, M.P., and seconded by Sheriff Guthrie, who in the course of his speech pointed out the immense amount of harm that had been done to the cause of education in this country by certain classes of writers and speakers whose sole function had been to act the part of destructive critics without making any constructive contributions of any kind. Mr. Carnegie replied on behalf of the donors.

The school thus launched is intended to accommodate forty residential pupils and a limited number of day pupils from the immediate neighbourhood. The building will contain fifty-six rooms, of which fourteen are to be used as class-rooms, laboratories, and workshops. The cost of erection and equipment is estimated at 16,000*l.*, of which 8000*l.* have been contributed by the Duke of Sutherland and 8000*l.* by Mr. Carnegie. The Duke of Portland and many others interested in the district have also given substantial aid. Forty bursaries of 30*l.* each have been given by the Duchess of Sutherland, Mrs. Carnegie, and many other generous friends of the movement. The site of the school has been given by the Duke of Sutherland. The educational experiment which the enlightened zeal of the Duchess of Sutherland has now set going in the extreme north merits the warmest sympathy of our readers and of all who have the cause of scientific education at heart. The undertaking is unquestionably a bold one, and if, as Lord Balfour intimates, it is to be left solely to private enterprise in this country to initiate this kind of work, it is a matter of congratulation that we have among us such enthusiasts as the noble sisters whose names will always be associated with the cause of scientific education in rural districts. The school at Golspie will be unique of its kind in the north of Scotland. The Highlander by temperament and the surroundings of his birth, by

the excellence of his primary education and by the natural zeal which he possesses for the acquisition of knowledge is certain to rise to the opportunity now to be placed in his way. It is unnecessary to institute comparisons, but it may be safely said that this Highland school will have raw material to deal with of which many an English rural district might well be envious.

RESIN-TAPPING.

CRUDE resin is almost always obtained from pines of various species, *e.g.* *Pinus Pinaster* or *P. maritima* in Europe, *P. palustris*, *P. Taeda* and *P. australis* in America, and *P. longifolia*, *P. excelsa*, &c., in India. It may also be obtained from other Conifers

Fig. 1.—Cup and Gutters used in collecting Crude Turpentine.

(spruce, larch, &c.), and even from some Dicotyledons. The universal practice is to cut through the cortex and to allow the crude viscous liquid oleo-resin to drip into some form of receptacle, *e.g.* a hole in the sandy soil, or an excavated "box" in the foot of the bole, or a metal or earthenware "pot" hung on to the tree.

From the crude resin thus obtained, numerous other products are derived by means of distillation, &c. Among these spirits or oil of turpentine, colophany (rosin), pitch and tar are the most important, and the quantities of these substances required annually for naval purposes, for making varnishes, sealing-wax, &c., are so great that the resin industry is a large and lucrative one.

There are certain limits to the working of a pine-tree as a resin-factory which increase the expense of production so considerably that it has long been the practice in America recklessly to abandon a tract worked for resin and push forward into newer regions. These limits of production depend especially on the fact that cutting large holes in the basal parts of the bole of a tree is bound to result in disaster sooner or later; and since the American plan systematically pursued has been that of "boxing"—*i.e.* cutting large holes in the wood below, into which the resin from the cut and scarified cortex should slowly drain—the inevitable result has been the wholesale destruction of the trees by means of rot-fungi, wind throwing, ground fires, &c.

This state of affairs has naturally driven the authorities to seek for some better methods of extracting the resin, and in a recent publication[1] Dr. Hertz brings forward the results of a very complete set of experiments designed to compare the yield and value of the resin obtained by the old "boxing" method, and that obtained by a modification of the European systems.

The latter consists in allowing the resin from the periodically scarified cortex and young wood to drain down into two slanting spouts of thin tin, which direct it into a pot hung properly beneath. The advantages claimed for the improved system are, a longer life of the tapped tree, a greater yield of resin all the time, less waste in catching the resin, diminished evaporation of volatile products, and less dirt and discoloration as the liquid flows over the face exposed, as well as other and minor points.

These matters, expressed in terms of money value, are given in a series of tables, from which the following is one extract only:—

Half crop.	From dip.	From scrape.	Total.	Excess.
Second year.	Dollars.	Dollars.	Dollars.	Dollars.
Cups	266.34	49.25	315.59	144.13
Boxes	104.51	66.95	171.46	—
Third year.				
Cups	171.27	27.44	198.71	132.65
Boxes	39.49	26.57	66.06	—
Fourth year.				
Cups	167.33	29.23	196.56	132.56
Boxes	36.09	27.91	60.00	—

The bulletin is admirably written, and affords an excellent example of what may be done by a properly trained expert in learning the methods of an old industry practised in another country, improving and adapting them to the wants of his own locality, and, above all, in demonstrating his points so convincingly by means of experiments that the most prejudiced of his workmen becomes reconciled to the innovations.

The illustrations, of which we select one, are well chosen, sufficient, and admirably executed.

THE SOUTHPORT MEETING OF THE BRITISH ASSOCIATION.

THE Southport meeting of the British Association was concluded as we went to press last week. At the meeting of the General Committee on Wednesday, September 16, the resolutions sent forward by the Committee of Recommendations, and printed in last week's NATURE, were adopted. In addition, the two following resolutions were carried:—

(1) That the systematic investigation of the upper currents of the atmosphere by means of kites or

1 "A New Method of Turpentine Orcharding," by Dr. C. H. Hertz. U.S. Department of Agriculture, *Bull.* xl., 1903.

balloons is of great importance in meteorology, and that the Council should take such steps as they might think fit to urge upon the Treasury the importance of providing the Meteorological Council with the funds necessary for the purpose. (2) That the Sectional Committees be continued in existence until the appointment of the Sectional Committees for the succeeding year, on being summoned by the president of the committee or by the Council, and that they be authorised to bring to the notice of the Council in the interval between the annual meetings any matter which might be desired in the interest of the several sections.

At the concluding meeting, held on the same day, resolutions were proposed and unanimously carried conveying thanks to the Mayor and Corporation, Local Committee, and other bodies who had helped to make the meeting a success by their personal services and generous hospitality. Appreciation of the handsome way in which the visitors were treated was also expressed at a dinner which the Mayor of Southport, Mr. T. T. L. Scarisbrick, gave on Wednesday evening, when a distinguished company was entertained by him at Greaves Hall, Banks, to meet Sir Norman Lockyer and Prof. E. Mascart, president of the International Meteorological Committee.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY CAPTAIN ETTRICK W. CREAK, C.B., R.N., F.R.S., PRESIDENT OF THE SECTION.

OF the six distinguished naval officers who have previously presided over this Section, four were Arctic explorers; and therefore, possessing personal experience in Arctic regions, they naturally gave prominence to the deeply interesting subject of the past and future of Arctic discovery in their addresses, whilst not forgetting other matters relating to the geography of the sea. The remaining officers, from their immediate connection with all that relates to the physical condition of the ocean, in its widest sense, coupled with the great importance of giving the fruits of their knowledge to the world, took that subject as their principal theme.

Valuable as are contributions to our knowledge of the physics of the ocean to the world in general, and especially to the mariner and water-borne landsman, I propose to take a different course, and bring to your notice the subject of Terrestrial Magnetism in its relation to Geography. In doing so, I shall endeavour to show that much may be done by the traveller on land and the seaman at sea in helping to fathom the mysteries connected with the behaviour of the freely suspended magnetic needle, as it is carried about over that great magnet, the Earth, by observations in different regions, and even in limited areas.

I would, however, pause a moment to call attention to the presence of several distinguished meteorologists at this meeting, who will surely attract many to the consideration of matters connected with the important science of meteorology, which already occupies considerable attention from travellers. I feel sure, therefore, that geographers will be glad to accord a hearty welcome to the members of the International Meteorological Congress now assembled in this town, and especially to the foreign visitors who honour us by their presence.

Someone may ask, What has Terrestrial Magnetism to do with Geography? I reply, excellent lectures on that subject of growing importance have been given under the direct auspices of the Royal Geographical Society; one in 1878 by the late Captain Sir Frederick Evans, and another in 1897 by Sir Arthur Rücker. And I would here quote the opinion of Dr. Mill when defining geography, in my support: "Geography is the science which deals with the forms of the Earth's crust, and with the influence which these forms exercise on the distribution of other phenomena."

We know now that the normal distribution of the Earth's magnetism for any epoch is in many localities seriously affected accordingly as the nature of the country surveyed be mountainous, or generally a plain, in the form of islands (or mountains standing out of the sea), and from land under the sea. There is also reason to suspect that the magnetism of that portion of the earth covered by the oceans differs in intensity from that of the dry land we inhabit. A connection between the disturbances of the earth's crust in earthquakes and disturbances of the magnetic needle also seems to exist, although the evidence on this point is not conclusive.

Magnetic Surveys.

Previously to the year 1880 there were two periods of exceptional activity on the part of contributors to our knowledge of the earth's magnetism, during which the scientific sailor in his ship on the trackless ocean combined with his brethren on land in making a magnetic survey of the globe.

The first period was that of 1843–49, during which not only were fixed observatories established at Toronto, St. Helena, Capetown, and Hobart for hourly observations of the movements of the magnetic needle, but, to use Sabine's words, "that great national undertaking, the Magnetic Survey of the South Polar Regions of the Globe," the forerunner of our present Antarctic Expedition, was accomplished by Ross and his companions almost entirely at sea.

This Antarctic survey was carried out during the years 1840–45, and the results given to the world as soon as possible by Sabine. The results afterwards formed a valuable contribution when constructing his maps of equal lines of Magnetic Declination, Inclination, and Intensity for the whole world, a great work for the completion of which Sabine employed every available observation made up to the year 1870, whether on land or at sea.

Readers of these contributions cannot fail to be struck with the great number of observations made by such travellers as Hansteen and Due, Erman and Wrangel, extending from Western Europe to far into Siberia.

The second period was that of 1870–80, during which not only was there much activity amongst observers on land, but that expedition so fruitful to science, the voyage of H.M.S. *Challenger*, took place. During the years 1872–76 we find the sailor in the *Challenger* doing most valuable work in carrying out a magnetic survey of certain portions of the great oceans, valuable not only for needful uses in making charts for the seaman, but also as a contribution to magnetic science.

Prior to this expedition very little was known from observation of the distribution of Terrestrial Magnetism in the central regions of the North and South Pacific Oceans, and Sabine's charts are consequently defective there.

Combining the *Challenger* magnetical results with those of all available observations made by others of H.M. ships, and by colonial and foreign Governments, I was enabled to compile the charts of the magnetic elements for the epoch 1880, which were published in the report of the scientific results of H.M.S. *Challenger*. I will venture to say that these charts give a fairly accurate representation of the normal distribution of the earth's magnetism between parallels of 70° N. and 40° S. Beyond these limits, either northward or southward, there is a degree of uncertainty about the value of the lines of equal value, especially in the Southern regions, an uncertainty which we have reason to hope will be dissipated when we know the full results obtained by Captain Scott and the gallant band he commands, for as yet we have to be content with some eddies of the full tide of his success.

Until the *Discovery* was built, the *Challenger* was the last vessel specially selected with the view of obtaining magnetic observations at sea, so that for several years past results obtained on land have been our mainstay. Thus, elaborate magnetic surveys with fruitful results have been carried out in recent years in the British Isles by Rücker and Thorpe. France, Germany, Holland, and some smaller districts in Europe have also been carefully surveyed, and British India partially so, by Messrs. Schlagintweit in 1857–58. The latter country is being again magnetically surveyed under the auspices of the Indian Government.

On the American continent the Coast and Geodetic survey of the vast territories comprised in the United States, which has been so many years in progress, has been accompanied by an extended magnetic survey during the last fifty-two years, which is now under the able direction of Dr. L. A. Bauer. Resulting from this some excellent charts of the magnetic declination in the United States have been pub-

lished from time to time; and the last, for the epoch 1902, is based upon 8000 observations.

There are other contributions to terrestrial magnetism for positions on various coasts from the surveying service of the Royal Navy, and our ships of war are constantly assisting with their quota to the magnetic declination, or variation, as sailors prefer to call it; and wisely so, I trow, for have they not the declination of the sun and other heavenly bodies constantly in use in the computation of their ship's position?

This work of the Royal Navy and the Indian Marine is one of great importance, both in the interests of practical navigation and of science; for besides the equipment of instruments for absolute determinations of the declination, dip, and horizontal force supplied to certain of our surveying ships, every seagoing vessel in the service carries a landing compass, specially tested, by means of which the declination can be observed with considerable accuracy on land.

Although observers of many other objects may still speak of their "heritage the sea" as a mine of wealth waiting for them to explore, unfortunately for magnetic observations we can no longer say "the hollow oak our palace is," for wood has been everywhere replaced by iron or steel in our ships, to the destruction of accurate observations of dip and force on board of them. Experience, however, has shown that very useful results, as regards the declination, can be obtained every time a ship is "swung," either for that purpose alone, or in the ordinary course of ascertaining the errors of the compass due to the iron or steel of the ship.

As an example of this method, the cruise of the training squadron to Spitsbergen and Norway in 1895 may be cited, when several most useful observations were made at sea in regions but seldom visited. Again, only this year a squadron of our ships, cruising together near Madagascar, separated to a distance of a mile apart and "swung" to ascertain the declination.

I would here note that all the magnetic observations made by the officers of H.M. ships during the years 1890–1900 have been published in a convenient form by the Hydrographic Department of the Admiralty.

The fact remains, however, that a great portion of the world, other than the coasts, continues unknown to the searching action of the magnetic needle, whilst the two-thirds of the globe covered by water is still worse off. Amongst other regions I would specify Africa, which, apart from the coasts, Cape Colony, and the Nile valley to lat. 5½° N., is absolutely a new field for the observer.

Moreover, the elaborate surveys I have mentioned show how much the results depend upon the nature of the locality. I am therefore convinced that travellers on land, provided with a proper equipment of instruments for conducting a land survey of the strange countries which they may visit, and mapping the same correctly, can, with a small addition to the weight they have to carry, make a valuable contribution to our knowledge of terrestrial magnetism, commencing with observations at their principal stations and filling in the intermediate space with as many others as circumstances will permit.

The Antarctic Expedition.

Of the magnetic work of our Antarctic expedition we know that since the *Discovery* entered the pack—and, so far as terrestrial magnetism is concerned, upon the most important part of that work—every opportunity has been seized for making observations.

Lyttelton, New Zealand (where there is now a regular fixed magnetic observatory), was made the primary southern base-station of the expedition; the winter quarters of the *Discovery*, the secondary southern base-station. Before settling down in winter quarters, magnetic observations were made on board the ship during the cruise to and from the most easterly position attained off King Edward VII. Land in lat. 76° S., long. 152½° W., and she was successfully swung off Cape Crozier to ascertain the disturbing effects of the iron upon the compasses and dip and force instruments mounted in the ship's observatory.

As a ship fitted to meet the most stormy seas and to buffet with the ice, the *Discovery* has been a great success. Let me add another tribute to her value. From Spithead until she reached New Zealand but small corrections were required for reducing the observations made on board. The experience of Ross's Antarctic expedition had, however, taught the lesson that two wood-built ships, the *Erebus* and *Terror*, with but some 3° to 4° of deviation of the compass at Simon's Bay, South Africa, found as much as 56° of deviation at their position farthest south, an amount almost prohibitory of good results being obtained on board.

How fared the *Discovery*? I have been told by Lieutenant Shackleton—for the cause of whose return to England we must all feel great sympathy—that a maximum of only 11° of deviation was observed at her most southerly position. From this we may look forward hopefully to magnetic results of a value hitherto unattained in those regions.

At winter quarters, besides the monthly absolute observations of the magnetic elements, the Eschenhagen variometers or self-registering instruments for continuously recording the changes in the declination, horizontal force, and vertical force were established, and in good working order at the time appointed for commencing the year's observations.

I may here remind you that some time previously to the departure of the British and German Antarctic expeditions, a scheme of co-operation had been established between them, according to which observations of exactly the same nature, with the same form of variometers, were to be carried out at their respective winter quarters during a whole year, commencing March 1, 1902. Besides the continuous observations with the variometers, regular term-days and term-hours were agreed upon for obtaining special observations with them at the same moment of Greenwich mean time. Both expeditions have successfully completed this part of their intended work.

To co-operate in like manner with these far southern stations, the Argentine Government sent a special party of observers to Staten Island, near Cape Horn, and the Germans another to Kerguelen Land, whilst New Zealand entered heartily into the work. In addition, similar observations were arranged to be made in certain British and colonial observatories, which include Kew, Falmouth, Bombay, Mauritius, and Melbourne; also in German and other foreign observatories.

We have all read thrilling accounts of the journeys of the several travelling parties which set out from the *Discovery*, and of the imminent dangers to life they encountered and how they happily escaped them except one brave fellow named Vince, who disappeared over one of those mighty ice-cliffs, upon which all Antarctic voyagers descant, into the sea. In spite of all this there is a record of magnetic observations taken on these journeys of which only an outline has yet been given. Anticipations of the value of these observations are somewhat clouded when we read in one report that hills "more inland were composed of granite rock, split and broken, as well as weatherworn, into extraordinary shapes. The lower or more outer hills consisted of quartz, &c., with basaltic dykes cutting through them." Consequently, we have to fear the effects of local magnetic disturbances of the needle in the land observations, whilst buoyed up with the hope of obtaining normal results on board the ship.

Judging from some land observations which have been received, it appears that considerable changes have taken place in the values of the magnetic elements in the regions we are considering, but when making comparisons we have to remember the sixty years which have elapsed since Ross's time, and that he had nothing like the advantage of steam for his ships, or of instruments of precision like our present ship *Discovery*. His ships also were, as we have already remarked, much worse magnetically, causing far more serious disturbance of the instruments. Hence the changes we note may not be entirely due to changes in the earth's magnetism.

The observations made by the officers of the *Southern Cross* at Cape Adare in 1899–1900 also contribute to this question of magnetic change.

The Magnetic Poles of the Earth.

I will now refer to those two areas on the globe where the dipping needle stands vertically, known as the magnetic poles. The determination of the exact position of these areas is of great importance to magnetic science, and I will just glance at what is being done to solve the problem.

Let us consider the North Pole first, the approximate position of which we know best from observation. If one were asked to say *exactly* where that pole has been in observ-

ation times, whether it has moved, or where it now is, the answer must be "I do not know." It is true that Ross in 1831, by a single observation, considered he had fixed its position, and I believe hoisted the British flag over the spot, taking possession thereof; but he may or may not have set up his dip circle over a position affected by serious magnetic disturbance, and therefore we must still be doubtful of his complete success from a magnetic point of view. Although eminent mathematicians have calculated its position, and Neumayer in 1885 gave a place to it on his charts of that year, we have still to wait for observation to settle the question, for one epoch at least.

Happily, I am able to repeat the good news that the Norwegian, Captain Roald Amundsen, sailed in June last with the express object of making a magnetic survey of Ross's position and of the surrounding regions, in order to fix the position of the north magnetic pole. Furnished with suitable instruments of the latest pattern, he proposes to continue his investigations until 1905, when we may look for his return and the fulfilment of our hopes.

So far as we can now see, the south magnetic pole cannot be approached very nearly by the traveller, and we can only lay siege to it by observing at stations some distance off but encircling it. We have our own expedition on one side of it, and now with the return of the *Gauss* to South Africa in June last, we have learnt that that vessel wintered in lat. 66° 2′ S., long. 89° 48′ E., a position on the opposite side of the supposed site of the magnetic pole to that of the *Discovery*. We may now pause to record our warm congratulations to Dr. von Drygalski and his companions on their safe return, accompanied by the welcome report that their expedition has proved successful.

In addition to the British and German expeditions, there are the Swedish expedition and the Scottish expedition. Therefore, with so many nationalities working in widely different localities surrounding it, we have every reason to expect that the position of the south magnetic pole will be determined.

The Secular Change.

When in the year 1600 Gilbert announced to the world that the earth is a great magnet, he believed it to be a stable magnet; and it was left to Gellibrand, some thirty-four years later, by his discovery of the annual change of the magnetic declination near London, to show that this could hardly be the case. Ever since then the remarkable and unceasing changes in the magnetism of the earth have been the subject of constant observation by magneticians and of investigation by some of the ablest philosophers in Europe and America. Year after year new data are amassed as to the changes going on in the distribution of the magnetism of the earth, but as yet we have been favoured by hypotheses only as to the causes of the wondrous changes which the magnetic needle records.

These hypotheses were at one time chiefly based upon a consideration of the secular change in the declination, but it is now certain that we must take into account the whole of the phenomena connected with the movements of the needle, if we are to arrive at any satisfactory result. Besides, it will not suffice to take our data solely from existing fixed observatories, however relatively well placed and equipped, and valuable as they certainly are, for it now appears that the secular change is partly dependent upon locality, and that even at places not many miles apart differences in results unaccounted for by distance have been obtained.

The tendency of observation is increasingly to show that the secular change of the magnetic elements is not a world-wide progress of the magnetic needle moving regularly in certain directions, as if solely caused by the regular rotation during a long series of years of the magnetic poles round the geographical poles, for if you examine Map No. 1, showing the results of observations during the years 1840–80 as regards secular change, you will observe that there are local causes at work in certain regions, whilst in others there is rest, which must largely modify the effect of any polar rotation.

Allow me to explain further. The plain lines on Map No. 1 indicate approximate regions of no secular change in the declination, and the small arrows the general direction (not the amount) in which the north-seeking end of the horizontal needle was moving during those forty years. The foci of greatest change in the declination, with the approximate amount of annual change in the northern hemisphere, are shown in the German Ocean and N.W. Alaska, in the southern hemisphere off the coast of Brazil, and in the South Pacific between New Zealand and Cape Horn. The two foci of greatest annual change in the dip are shown, one in the Gulf of Guinea where the north-seeking end of the needle was being repelled strongly upwards, the other on the west side of Tierra del Fuego, where the north-seeking end of the needle was being attracted strongly downwards.

It is remarkable that the lines of no change in the declination pass through the foci of greatest change in the dip. If the needle be repelled upwards, as at the Gulf of Guinea focus, it will be found to be moving to the eastward on the east side of the whole line of no change in the declination from the Cape of Good Hope to Labrador; to the westward on the west side. If the needle be attracted downwards, as at the Tierra del Fuego focus, it will be found moving to the westward on the east side of the whole line of no declination from that focus to near Vancouver Island; to the eastward on the west side.

A similar result may be seen in the line passing through a minor focus of the dip near Hong Kong.

Judging from analogy there should be another focus of change in the dip in lat. 70° N., long. 115° E., or about the position assigned to the Siberian focus of greatest force.

On Map No. 2 are shown lines of equal value of the declination—the red lines for the year 1880, the black lines for the year 1895. From these, when shown on a large scale, we may deduce the mean annual change which has taken place in the declination during the fifteen years elapsed.

In this map we are reminded of the different results we obtain in different localities, for if a line be drawn from Wellington in New Zealand past Cape York in Australia to Hong Kong, little or no change will be found in the neighbouring region since 1840. Again, the line of no change in the declination shown on Map No. 1 to be following much the same direction as the great mountain ranges on the west side of the American continent has hardly moved for many years according to the observations available.

On the other hand, let us now turn to an example of the remarkable changes which may take place in the declination unexpectedly and locally. The island of Zanzibar and the east coast of Africa were constantly being visited by our surveying-ships and ships of war up to the year 1880, observations of the declination being made every year at Zanzibar during the epoch 1870–80. The results showed that from Capetown nearly to Cape Guardafui the annual change of that element hardly exceeded 1′.

During the succeeding years of 1890–91 observations were made by the Germans at Dar-es-Salaam and some other places on the neighbouring coasts, with the result that the declination was found to be changing at first 3′ annually, and since that period it had reached 10′ to 12′ at Dar-es-Salaam. Subsequent observations at the latter place in 1896–98 confirmed the fact of the great change, and in addition our surveying-ship on the station, specially ordered to "swing" at different places in deep water off the coast, generally confirmed the results. It is remarkable that whilst such great changes should have taken place between Capetown and Cape Guardafui, Aden and the region about the straits of Bab-el-Mandeb seem to be comparatively unaffected.

Local Magnetic Disturbance.

In Map No. 2 normal lines of equal value of the declination are recorded, and so far as the greater part of the globe covered by water is concerned, we may accept them as undisturbed values, for we have yet to learn that there are any local magnetic disturbances of the needle in depths beyond 100 fathoms.

When, however, we come to the land, there is an increasing difficulty in finding districts of only a few miles in extent where the observed values of the magnetic elements at different stations therein do not differ more widely than they should if we considered only their relative position on the earth as a magnet. Take Rücker and Thorpe's maps of the British Isles and those of the United States, for example, where the lines of equal value are drawn in accordance with the observations, with the result that they form extraordinary loops and curves differing largely from the normal curves of calculation.

From among numerous examples of disturbance of the declination on land, two may be quoted. In the Rapakivi district, near Wiborg, a Russian surveying officer in the year 1890 observed a disturbance of 180°, or, in other words, the north point of his compass pointed due south. At Invercargill, in New Zealand, within a circle of 30 feet radius, a difference of 56° was found. Even on board ships in the same harbour different results are sometimes observed, as our training squadron found at Reikiavik in Iceland, and notably in our ships at Bermuda.

It is hardly necessary to add that the dip and force are often largely subject to like disturbance, but I do so in order to warn travellers and surveyors that observations in one position often convey but a partial truth; they should be supplemented by as many more as possible in the neighbourhood or district. Erroneous values of the secular change have also been published from the various observers not having occupied exactly the same spot, and even varied heights of the instrument from the ground may make a serious difference, as at Rapakivi before mentioned, and at Madeira, where the officers of the *Challenger* expedition found the dip at a foot above the ground to be 48° 46′ N.; at 3½ feet above the ground 56° 18′ N. at the same spot.

All mountainous districts are specially open to suspicion of magnetic disturbance, and we know from comparison with normal observations at sea that those mountains standing out of the deep sea, which we call islands, are considerably so affected.

Magnetic Shoals.

The idea that the compasses of ships could be affected by the attraction of the neighbouring dry land, causing those ships to be unsuspectingly diverted from their correct course, was long a favourite theory of those who discussed the causes of shipwreck, but it was "a fond thing vainly invented." I can hardly say this idea is yet exploded, but from what has already been said about local magnetic disturbance on land, it is not a matter of surprise that similar sources of disturbance should exist in the land *under* the sea, for it has been found that in certain localities, in depths of water sufficient to float the largest ironclad, considerable disturbances are caused in the compasses of ships.

An area of remarkable disturbance having been reported as existing off Cossack, N.W. Australia, H.M.S. *Penguin*, a surveying-ship provided with the necessary magnetic instruments, was sent by the Admiralty in 1891 to make a complete magnetic survey of the locality, with a view to ascertain the facts and place them on a scientific basis. An area of disturbance 3·5 miles long by 2 miles broad, with not less than 8 fathoms of water over it, was found lying in a N.E. by E. and S.W. by W. direction. At one position the disturbing force was sufficient to deflect the *Penguin's* compass 56°; in another—the focus of principal disturbance—the dip on board was increased by 29°, and this at a distance of more than 2 miles from the nearest visible land, upon which only a small disturbance of the dip was found.

This remarkable area of disturbance was then called a "Magnetic Shoal," a term which at first sight hardly appears to be applicable. We have, however, become familiar with the terms "ridge line, valley line, peak, and col," as applied to areas of magnetic disturbance on land; therefore I think we may conveniently designate areas of magnetic disturbance in land under the sea "Magnetic Shoals."

This year H.M. surveying-ship *Research* has examined and placed a magnetic shoal in East Loch Roag (Island of Lewis), but as all our surveying-ships are practically iron ships, it was impossible from observations on board to obtain the exact values of the disturbing forces prevailing in this shoal. The reason for this is that, although we may accurately measure the disturbing forces of the iron of the ship in deep water, directly she is placed over the shoal induction takes place, and we can no longer determine to what extent the observed disturbances are due to the ship's newly developed magnetism, or to what extent the shoal alone produces them.

We can, nevertheless, even in an iron ship, accurately *place* and show the dimensions of a magnetic shoal and the *direction* in which a ship's compass will be deflected in any part of it by compass observations only. Is it not, therefore, the duty of any ship meeting with such shoals to stop and fix their position?

The general law governing the distribution of magnetism on these magnetic shoals is that in the northern hemisphere the north point of the compass is drawn *towards* the focus of greatest dip; in the southern hemisphere it is *repelled*. The results at East Loch Roag proved an exception, the north point of the compass being *repelled*.

Terrestrial Magnetism and Geology.

I have already referred to the question of local magnetic disturbance as one of great importance in magnetic surveys. The causes of these disturbances were at one time a matter of opinion, but the evidence of the elaborate magnetic surveys I have alluded to, when compared with the geological maps of the same countries, points clearly to magnetic rocks as their chief origin.

Magnetic rocks may be present, but from their peculiar position fail to disturb the needle; but, on the other hand, as Rücker writes in his summary of the results of the great magnetic survey of the British Isles conducted by Thorpe and himself, "the magnet would be capable of detecting large masses of magnetic rock at a depth of several miles," a distance not yet attained by the science of the geologist.

Again, Dr. Rijckevorsel, in his survey of Holland for the epoch 1891, was convinced that "in some cases, in many perhaps, there must be a direct relation between geology and terrestrial magnetism, and that many of the magnetic features must be in some way determined by the geological structure of the under-ground."

During the years 1897–99 a magnetic survey was made of the Kaiser-stuhl, a mountainous district in the neighbourhood of Freiburg, in Baden, by Dr. G. Meyer. Exact topographical and geological surveys had been previously made, and the object of the magnetic survey was to show how far the magnetic disturbances of the needle were connected with geological conformations. Here, again, it was found that the magnetic and geological features of the district showed considerable agreement, basaltic rocks being the origin of the disturbance. This was not all, for in the level country adjacent to the Rhine and near Breisach unsuspected masses of basalt were found by the agency of the magnetic needle.

More recently we find our naval officers in H.M.S. *Penguin*, with a complete outfit of magnetic instruments, making a magnetic survey of Funafuti atoll and assisting the geologist by pointing out, by means of the observed disturbance of the needle, the probable positions in the lagoon in which rock would be most accessible to their boring apparatus.

Leaving the geologist and the magnetician to work in harmony for their common weal, let us turn to some other aspects of the good work already accomplished and to be accomplished by magnetic observers.

Magnetic Charts.

Of the valuable work of the several fixed magnetic observatories of the world, I may remark that they are constantly recording the never-ceasing movements of the needle, the key to many mysteries to science existing in the world and external to it, but of which we have not yet learnt the use. Unfortunately many of these once fixed observatories have become travellers to positions where the earth can carry on its work on the needle undisturbed by electric trams and railways which have sprung up near them, and it is to be hoped they will find rest there for many years to come.

Of the forty-two observatories which publish the values of the magnetic elements obtained there, thirty-two are situated northward of the parallel of 30° N., and only four in south latitude; and it is a grief to magneticians that so important a position as Capetown or its neighbourhood does not make an additional fixed magnetic observatory of the first order.

Thus, so far as our present question of magnetic charts and their compilation is concerned, the observatories do not contribute largely, but we should be very grateful to them for the accurate observations of the secular change they provide which are so difficult to obtain elsewhere.

Of the value of magnetic charts for different epochs I have much to say, as they are required for purely scientific inquiry as well as for practical uses. It is only by their means that we can really compare the enormous changes which take place in the magnetism of the globe as a whole; they are useful to the miner, but considerably more so to the seaman.

Had it not been for the charts compiled from the results of the untiring labours of travellers by land and observers at sea in the field of terrestrial magnetism during the last century, not only would science have been miserably poorer, but it is not too much to say that the modern iron or steel steamship traversing the ocean on the darkest night at great speed would have been almost an impossibility, whereas with their aid the modern navigators can drive their ships at a speed of 26·5 statute miles an hour with comparative confidence, even when neither sun, moon, nor stars are appearing.

Of the large number of travellers by sea, including those who embark with the purpose of increasing our geographical knowledge of distant lands and busying themselves with most useful inquiries into the geology, botany, zoology, and meteorology of the regions they visit, few realise that when they set foot on board ship (for all ships are now constructed of iron or steel) they are living inside a magnet. Truly a magnet, having become one by the inductive action of that great parent magnet—the Earth.

How fares the compass on board those magnets, the ships, that instrument so indispensable to navigation, which Victor Hugo has forcibly called "the soul of the ship," and of which it has been written,

> "A rusted nail, placed near the faithful compass,
> Will sway it from the truth, and wreck an argosy"?

And if so small a thing as an iron nail be a danger, what are we to say to the iron ship? Let us for a moment consider this important matter.

If the nature of the whole of the iron or steel used in construction of ships were such as to become permanently magnetic, their navigation would be much simplified, as our knowledge of terrestrial magnetism would enable us to provide correctors for any disturbing effects of such iron on the compass, which would then point correctly. But ships, taken as a whole, are generally more or less unstable magnets, and constantly subject to change, not only on change of geographical position, but also of direction of the ship's head with regard to the magnetic meridian. Thus a ship steering on an easterly course may be temporarily magnetised to a certain extent, but on reversing the ship's course to west she would after a time become temporarily magnetised to the same amount, but in the opposite direction, the north point of the compass being attracted in each case to that side of the ship which is southernmost.

Shortly, we may define the action of the earth's magnetism on the iron of a ship as follows: The earth being surrounded by a magnetic field of force differing greatly in intensity and direction in the regions from the North Pole to the Equator and the Equator to the South Pole, the ship's magnetic condition is largely dependent upon the direction of her head whilst building and the part of that field she occupied at the time; partly upon her position in the magnetic field she traverses at any given time during a voyage.

For the reasons I have given, magnetic charts are a necessity for practical purposes and in the following order of value. That of the magnetic declination or variation which is constantly in use, especially in such parts of the world as the St. Lawrence and the approaches to the English Channel, where the declination changes very rapidly as the ship proceeds on her course. Next, that of the dip and force, which are not only immediately useful when correcting the ship's compass, but are required in the analysis of a ship's magnetism both as regards present knowledge and future improvements in placing compasses on board.

If astronomers have for a very long time been able to publish for several years in advance exact data concerning the heavenly bodies, is it too much to hope that magneticians will before long also be able to publish correct magnetic charts to cover several years in advance of any present epoch? If this is to be done within reasonable time there must be a long pull, a strong pull, and a pull all together of magnetic observers in all lands, and accumulated data must also be discussed.

On Magnetic Instruments for Travellers.

Travellers in unsurveyed countries, if properly instructed and equipped, can do good service to science by observing the three magnetic elements of declination, inclination or dip, and force at as many stations as circumstances will permit; hence the following remarks.

For the purpose of making the most exact magnetic survey the best equipment of instruments consists of the well-known unifilar magnetometer, with fittings for observing the declination, and a Barrow's dip circle. To some travellers these instruments might be found too bulky, and in some regions too delicate as well as heavy to carry.

Of suitable instruments made abroad, those used by M. Moureaux in his survey of France may be mentioned, as they are of similar type, but much smaller and lighter than the instruments above mentioned.

Another form of instrument, called an L.C. instrument, for observing both the inclination and total force, is shown in the instrument before you. Originally designed for observations on board ships at sea where the ordinary magnetic instruments are unmanageable, it has also been found to give satisfactory results in a land survey, where greater accuracy is expected than at sea. Thus, during a series of observations extending from the north side of Lake Superior to the southern part of Texas last year, comparisons were made between the results obtained with an L.C. instrument and those of the regular unifilar magnetometer and dip circle, when the agreement was found satisfactory.

I am therefore of the opinion that a traveller furnished with a theodolite for land-surveying purposes, but fitted with a reversible magnetic needle, can at any time he observes a true bearing obtain a trustworthy value of the declination. Dismounting the theodolite from his tripod, the latter will serve for mounting an L.C. instrument with which to observe the inclination and force. Thus, by adding to his ordinary equipment an instrument weighing in its box about 21 lb., he can obtain valuable contributions to terrestrial magnetism, and at the same time give useful assistance to geological investigations.

Concluding Remarks.

Although a great subject like terrestrial magnetism, even to exhibit our present knowledge of the science, cannot be brought within the compass of an address—for it requires a treatise of many pages—I have brought some of the broad features of it before the Section in order to show its connection with Geography.

I also entertain the hope that geographers will become more interested in a subject so important to pure science and in its practical applications, and that it will become an additional subject to the instruction which travellers can now obtain under the auspices of the Royal Geographical Society in geology, botany, zoology, meteorology, and surveying.

There is a wide field open to observers, and where results often depend so much upon locality we require to explore more and more with the magnetic needle. To look over the great oceans and think how little is being done for terrestrial magnetism is a great matter for regret. Yet even there we may begin to be hopeful, for the United States Coast and Geodetic Survey authorities are making arrangements to fit out its vessels with the necessary instruments for determining the magnetic elements at sea.

We wish them all success; but I must again remind you that although we cannot compel observers to start, there is room for them and to spare.

I would fain make some remarks on the prevailing ignorance of sound geography in many quarters, and on the defective methods of teaching the science; but I feel that the subject is placed in very able hands, and will be fully discussed elsewhere during the present meeting.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY MR. CHARLES HAWKSLEY, PAST PRESIDENT INST.C.E., PRESIDENT OF THE SECTION.

SINCE the last meeting of the British Association there has passed from our midst, to the deep regret of all who had the privilege of knowing him, one who, though full of years, actively followed his profession as a Civil Engineer until within a few days of his death. I refer to Mr. Edward Woods, who presided over Section G of the British Association at Plymouth in 1877. Mr. Woods commenced his professional career on the Liverpool and Manchester Railway soon after it was opened for traffic. In 1875 Mr. Woods was invited by the Royal Commission on Railway Accidents to undertake, in conjunction with Colonel Inglis,

R.E., an exhaustive series of trials of the different kinds of railway brakes then in use in England, the results of which were recorded in an elaborate and valuable report. These trials were referred to by Mr. Woods in his address as President of Section G. Mr. Woods was President of the Institution of Civil Engineers in 1886–1887, and he died on June 14, 1903, at the ripe age of eighty-nine.

TECHNICAL EDUCATION.

The subject of the technical education of engineers was treated very fully in the interesting address delivered by Prof. Perry, as President of Section G at the meeting of the British Association in Belfast last year. This question also received thorough consideration at the meeting of the Engineering Conference held in London in June last, as well as at recent meetings of the Institution of Mechanical Engineers and of the Institute of Naval Architects. The systems in vogue in the United States of America and on the Continent of Europe were on those occasions brought forward in carefully prepared papers and fully discussed. The main points at issue are: (1) whether actual handicraft should be taught in the Technological School or College along with the principles underlying the Engineers' art; (2) whether the year should be divided into periods in one or more of which the science of engineering should be taught, and in another or others of which craft skill should be acquired at works; (3) whether the principles should be first acquired, during a longer or shorter term, leaving experience in applying those principles to be gained at the termination of the course. As regards the first of these suggestions it appears to be in opposition to the judgment of the most experienced teachers. In respect to the second, the Admiralty have carried it out for the last forty years, and with satisfaction to the Service; it is also common in Glasgow, and Mr. Yarrow has included this system in the apprenticeship rules he has recently laid down, whilst it is to be tried experimentally in the Engineering Course at King's College, London. At the Engineering Conference it was determined that the subject was of such importance that its further consideration should be left to a Committee, to be subsequently appointed.

Since the British Association last met in Lancashire (in 1896) there have been important events and changes in the chief technical institutions of the county. First, there were last year the Jubilee celebrations of Owens College, Manchester, when it received congratulations on its half-century of work from universities and learned societies in all parts of the world. Here, as I need hardly remind you, the engineering laboratory is under the able direction of Prof. Osborne Reynolds, F.R.S., who presided over Section G of the British Association at their Meeting in Manchester in 1887. Then, also in Manchester, there is the recently completed and admirable Municipal School of Technology; but as a paper will be read on this subject, and members will have an opportunity of visiting the school and inspecting its engineering laboratory, I will content myself with wishing it every success in the manifold fields of industrial education in which it is engaged. Again, only this year Victoria University has lost a College, and Liverpool has gained a University. At University College, Liverpool, in the Session of 1884–5, a Professorship of Engineering was instituted as a provisional measure. The erection of engineering laboratories and the endowment of the Chair were afterwards provided for by gifts in commemoration of the Jubilee year of the reign of Her late Majesty, Queen Victoria. Prof. H. E. Hele-Shaw, F.R.S., was appointed to the Chair in the first instance, a position which he still continues to hold.

This year a Royal Charter has been granted establishing the University of Liverpool, and transferring to it the powers of University College, Liverpool. I think one cannot offer to the University of Liverpool a heartier wish than that it may be as successful in the future as University College, Liverpool, has been in the past, a wish in which I am sure you will all join.

There is yet one other college to which, though not in Lancashire, I should like to make a passing reference, the first to include engineering in its educational curriculum, viz. University College, London. It was originally founded in 1828 under the name of the "University of London," and has recently, together with King's College, become merged in the present University of London. The first engineering laboratory was established at University College in 1878, fifty years after the inauguration of the college, whilst a separate chair for electrical engineering was founded in 1885, and an electrical laboratory was added ten years ago. One cannot say farewell to it as it used to be without mentioning the name of Dr. A. B. W. Kennedy, F.R.S., who was President of this Section of the British Association in 1894 at Oxford, and who has done so much for engineering education.

Before leaving the subject of technical education, I venture to express the hope that in the training of engineering students increased attention will be paid to the combination of artistic merit with excellence of structural design, so that in respect to artistic treatment our engineering structures may not remain so far behind those of our Continental brethren as is unfortunately now frequently the case.

ENGINEERING STANDARDS.

A very important work has been going on quietly and unostentatiously in our midst for some time past, the results of which must affect the engineering profession at home and abroad. I refer to the work of the Engineering Standards Committee, which as many of my hearers know, was appointed in 1901 and is now composed of 178 members, among whom are many Government officials. I alluded to the earlier work of this Committee in my Presidential Address to the Institution of Civil Engineers in 1901, and that work has since been gradually but surely extended. The Committee has received not only the moral but the financial support of His Majesty's Government, and the results of its labours are being adopted by all the leading Government departments.

In addition to the main Committee there are no fewer than twenty-five separate committees and sub-committees engaged on work, covering a wide range of operations, many of the members sitting on more than one committee.

A few details of the work accomplished and in progress may be of interest. After careful deliberation the Committee published their first series of British standards sections, covering all rolled steel sections used in constructional work, shipbuilding and so forth. The Committee on Rails has just issued the standard sections and specification for British girder tramway rails, and it is now actively engaged in drawing up a series of standard sections of bull-headed and flat-bottomed rails for railway work.

Another committee of a thoroughly representative character is occupied in drawing up a standard specification and standard tests for cement, and a standard specification drawn up by so large a body of our leading engineers, contractors, and manufacturers must be of great interest to all those who are called on to specify tests for this material.

The Government of India control to a very considerable extent the working of railways in India, and they have referred to the Standards Committee the important question of drawing up a series of standard types of locomotives for use on the Indian railways. The Committee which investigated this difficult subject has just forwarded its report to the Secretary of State for India. Other committees are preparing standard specifications for locomotive copper fire-box plates and steel boiler plates, which it is hoped will be published at an early date.

The subject of screw-threads is one which has occupied a Committee of the British Association for some years past, and I am glad to learn that the Committee of this Association has been co-operating with the Standards Committee and discussing the question of screw-threads of both smaller and larger diameters, and also considering the cognate subject of limit gauges so essential to all accurate work in mechanical engineering.

Another Committee is dealing with standard flanges, and I understand it is shortly proposed to consider the standardisation of cast-iron pipes.

A very large and influential committee is engaged on the subject of the materials used in the construction of ships and their machinery, and most valuable information is being collected with a view to the preparation of a standard specification for steel and to the determination of forms for standard test-pieces to be used when testing plates, forgings, castings, and so forth.

There are about half a dozen committees engaged on various important electrical subjects, but as their work will

no doubt be referred to in another Section of this Association, I do not propose to make further reference to it here.

In my Presidential Address before the Institution of Civil Engineers in 1901, I raised a note of warning in regard to the stereotyping of design and the consequent cramping of originality. The constitution of the Standards Committee and the professional standing of its members afford a guarantee that its work will accord with the best practice of this country, since those engaged in drawing up the standards are not only in the forefront of engineering practice, but are alive to the necessity for extending the number of standards if and when needed to meet the requirements of the engineer.

National Physical Laboratory.

An outline scheme for a National Physical Laboratory was set forth in 1891, by Sir (then Dr.) Oliver Lodge, F.R.S., in his Address at Cardiff to Section A of the British Association. In his Presidential Address to this Association in 1895 at Ipswich, the late Sir Douglas Galton, F.R.S., emphasised the importance of such an Institution, a Committee of this Association reported in favour of it, and later, when after forwarding a petition to the late Lord Salisbury, a Treasury Committee with Lord Rayleigh, F.R.S., in the Chair was formed, Sir Douglas Galton gave evidence to the effect that if Great Britain was to retain its industrial supremacy, we must have accurate standards available to our research students and to our manufacturers.

In 1901, the National Physical Laboratory was inaugurated at Bushy House, near Teddington, and an annual grant of 4000*l.* towards its support was made by Government. It is divided into three departments, of which the one dealing with all branches of Civil, Mechanical, and Electrical Engineering is chiefly interesting to us in Section G In this department tests are now undertaken of the strength of materials of construction, of pressure and vacuum gauges, of indicators and indicator springs, and of length gauges and screw gauges, and photomicroscopic investigation is made of metals and alloys, and especially of steel rails.

But beside the ordinary work of testing, various investigations are in progress, such as measurement of wind pressure, elastic fatigue in nickel steel and other materials used by engineers, and the magnetic and mechanical properties of aluminium-iron and other alloys. For the British Association a set of platinum thermometers has been constructed and subjected to stringent tests, and an investigation has been undertaken for the Engineering Standards Committee into the changes in insulating strength of various dielectrics used in motors, transformers, &c., due to continued heating. In the language of Dr. Glazebrook, F.R.S., the Director, who it may be mentioned was previously Principal of University College, Liverpool, science is not yet regarded as a commercial factor in this country, but it is one of the aims of the National Physical Laboratory to bring about the alliance of science with commerce and industry. The expenditure of the National Physical Laboratory is met by an annual Treasury grant of 4000*l.*; 500*l.* a year from an endowment; fees for tests, now amounting to about 3500*l.* annually; and from donations and subscriptions.

The Director is anxious that the revenue derived from fees for testing should be largely augmented, and I would urge on engineers, contractors and manufacturers, as well as on private individuals, that they should avail themselves of the opportunity to have tests and experiments of interest to them, and which will be generally accepted as unimpeachable, conducted at this laboratory. I may add that an appeal has been made for further donations and annual contributions, as the funds now at the disposal of the Board of Management are insufficient to carry on the work of the laboratory on a sound financial basis, and I venture to hope that many of those who are interested in the practical applications of science will assist in supporting the work of this national institution.

Intercommunication.

General Progress.

At the commencement of the nineteenth century, Southport, which now has its parks, a promenade, and a pier more than three-quarters of a mile in length, its halls, free library, art gallery and science and art schools, and railway connection with all parts of the kingdom, was not even to be found on the maps, the first house having been erected in the year 1792. In 1851 the population of Southport and the adjoining place Birkdale was 5390, whereas at the census of 1901, Southport had a population of 48,083 and Birkdale 14,197, together 62,280. Here is evidence of great local enterprise, resulting in a development of which its people may be justly proud.

At the commencement of the nineteenth century the population of the United Kingdom was nearly 15¾ millions, at the beginning of the twentieth nearly 41½ millions. Then there was not a mile of railway in the United Kingdom: now there are about 22,000 miles. Here, too, is evidence not only of the prosperity which has prevailed throughout Great Britain during the century that has passed, but also of the enormously increased demands which have arisen during the same period on the means of locomotion.

It was towards the latter half of the eighteenth century that the formation of good roads was commenced in Lancashire and the adjoining counties by John Metcalf, the blind road-maker, and that Palmer in 1784 introduced mail coaches travelling at from six to seven miles an hour on the main roads. In 1801 the mail coach from London to Holyhead occupied nearly forty-six hours on the journey, and the mails reached Dublin on the third day after leaving London. Now the journey from London to Holyhead is performed in 5¾ hours, and Dublin is reached in 9¼ hours after leaving London.

In 1803, just one hundred years ago, Telford reported to the Government on the state of the roads, and as a result the great road to Liverpool from the Metropolis and the other great highways were constructed. It was enlightened wisdom that eighty years ago placed intercommunication in the forefront of the definition of engineering; it still maintains that position, and I purpose to say a few words on the present aspect of the question.

Road Traffic—Motors.

Speed in locomotion appears to be now the first consideration, whether as regards mails, passengers, or goods. I would refer in the first instance to locomotion on our main roads. Here three or four classes of machines appear to be ambitious to drive pedestrians, horsemen, and horse-drawn vehicles off the road.

The first practical steam carriage was used by Trevithick in the year 1802; and now, a hundred years later, it is found that for the traction of heavy loads on the main roads steam is still most suitable. The points of importance in connection with traction engines and their trailers are their speed, weight, and width; of course, there is no question that, as regards facilitating traffic, the large heavy waggon replacing many smaller horse-drawn ones will be found a boon. Mr. E. R. Calthrop, M.Inst.C.E., one of the founders of the Liverpool Self-propelled Traffic Association, is opposed to any weight restriction, but it must be remembered that the momentum of heavily laden waggons drawn by a powerful traction engine at the maximum speed of five miles an hour is very great, and causes uncomfortable vibration in the houses along the main thoroughfares of our towns; on the other hand, light traction engines are now being successfully used, drawing from four to five tons of market produce through the streets of London without causing undue vibration, and at a cost, I am informed, of about one-half that of horse traction.

But a far more burning question is that of the speed of motor cars along our public thoroughfares. The struggle to maintain a trophy at home, or to regain it from abroad, is one in which every inhabitant of this country sympathises. The great Gordon-Bennett Cup Race in July last redounded to the credit of the Automobile Club of Great Britain and Ireland, who made and carried out the arrangements and were at considerable pains to find a suitable course in a sparsely inhabited district; every measure which experience has shown to be needful having been taken to prevent accident. The race was decidedly international in character, French, Germans, Americans, and English contesting for the prize; and in heartily congratulating the German Automobile Club on their success, it may be noted that M.

Jenatzy covered a distance of 327½ miles in 6 hours 39 minutes, or at the rate of 49½ miles an hour, though he attained to a speed of 61 miles an hour between the points of control. Even this speed was exceeded at a trial in Phœnix Park, Dublin, when Baron de Forest attained to a rate of 86 miles an hour. But between racing speed and ordinary travelling speed there is necessarily a great difference, and our twenty miles maximum on country roads is in excess of that allowed in France, where it is now fixed, though I believe not enforced in the open country, at 18½ miles, and at 12½ miles where there is much traffic. The two classes of motors used for higher speeds are the petrol and the electric. The former are mainly internal-combustion engines; having to be light, they run at the comparatively high speed of 800 revolutions per minute. They are generally used in connection with bicycles, tricycles, or light carriages. They have also been used for light vans and coaches, and successful trials have been made with self-propelled lorries for military purposes, and by local authorities for watering and dust collecting. Their application to omnibuses has not proved economical, owing to the difficulty of providing pneumatic tyres for such heavy vehicles.

The electric motor depends on storage batteries; those in general use are of Planté's lead-couple type. Like the petrol motor, the electric motor is rather a luxury; most of the automobile carriages used in London are of this class; there is liability of injury to the batteries by over-discharging them. Colonel Crompton, in a paper recently read at the Engineering Conference, suggested the use of "standardised accumulators," to be supplied to the owners of electrical vehicles at depôts on production of a subscription ticket, and the Engineering Standards Committee has appointed a sub-committee to consider the question. Motor cars are now used by some of the railway companies as feeders to their lines, and also in competition with tramway lines.

The increasing use of motor cars renders more than ever necessary the regulation of traffic in crowded thoroughfares, a subject which will doubtless be dealt with in the paper on "The Problem of Modern Street Traffic," which Colonel Crompton is about to read before this Section of the British Association.

The use of motor-driven vehicles for road traffic is so intimately associated with improvements in prime movers that it will interest the members of this Section to be reminded of the opinion expressed more than twenty years ago by Sir Frederick Bramwell, F.R.S., Past President Inst.C.E., who presided over the Meeting of the British Association at Bath in 1888. In a paper read before this Section at the Jubilee Meeting of our Association at York in 1881, and afterwards printed *in extenso*, Sir Frederick Bramwell said: "However much the Mechanical Section of the British Association may to-day contemplate with regret even the mere distant prospect of the steam-engine becoming a thing of the past, I very much doubt whether those who meet here fifty years hence will then speak of that motor except in the character of a curiosity to be found in a museum." In a letter addressed to the President of this Association on July 2 last, Sir Frederick Bramwell directed attention to the largely increasing development of internal-combustion engines, and expressed a feeling of assurance that, although steam-engines might be at work in 1931, the output in that year would be small of steam as compared with internal-combustion engines.

To keep alive the interest of the Association in this subject, Sir Frederick Bramwell has kindly offered, and the Council has accepted, the sum of 50*l*. for investment in 2½ per cent. self-accumulative Consols, the resulting sum to be paid as an honorarium to a gentleman to be selected by the Council to prepare a paper having Sir Frederick's utterances in 1881 as a sort of text, and dealing with the whole question of the prime movers of 1931, and especially with the then relation between steam-engines and internal-combustion engines. That paper will doubtless prove to be a very valuable contribution to the proceedings of this Association, and one can only regret that many of those assembled here to-day cannot hope to be present when it is read, and to listen to an account of the nearest approach which has then been made towards the production of a perfect prime mover.

Electric Tramways and Light Railways.

I now pass to the application of electricity to tramways, and in doing so may quote from the careful expression of opinion given in this town from this Chair twenty years ago by the late Sir (then Mr.) James Brunlees, President of the Institution of Civil Engineers: "The working of railways by electricity has not advanced further than to justify merely a brief reference to it in this paper as among the possibilities, perhaps the probabilities, of the not distant future."

It was stated in a paper read by Mr. P. Dawson in April last before the Tramways and Light Railways Association, that the total route-length of electric tramways and light railways in the United Kingdom, either completed, under construction, or authorised, amounted at the end of last year to 3000 miles, the length of single track being 5000 miles, on which some 6000 cars were running.

It cannot, in my opinion, be regarded as being fair to the railway companies—which have to pay large sums of money for the land on which their lines have been constructed—to have to compete with tramways which are laid along the public roads without any payment being made for their use. The roads are disfigured by aërial conductors and the supporting posts by which the electric current is conveyed to the cars, except in those comparatively rare instances in which the conduit system is used; nor can it be denied that tramways greatly interfere with the use of the roads for ordinary traffic. The effect of electrolytic action on iron pipes laid beneath the roads is still undergoing investigation.

Railways.

Turning now to railways, it may be noted that on some of the principal lines in Great Britain the length of the runs without a stop is being increased in the case of fast trains, the speed of which is in some cases from forty-eight to fifty-nine miles an hour.

Railway companies are turning their attention to the introduction of electric traction wherever it can be beneficially used, as for instance on the Mersey Railway, the North-Eastern Railway between Newcastle-upon-Tyne and Tynemouth, and the Lancashire and Yorkshire Railway between Liverpool and Southport. With the object of facilitating the introduction and use of electrical power on railways, Parliament has passed an Act entitled the "Railways (Electrical Power) Act, 1903," which will come into operation on January 1 next.

The electrical service on the Mersey Railway has now been in regular and uninterrupted operation since the beginning of May in the present year. Trains are run at three-minute intervals, there being 750 trains in all between 5 a.m. and 12 midnight; and as it is the first example of a British steam railway converted to the use of electric traction, a short description of it cannot fail to be of interest.

The Mersey Railway was first opened for traffic on February 1, 1886, and was afterwards extended at both ends, the last extension to the Liverpool Central Station being opened for traffic in January, 1892. With steam locomotives, largely owing to the want of adequate ventilation, the railway was not a success. Electrification was decided upon, and in the latter part of 1901 the British Westinghouse Electric and Manufacturing Company, Limited, undertook the entire contract. The length of the railway is about 3¾ miles, and there are gradients in the tunnel below the river of 1 in 27 and 1 in 30.

The power station is at Birkenhead, and contains plant aggregating more than 6000 horse-power, comprising three engines of the Westinghouse-Corliss vertical cross-compound type.

The generators are all three alike, mounted on the engine shaft between the cylinders. They are standard Westinghouse multipolar machines, of the double-current type, of 1250 kilowatts capacity. Direct-current is collected from the armature at 650 volts, no alternating current being used at present.

Leads are carried below the floor from the machines to a switchboard, from which are controlled the main generators, the auxiliary lighting sets, battery, booster, and feeders. The battery consists of 320 chloride cells connected in parallel with the generators through a differential booster, and charge or discharge according as the line

load is light or heavy. They have a capacity of 1000 ampere-hours, and a momentary discharge capacity of 2000 amperes.

The auxiliary sets, two in number, are for lighting purposes, and yielding direct current at 650 volts, are available in case of need to supply current to the main traction circuits. 210 volt incandescent lamps are used for lighting, arranged in groups of three in series.

The feeders are carried from the switchboard down the ventilation shaft to feed the insulated electrical collector rails, which are placed in the space between the up and the down lines, and somewhat above the level of the rails, an insulated return collector rail being placed between each pair of rails. A train consists of two motor cars, one at each end, and from one to three trailers as required, depending on the amount of traffic. The motor cars each carry an equipment of four Westinghouse motors of 100 horse-power, making 400 horse-power per car, or 800 horse-power per train. These motors are all controlled in unison from the motorman's compartment at either end of the train by means of the Westinghouse multiple controlled system, which has worked from the start without a hitch.

In conclusion, it may be noted that every precaution has been taken against fire. The electrical equipment is all thoroughly fireproof, and the motorman's compartment is encased in asbestos slate, cutting it off completely from the remainder of the train.

Of tube railways with electric traction there are three now working in London, two between the City and the south side of the River Thames, using the ordinary two wire 500 volts continuous current system, and another (the Central London) extending from the City to Shepherd's Bush, using the composite system. This railway conveyed during the year 1902 no fewer than 45 million passengers. There are eight other tube railways now in course of construction in London. The recent terrible catastrophe in Paris must serve as a warning in the future equipment of such lines where currents at high tension are employed, and where short-circuiting may bring about disastrous results.

A paper will be read before this Section by Mr. F. B. Behr on the authorised Manchester and Liverpool Express Railway, which is intended to be constructed on the Mono-rail system, and to be worked electrically.

Canals.

Concurrently with the construction of roads in this country was the formation of canals, as a means of inland communication, mainly for the carriage of minerals and merchandise, though they also conveyed passengers by express boats. The only recent structure of this character in the United Kingdom is the famous Manchester Ship Canal, with which the name of Sir E. Leader Williams, M.Inst.C.E., is associated. This, however, is hardly a canal in the sense in which that word was employed by Brindley, "the father of inland canal navigation in England," as the largest amount by far, in the proportion of 10 to 1, is its seaborne as compared with its local traffic. It is interesting to notice that a very important wheat trade is being carried on with India, exported both from Bombay and Kurrachee. The seaborne traffic and the barge traffic for 1894 was 686,158 tons and 239,501 tons respectively, and has during eight years increased, until in 1902 it had reached 3,137,348 tons and 280,711 tons respectively. The most interesting recent development of the works is the new Dock now in course of construction, with its five sets of transit sheds, which are being built on the Ferro-Concrete system.

Ships.

The intercommunication of the nations of the world is largely dependent on the navigation of the ocean. The first vessel to cross the Atlantic fitted with steam power was the *Savannah*, of about 300 tons, which arrived at Liverpool from Savannah, in Georgia, in thirty days, partly under steam and partly under sail. Ocean steam traffic has been extending ever since. Two years ago I had occasion, in connection with my Presidential Address to the Institution of Civil Engineers, to collect some statistics with regard to shipping, and found that according to Lloyd's Register the largest British vessels then afloat were the twin-screw steamers *Oceanic*, of 17,274 tons, and the *Celtic*, of 20,904 tons, both gross register, built for the White Star line, and regularly making the passage between Liverpool and New York in seven days and eight days respectively; and the *Celtic* is still the largest mercantile steamship afloat, the tonnage of the new German steamer, *Kaiser Wilhelm II.*, being 19,360 tons gross register.

Unfortunately these fine ships, with many others, are now no longer owned in this country, although still flying the British flag. The latest German steamer on the American line, together with others recently launched from the Vulcan Works at Stettin, have maintained a speed averaging more than 23 knots, whilst the Cunard Company's liners—still, happily, English—the *Campania* and *Lucania*, built ten years ago, average 22 knots. This company is under contract with the Government to build two liners to maintain an average speed of $24\frac{1}{2}$ knots. The secretary of "Lloyd's Register of British and Foreign Shipping" has kindly supplied me with a list of the steamers of 10,000 tons and upwards which have been launched in the United Kingdom between 1900 and June, 1903. It is given in aggregate below:—

Year	No. of ships	Aggregate gross tonnage
1900	8	95,275
1901	8	107,396
1902	7	98,505
1903 (six months to June 30)	6	67,600 (approximate)

In the Address already referred to I mentioned the application as having been then recently made of the Parsons steam turbine to H.M. torpedo-boat destroyers. The South-Eastern and Chatham Railway Company's new steamer *The Queen* has been fitted with this class of engine of latest design. There is a central high-pressure turbine, driving its shaft at 700 revolutions a minute, and two side low-pressure turbines, each driving its separate shaft at 500 revolutions a minute. The steamer is 310 feet long, and is now running successfully in the service between Dover and Calais.

For some time past much attention has been paid, more especially in France, to the perfecting of submarine vessels for the purposes of naval warfare, but it cannot yet be said that they have passed beyond the experimental stage, although the advance made has been such as to cause our Admiralty to order several additional vessels of the submarine type. These vessels are to be propelled by internal-combustion engines when on the surface of the water and by electric motors when submerged.

Aëronautics.

Another of the attempted means of locomotion is that of aërial navigation. How little we appear to have advanced beyond where we were fifty years ago, when on September 24, 1852, that eminent French engineer, Henri Giffard, succeeded during an experimental ascent in Paris in driving a balloon against the wind for a very short distance, although on October 19, 1901, M. Santos Dumont was successful in navigating his balloon from St. Cloud round the Eiffel Tower in Paris and back to the spot where he had started only half an hour previously. Many have been engaged in this so far unsolved problem of aërial navigation, but there is one of whom we seldom hear. I will quote what Dr. Janssen said in his Presidential Address to the International Aëronautic Congress, held in France on September 15, 1900, regarding Mr. Langley, Correspondent of the Institute of France and Secretary of the Smithsonian Institution at Washington. "Independently of the fine and profound researches of this investigator upon the resistance of air, Mr. Langley has constructed an aëroplane which has progressed and has sustained itself during a time notably longer than any of the apparatus previously constructed."

In the last report of the Smithsonian Institution, that for 1901, it is stated that this steel flying-machine had a supporting area of 54 square feet, a weight of 30 lb., developed $1\frac{1}{2}$ horse-power, and repeatedly flew from one-half a mile to three-quarters of a mile. I cannot close this portion of my Address without referring to the death on February 7

last, in the ninety-fourth year of his age, of that eminent scientific aëronaut, Mr. James Glaisher, F.R.S., who in 1863 made his famous ascent to an altitude of seven miles, and who described at the Newcastle-upon-Tyne Meeting in that year, in an evening lecture, the balloon ascents made for the British Association.

Wireless Telegraphy.

In addressing this Section I feel that I ought to say a few words on the subject of "wireless telegraphy." With regard to signalling Signor Marconi certainly seems to have made progress. In January, 1901, signals were conveyed from Poldhu in Cornwall to the Isle of Wight, a distance of 200 miles, and in December of the same year, between Cornwall and St. John's, Newfoundland, a distance of 2000 miles. In the year 1902 signals were transmitted from England to the Baltic and the Mediterranean, which had thus passed over both sea and land. It seems to be not improbable that signals can be sent any distance, so long as the sending station can develop sufficient energy. The question of "syntonism," by which it is proposed to assure the secrecy of messages, appears to be still *sub judice*, but is undergoing further investigation.

There appears to be a practical field for the development of "wireless telegraphy," more especially where ordinary telegraphy cannot be applied, as, for instance, between shore and ships at sea or between one ship and another.

The Marconi Wireless Telegraph Company have obligingly furnished me with a list of eighteen land stations fitted on the Marconi system for commercial ship signalling, together with a list of forty-three passenger-steamers already furnished with the Marconi apparatus, thus affording evidence of its application to practical purposes.

The system of "wireless telegraphy" by Sir Oliver Lodge and Dr. Muirhead has, I understand, been fitted to cable steamers of the Eastern Extension Telegraph Company, to enable communication to be made with their cable stations.

SEWAGE DISPOSAL.

The bacterial treatment of sewage is receiving much attention, and by the courtesy of Mr. J. Corbett, M.Inst.C.E., the Borough Engineer of Salford, I am enabled to make a brief reference to the system of sewage treatment now carried on at the Salford Corporation Sewage Works, adjoining the Manchester Ship Canal. Twenty years ago the works were constructed with precipitation tanks for lime treatment of the sewage. After fourteen years of experiments with various precipitation and filtration processes, ten of the original precipitation tanks were formed into two large tanks in which precipitation takes place with the aid of milk of lime and salts of iron. The other two original tanks were converted into six roughing filters containing 3 feet in depth of fine gravel, to intercept particles which have escaped the precipitation process, and which would tend to choke the final filters. The final purification is on bacteria beds or aërated filters, with an open false floor of perforated tiles and large open culverts giving constant ventilation through the beds, some of which are filled to a depth of 5 feet and others to a depth of 8 feet with crushed clinkers of from $\frac{1}{8}$ inch to $\frac{1}{4}$ inch diameter. The liquid is "rained" on to the surface by spray jets, and the beds are used generally in shifts of two hours each for eight hours a day in dry weather and for twenty-four hours during heavy rainfall. An average quantity of from 400 to 500 gallons of sewage per square yard per day is treated with satisfactory results.

LIVERPOOL DOCKS.

Although there may seem little of interest in the vast areas of sand which separate Southport from the sea, yet if the whole sea coast from the Dee to the Ribble be taken into consideration, there are few areas of greater interest to the hydraulic engineer than these rivers with the shores that bound them, and few in which stranger changes in land level have occurred within historic times. In the Itinerary of Ptolemy, the Ribble is named immediately after the Dee, the Mersey being omitted altogether.

At the meeting of this Association at Liverpool in 1896, reference was made to these matters, not only by the President of this Section, Sir Douglas Fox, Past President Inst.C.E., but also in papers read, one of which, by Mr. T. M. Reade, F.G.S., is entitled "Oscillations in the Level of the Land, as shown by the Buried River Valleys and Later Deposits in the neighbourhood of Liverpool."

Evidence of the gradual sinking of the land is given by the very interesting discovery in 1850 of a Roman bridge at Wallasey Pool, Birkenhead. After excavating fourteen feet, the workmen came upon a bridge of solid oak beams, supported in the centre by stone piers and resting at the ends upon the solid rock at the sides of the creek. The length of the bridge was 100 feet and its width 24 feet, and the beams were each 33 feet long, 18 inches wide, and 9 inches thick; there were 36 beams formed into 12 compound beams, each 27 inches in depth. Careful drawings of this bridge were made by Mr. Snow, an engineer employed on the work then in progress. The drawings show that the rocky bed of the stream was some 13 feet below the bridge, which was itself about 16 feet below present high-water level.

Formerly Liverpool was one of the ports subordinate to the Comptroller of Chester, and is styled in the Patent "a creek in that port."

The first Act of Parliament authorising the construction of Dock works was obtained in 1709, and in 1853 the water area of the docks had been increased to 178 acres. Since 1853 the progress has been much more rapid, especially within the last thirty years. The total area of the docks and basins at Liverpool and Birkenhead is now 566 acres, whilst in connection therewith there are rather more than 35 miles of quayage. The marked tendency in recent years to increase the length, beam, and depth of ocean-going steamers has necessitated the provision of dock accommodation for a much larger class of vessel than formerly existed; and during the last decade works of great magnitude have been successfully carried out by the Mersey Docks and Harbour Board, under the able direction of the late Mr. G. F. Lyster, M.Inst.C.E., and, since his death, of his son, Mr. Anthony G. Lyster, M.Inst.C.E. In the northern section a new graving-dock has been constructed, extensive additions have been made to the Canada and Huskisson Docks, whilst the difficult work of constructing new river entrances has also been satisfactorily completed. In the southern section, the Queen's Dock has been enlarged and other important additions have been executed and brought into use.

To convey some idea of the magnitude of the works executed, it may be mentioned that the amount expended by the Dock Board in the extensions above indicated exceeds 1,750,000*l*.

The largest lock connected with the port of Liverpool is the Canada, 600 feet long by 100 feet wide, the sill being 14 feet below the datum of Old Dock sill, which datum is 4 feet 8 inches below Ordnance datum, or mean sea-level. Two large river-entrance locks into the Brunswick Dock are now approaching completion, the larger lock having a length of 350 feet and a width of 100 feet, with a sill 19 feet 6 inches below the datum of Old Dock sill.

One of the striking features in connection with the port of Liverpool is the difficult and extensive work connected with the dredging operations at the Mersey Bar. Since the commencement in 1890, to August, 1903, no less than 72,000,000 tons of material have been dredged and removed from the Bar and sea channels, and the average quantity for the last five years has been in round figures, 7,000,000 tons per annum. The total tonnage of the port for the year ended July 1, 1903, was 13,308,305, and the receipts therefrom amounted to 1,185,066*l*., exclusive of graving dock and other rates.

IRRIGATION.

This being the first Meeting of the British Association since the completion of the Assuan dam, which I had the opportunity to inspect when visiting Egypt in the early part of this year, I should like to devote to it a short portion of my Address. Those who desire to learn all about that work in detail I would refer to the papers (to which, indeed, I am indebted for my information on the subject) read before the Institution of Civil Engineers on January 27 last by Mr. Maurice Fitzmaurice, C.M.G., M.Inst.C.E., who had charge of the work on behalf of the Egyptian Government from its commencement in 1898 until December, 1901, and by Mr. F. W. S. Stokes, M.Inst.C.E.,

managing director of Messrs. Ransomes and Rapier, of Ipswich, who undertook the manufacture and erection of the sluices and lock-gates.

The Nile reservoir has been constructed for the purpose of impounding the water of the River Nile during the winter months, and discharging it in the months of May, June, and July, so as to supplement the ordinary flow of the river, and thus enable land to be irrigated which would otherwise receive either no water, or an insufficient supply. The situation chosen for the dam was the head of the Assuan cataract. There were various reasons for the choice: there was a wide section of the river, the waterway being about seven-eighths of a mile, thus permitting the construction of sufficient sluices at different levels to discharge the whole volume of the Nile in flood without weakening the dam by placing them too close together; the height of the dam would be moderate; the site chosen seemed to promise good rock foundation throughout, and there were several natural channels when the water was low, each of which could be dealt with separately if desired.

Arrangements had to be made to house and feed a population of 15,000; offices, workshops, a hospital, and other temporary buildings had to be erected, and a line of railway about 3 miles in length had to be constructed to connect the railway from Luxor to Assuan with the works at the dam. This preliminary work was carried out in 1898, and on February 12, 1899, H.R.H. the Duke of Connaught laid the foundation-stone of the dam.

To enclose the site of the permanent masonry dam, and to render it dry for the purpose of excavation and laying the masonry, temporary dams, known in Egypt as "sudds," had to be formed both above and below the site of the permanent dam. At low Nile the river at the Assuan cataract divides itself into five channels, and this work was done in five sections. The down stream "sudds" were first made, and consisted of stones. After the rush of water had been thus stopped, the up-stream "sudds" were formed of bags of sand.

It was found that the rock on the site of the dam was decomposed. The importance of a solid rock foundation was paramount, and to obtain it the excavation had to be carried down to a considerable depth, necessitating the removal of double the amount of material which had been contracted for, and the construction of nearly one and a half times the quantity of masonry that had been anticipated. The masonry, consisting of local granite set in Portland cement mortar, was commenced in May, 1900, was carried on vigorously during two working seasons in which the Nile was abnormally low, and was finished in June, 1902, less than 3½ years after the first stone was laid, and one year before the expiration of the contract time. The dam is nearly 1¼ miles in length, and the difference between the surface of the water on the up-stream side and that on down-stream side is 65½ feet when the reservoir is full. The masonry is pierced by 180 sluices, of which 140 are 23 feet high by 6 feet 6¾ inches wide and 40 are 11 feet 6 inches high by 6 feet 6¾ inches wide.

The construction of the dam having closed the river to navigation, provision for the passage of vessels was made by means of a canal formed on the west bank of the Nile and having a succession of four locks.

The capacity of the Nile reservoir when filled to the top water height of 348 feet above mean sea level is about 37,600 million cubic feet, a quantity which might have been greatly increased had not the desire to preserve the Temple of Philæ prevented the raising of the water to the level originally proposed. Even now many portions of the temple or its adjacent buildings are partially submerged.

It is anticipated that by allowing the whole volume of the Nile to pass through the sluices when most laden with mud during floods, the silting up of the reservoir to any considerable extent will be prevented. The cost of the works was nearly 2,450,000*l.* or about 10*l.* per million gallons of water impounded.

The original surveys and designs for the works were prepared by Mr. Willcocks (now Sir William Willcocks, K.C.M.G.), under the instructions of Lord Cromer and Sir William Garstin, Sir Benjamin Baker, K.C.B., K.C.M.G., F.R.S., Past President Inst.C.E., being the consulting engineer. On the retirement of Mr. Fitzmaurice, he was succeeded by Mr. C. R. May, M.Inst.C.E., as engineer in charge. The work was carried out by Messrs. John Aird and Co., as contractors, Mr. John A. C. Blue, Assoc.M.Inst.C.E., acting as their agent.

All concerned in the inception and execution of this great undertaking are to be congratulated on its successful and speedy completion, in the face of the many difficulties which were encountered and overcome.

WATER SUPPLY.

To everyone a plentiful supply of good water is not only a luxury, but almost a necessity of existence, yet how few even amongst the more intelligent of the millions who are accustomed to find such a supply ready to hand at the nearest tap have more than a very imperfect notion of the works that have to be constructed to obtain it, or the daily care and attention given to secure and maintain its purity, to ensure its efficient distribution, and to prevent its waste by careless, ignorant, or reckless consumers. It may therefore not be out of place that when the chair of this Section of the British Association happens, as now, to be occupied by one whose professional life has been largely associated with waterworks undertakings, he should address you on that subject, and endeavour briefly to direct attention to some of the main features of waterworks construction and management. In following that course I shall, however, necessarily have to describe what is already well known to at least a portion of my audience, on whose indulgence I must therefore rely.

Water supplies may be divided into two main classes, namely, "Gravitation" and "Pumping." In some instances a combination of gravitaiton and pumping is resorted to, especially in those cases in which the more elevated portions of the district to be supplied are situate above the gravitation level. In selecting a suitable source of supply the main points for consideration are the *quantity* and the *quality* of the water. The quantity should be such as will not only suffice to meet the requirements throughout the most protracted periods of drought and frost of the existing population to be served, but should provide for the probable growth of that population during a reasonable number of years to come. The quality of the water selected should be the best that can be obtained, having due regard to considerations of expense. The question of the altitude being sufficient to permit of a supply by gravitation is of far less moment than those of quantity and quality, because the difference in cost between water derived by gravitation and that obtained by pumping is, in the United Kingdom, less than is generally supposed; indeed, contrary to popular belief, gravitation water is frequently more costly than pumped water, owing to the much greater capital outlay usually incurred in the construction of the works for storing and conveying it.

Gravitation works may be divided into three classes, namely, those in which water is taken directly from a spring or stream without storage, those in which it is taken from a natural lake, in which case the surface level of the water is usually raised so as to increase the capacity of the lake as at Thirlmere, and those more numerous cases in which the water of a spring is impounded in an artificial reservoir generally formed by the construction of an earthen or masonry dam across the valley along which flows the stream to be taken.

In the more populated portions of England it is becoming more and more difficult to find an unappropriated gathering ground available as a source of water supply. The gathering ground, or drainage area as it is frequently termed, should either be free from human habitations and other sources of possible pollution, or any pollution arising therefrom should be capable of being efficiently disposed of by removal from the area of the gathering ground or otherwise.

The gathering ground must also possess a site suitable for the formation of an impounding reservoir. When this has been selected it next becomes necessary to ascertain the amount of the available rainfall, as recorded by rain-gauges situate in the drainage area or its immediate vicinity, or where these are not available, as deduced from the returns obtained from more distant rain-gauges, care being always taken that some at least of the gauges have been observed for a sufficient number of years to enable the true average rainfall to be determined. To store the whole of the water flowing from a gathering ground during a cycle of wet years in order to utilise it during a cycle of dry years would

entail the construction of reservoirs of enormous capacity, at a cost incommensurate with the object to be attained; it is therefore customary to make them of such size as to enable the supply to be maintained without risk of failure throughout the three driest consecutive years, the mean annual rainfall of which years generally amounts to about four-fifths of the average taken over a long period—say, forty or fifty years. From the mean rainfall of the three driest consecutive years a deduction must be made for loss by evaporation, which is usually between twelve and sixteen inches. The result is known as the available rainfall, and represents the quantity of water which can be drawn continuously from an impounding reservoir without fear of failure in the driest years. But the whole of this water can rarely be abstracted from a stream without injuriously affecting mill-owners or other riparian owners on the stream below the reservoir; therefore they have to be compensated for the injury they sustain. This is sometimes done by payments in money, but where the mills on the stream are numerous it is generally more economical to make compensation in water delivered into the stream immediately below the reservoir, because the same water compensates each mill in succession as it flows down the stream.

It has now become an accepted principle that one-third of the available rainfall flowing down a stream in a regulated quantity day by day throughout the year is of greater benefit to the mill-owners (with a few exceptions) than the whole of the rainfall allowed to flow in the irregular manner in which it is provided by nature. This compensation water is discharged from the reservoir into the stream either during certain hours on working days or by a uniform flow throughout the twenty-four hours of every day; a method now frequently demanded by County Councils on so-called sanitary grounds, but which is in my opinion not infrequently detrimental to the interests of mill-owners without a corresponding advantage to the public.

Where compensation in water is given there remains for distribution in the district to be supplied a quantity equal to only two-thirds of the *available* rainfall.

Assume for the sake of illustration a case in which the gross annual rainfall is 40 inches. Then we have:—

	Inches
Gross annual rainfall	40
Deduct to arrive at the mean annual rainfall of the three driest consecutive years—say one-fifth of forty	8
Mean annual rainfall of three driest consecutive years	32
Deduct for evaporation, say	14
Available for supply if no compensation water be given	18
Or if compensation water be given *deduct* one-third	6
Leaving available for supply	12

Having now ascertained the amount of the rainfall available for the supply of the district, it remains to be seen whether or not the area of the gathering ground above the reservoir is sufficient to give the required quantity of water. If it is not, the area may in some cases be extended by means of catch-waters in the form of open conduits cut along the sides of the valley below the embankment of the reservoir, and at such an elevation as will enable them to discharge the waters they collect into the reservoir above its top water line.

Almost all waters derived from gathering grounds are much improved by filtration before use for potable purposes. In some cities and towns in this country, more especially in Lancashire and Yorkshire, the benefit derived from filtration has not been sufficiently appreciated, and the water is still delivered into the houses unfiltered; but I am of opinion that the time will come when nearly every town of importance supplied with water derived from gathering grounds will adopt filtration, for it not only removes matters in suspension but it also diminishes the discoloration due to peat which is to be found in most moorland waters.

Reservoir dams in Great Britain consist either of earthen embankments or masonry walls. Of the former, examples of considerable size may be seen at the reservoirs of the Manchester Waterworks, designed by Mr. J. F. Bateman, F.R.S., Past President Inst.C.E., who was President of Section G of the British Association at the Manchester Meeting in 1861; and at the Rivington reservoirs of the Liverpool Waterworks, designed by my father, the late Mr. Thomas Hawksley, F.R.S., Past President Inst.C.E., who was President of this Section at the Meeting at Nottingham in 1866.

Earthen embankments are formed of the most suitable materials to be obtained by excavation in their neighbourhood; the water is retained by a wall of watertight clay puddle forming the core of the embankment, extending for its whole length and continued at each end into the natural ground forming the hillsides. This puddle core has to be carried down into the ground until watertight strata be met with, occasionally necessitating a puddle trench having a depth of 80 feet or more below the bottom of the valley and 200 feet or more in depth in the hillsides. Where the strata forming the sides of the valley are not watertight, it is necessary to continue the puddle core along the sides of the reservoir by means of wing trenches. The determination of the depth and extent of the puddle trench in order to secure the watertightness of the reservoir is one of the most difficult and anxious duties of the engineer on whom rests the responsibility of its construction. In forming his judgment he has to rely entirely on his experience for guidance, this being one of those matters which cannot be learnt at an engineering school or even in an engineer's office. How much depends on the exercise of a wise and trained judgment may be understood when it is realised that an error in this respect may result in very costly works having subsequently to be undertaken to stop an escape of water which might in the first instance have been prevented by a comparatively small outlay.

Provision has to be made for the passage of flood-waters during the construction of the embankment. This is ordinarily effected by the construction at about the level of the stream of a tunnel of sufficient diameter to convey with only a slight head the volume of water produced by the greatest flood which experience has taught us to anticipate. This tunnel is sometimes formed beneath the embankment, but preferably, where the circumstances are favourable, it is carried through the natural ground near to one end of the embankment. A shaft is built in connection with the tunnel, in which, after the embankment has reached its full height, are placed the outlet valves of the reservoir.

It is of the utmost importance that ample provision should be made for carrying off the flood and other surplus waters coming from the gathering ground when the reservoir is full, for if this be not done serious consequences may ensue, including the washing away of the embankment with resulting destruction of property and even of life. The surplus waters sometimes fall down a shaft erected within the reservoir, and make their escape by means of the tunnel previously mentioned, but more frequently they flow over a masonry weir and reach the stream below the embankment by means of a bye wash formed in the hillside. In my opinion the latter method is in most cases to be preferred, as being free from the risk of blockage by ice to which the shaft and tunnel are liable. Engineers are occasionally reproached with extravagance in the magnitude of the provision made for the escape of flood waters, but it must always be borne in mind that a *maximum* flood has to be provided for, such a flood as may occur only once in twenty or thirty years, but which must find a means of escape when it does occur, without danger to life or property.

Masonry dams are not so frequent in this country as earthen dams, partly by reason of their greater cost and partly because the geological conditions are generally not favourable to their formation, for not only do they require a supply of suitable stone near to hand for their construction, but they also need an incompressible foundation, such as rock or very strong shale. Any irregularity in the compression of the foundation occasioned by the weight of the dam would be liable to fracture the masonry of which it was built.

In the case of masonry dams a tunnel for the passage of flood waters during construction is formed at a suitable level in the masonry of the dam, and after completion of the work they are generally allowed to pass over the top

of the dam for the whole or a portion of its length, thus obviating the necessity for and the cost of an independent bye wash.

Whilst masonry dams have the advantage over earthen dams of not being liable to be breached by a waterspout, I am not aware of any case in which an earthen dam has been destroyed in that manner, and so far as I am able to form an opinion the accidents due to other causes have been as frequent in the case of masonry dams as in that of earthen dams. The destruction of masonry dams has in some instances been the result of too great reliance having been placed on theoretical calculations, without sufficient allowance having been made for the many defects in material and workmanship which might occur in a work of that kind. It was the opinion of the late Mr. Thomas Hawksley that in some cases the destruction of masonry dams had been occasioned by the neglect of the effects of uplift due to the pressure exerted by water finding its way beneath the bottom of the dam, a possible condition which he was very careful to take into account when designing the masonry dam of the Vyrnwy reservoir of the Liverpool Waterworks.

Examples of large masonry dams in the United Kingdom may be seen in that constructed by Mr. G. H. Hill at Thirlmere Lake, from which the city of Manchester is partly supplied with water. Also at the Vyrnwy reservoir of the Liverpool Corporation Waterworks, designed by and partially carried out under the direction of the late Mr. Thomas Hawksley, after whose retirement it was completed by Mr. G. F. Deacon, who presided over Section G on the occasion of the visit of the British Association to Toronto in 1897; and again at the reservoirs near Rhayader, in Wales, now approaching completion, from the designs and under the direction of Mr. James Mansergh, F.R.S., Past President Inst.C.E., for the supply of water to the city of Birmingham.

From the impounding reservoir the water has to be conveyed to the point of distribution by an aqueduct. This aqueduct, which is sometimes of great length, may consist either wholly of metal pipes, usually of cast iron, or partly of a conduit constructed of masonry, brickwork or concrete following the contour of the ground, with occasional tunnels where high ground has to be passed through, and metal (inverted syphon) pipes where valleys have to be crossed. These conduits may be either open or covered, the latter method being generally adopted, when they become what is technically known as "cut and cover" conduits. In the case of a continuous pipe-line of considerable length it is divided into sections by means of break-pressure tanks interposed at suitable elevations, each tank being say 100 feet or thereabouts below the preceding tank, by which means the pipes are relieved from the excessive pressure to which they would be subjected if the head due to the elevation of the impounding reservoir was carried forward to the service reservoir, from which the water is distributed to the consumer. Steel pipes are frequently used abroad where the cost of carriage is great, but they have not yet been much employed in this country, sufficient experience not having yet been gained in reference to the deterioration of steel pipes due to the action of the water from within and of the ground in which they are laid from without.

The lines of pipe are provided at intervals with suitable stopcocks, sluice-valves, and air-valves, and also in some cases with self-acting valves which close automatically in the event of the velocity of the water in the pipe becoming abnormally increased owing to the bursting of a pipe beyond.

I have already stated that most waters obtained from gathering grounds are much improved by filtration. The process of filtration may be carried on where the water leaves the impounding reservoir or at any convenient point on the line of conduit thence to the place of distribution, provided the filter-beds are situate at such an elevation as to place them on the line of hydraulic gradient. Various considerations will influence the determination of their position, but it is desirable that the water should not be subjected to long exposure to light after filtration. Filtration by the slow passage of the water through a bed of sand from two to three feet in thickness, supported by small gravel or other suitable material, is the method usually adopted in Europe, though what is known as mechanical filtration has been used to a considerable extent in the United States, and may under certain conditions be usefully employed. However I do not think it is likely to take the place to any considerable extent in this country of the efficient system of sand-filtration introduced so long ago as the year 1828 by the late Mr. James Simpson, Past President of the Institution of Civil Engineers. The rate of filtration, to be thoroughly effective, must depend on the condition of the water to be filtered, but a rate of from 450 to 550 gallons per square yard of surface of sand per day (*i.e.* twenty-four hours) is usually found to be efficient. Filter-beds are generally open to the sky, but occasionally, when situate at considerable elevations, they are covered by roofs to prevent interruption by the formation of ice in times of severe frost. In certain exceptional cases in which the water is difficult to treat it is twice filtered with excellent results. The water after filtration should be discharged into a pure-water tank or service reservoir of sufficient capacity to enable the process of filtration to proceed at a uniform rate by night as well as by day, without regard to irregularities in the rate of demand in the district of supply.

The particles in suspension in the water, which are intercepted by the process of filtration, gradually form a film over the surface of the sand, and thus improve the filtration; but this film at last becomes so thick as unduly to reduce the rate at which the water passes through the sand. The filter-bed is then laid off and, the water having been withdrawn, the surface of the sand is scraped off to a depth of about a quarter of an inch; the sand thus removed is washed in suitable machines to free it from the matter intercepted during the process of filtration, and is afterwards replaced in the filter-bed either immediately or after several similar scrapings have taken place, care being taken that the thickness of the sand left in the bed shall not at any time be reduced below that required to ensure efficient filtration. From time to time the sand is removed to a depth of several inches and washed, and occasionally it is taken out and washed to its full depth. From the foregoing description it will be understood that the filtration of water, although a simple process, is one which necessitates constant watchfulness on the part of those responsible for the management of those waterworks undertakings in which the water undergoes filtration.

As near to the termination of the aqueduct conveying the water from the impounding reservoir to the point of distribution as the levels of the ground will permit, a service reservoir should be constructed for the purpose of equalising the flow of water along the aqueduct, and for maintaining the supply to the district during any temporary interruption on the line of aqueduct due to a burst pipe or otherwise. The service reservoir should contain not less than one day's supply, two or three days, and, in exceptional cases, even more being sometimes desirable. Service reservoirs should by preference be covered so as to exclude light, and thus prevent the growth of vegetation which would otherwise take place. The covering, when consisting of brick arches, has also the advantage of keeping the water cool in summer, and preventing the temperature from becoming too much reduced in winter. The rate of draught on the service reservoir is continually varying throughout the day and night according to the hourly requirements of the population which it serves. This variation is very considerable, amounting during certain hours of the day to at least twice the average rate of consumption during the twenty-four hours. It will therefore be apparent that were it not for the equalising effect of the service reservoir the aqueduct must have a capacity at least double that which is needful where a service reservoir is available. At Southport, for example, although the water is distributed from a service reservoir, that reservoir is situate at a distance of about seven miles from the town, because, owing to the great extent of comparatively flat land in the neighbourhood of Southport, it was impossible to obtain a suitable elevation nearer to the town than Gorse Hill, on the summit of which the reservoir stands. Consequently the main pipes thence to the town have to be of sufficient capacity to convey the water at a rate corresponding with the demand at the time of *maximum* consumption, or, in other words, of about twice the capacity which would have been needed if the service reservoir could have been placed close to the town, when these pipes would, for the greater part of their length,

have been situate on the inlet instead of on the outlet side of the reservoir.

Having now followed the water in the case of a gravitation supply from its source to the service reservoir from which it is to be distributed to the consumers, it will be convenient to follow in a similar manner water obtained by means of pumping, leaving until later the consideration of its distribution, which, after it leaves the service reservoir, is common to both gravitation and pumped water.

Pumping supplies may be divided into two sections—first, those where the water is drawn from a source only slightly below the level of the pumping engines, such as where the water is taken from a stream or lake, or from culverts formed in gravel beds, or is discharged from impounding reservoirs situate at too low a level to enable the water to gravitate to the point of distribution; and secondly, where the water is raised from deep wells sunk in the sandstone, chalk, or other water-bearing strata.

In the first-mentioned cases the water has usually to be filtered, when it is generally found convenient to place the filter-beds at the pumping station, the water being firstly lifted (unless it will gravitate) on to the filter-beds, and secondly, after filtration, and by means of a separate pump, forced through pipes up to the service reservoir whence it is to be distributed.

In the case of deep wells, the water seldom, if ever, requires filtration, and is usually raised either directly or through pipes into the service reservoir, the total lift being frequently divided between lift pumps and force pumps with the object of balancing the work to be done by the engine.

Sometimes the well alone will yield a sufficient supply of water, but often it has to be aided by boreholes or by drifts or headings driven horizontally in the water-bearing strata near the level of the bottom of the well, and occasionally continued for a considerable distance, even as much as a mile or more from the well, the length of the headings depending on the quantity of water which can be profitably obtained from them, and also on other considerations too various to be mentioned here. There are cases in which it is possible to obtain sufficient water by boring from the surface of the ground and lowering a pump down the bore hole. The expense of a large well is thus saved, but it is, of course, impossible to augment the supply by drifting.

The time at my disposal will not admit of any observations on the merits of the various kinds of engines and pumps employed in raising water; they are not only very numerous, but each has to be considered in relation to its suitability for the particular circumstances of the case in question. Suffice it to say that, although most of the water pumped in the United Kingdom is raised by means of steam engines, water turbines, gas engines, oil engines, and (to some slight extent) electric motors are also employed. It may be mentioned that one of the largest oil engines in this country is engaged in pumping water from a deep well, and it is not improbable that gas and oil engines will in the future become more largely employed for waterworks purposes.

It should here be mentioned that there are a few instances in this country, and many in the United States of America, in which a service reservoir is dispensed with, and water is pumped directly into the main and distributing pipes of the district to be served, a method which, although employed with success, should not, in my opinion, be adopted where the circumstances admit of the use of a service reservoir. Where direct pumping is used, provision must be made to ensure continuous pumping day and night without intermission, so as to avoid interruption to the supply of the district, and the speed of the engines must be constantly varied to meet the demands of the consumers for the moment. The maintenance of uniformity of pressure in the main pipes may be assisted by the employment of large air vessels, or by accumulators such as are used for the supply of hydraulic pressure, or preferably by a combination of air vessels and accumulators.

We will now return to the service reservoir. When this reservoir is situate between the source of supply and the district to be supplied, it receives the whole of the water and delivers it into the district as needed for use; but when the district lies between the source and the service reservoir, it receives the excess of supply over consumption, and on the other hand makes good any deficiency during those hours when the consumption exceeds the supply. In either case this reservoir has the effect of equalising the flow from the source to the reservoir throughout the twenty-four hours of the day.

From the service reservoir the water is conveyed by one or more main pipes into the district of supply. These pipes are gradually reduced in diameter as they pass through the district, the water which they convey is taken off by other main pipes branching from them, and finally enters the service pipes, which are usually from five inches to three inches diameter, and are those from which the consumers' communication pipes are taken. The service pipes should in all cases be controlled by valves, so that the water can be shut off from them without interfering with the flow through the main pipes. Consumers' communication pipes are not generally allowed to be attached to pipes of greater diameter than five inches, and where a pipe of six inches diameter and upwards is carried along a street, another pipe of three or four inches diameter (preferably the latter size), and called a ryder pipe, is laid alongside to receive the attachments of the communication pipes. The ryder pipe is divided into lengths of from 350 to 400 yards, each of which is controlled by a valve at its junction with the main pipe. Hydrants for use in case of fire are attached to the ryder and other service pipes throughout the district at a distance apart not exceeding 100 yards. Except in streets where the houses are small and not high, it is desirable to lay the service pipes of not less than four inches diameter, not because a smaller pipe would not suffice to meet the requirements of the domestic consumers, but in order to ensure an ample supply of water in case of fire. When determining the sizes of the main pipes to be laid throughout a town, the engineer commences with the pipes most remote from the service reservoir, and gradually increases the diameter according to the probable number and magnitude of the supplies to be taken from them.

Pipes of cast iron having sockets run with lead and set up with a hammer are mostly used for waterworks purposes, but in some instances turned and bored joints put together without lead have been used with success, but these are only suitable where there is an unyielding foundation. I remember a case in Yorkshire, where turned and bored pipes were, much against the advice of the engineer, used for the distribution of gas in a colliery district, with the result that in a few years nearly every joint was leaking; fortunately the engineer had anticipated that result, and had laid the pipes with sockets in addition to the turned and bored joints; consequently, by opening the ground at each joint and running the joint with lead, the leakage was stopped without necessitating the relaying of the system of pipes. The main pipe of forty-four inches diameter, conveying water from Rivington to Liverpool, passes for several miles over a coalfield, and the ground has in places subsided over the coal workings as much as four feet without interfering with the supply of water; the ground having been opened at the pipe joints, the lead, which had been partially drawn from the joints, was forced back by hammering, and the joint was again made sound.

In some countries, where the cold is intense, water pipes have to be laid at a depth of from 10 feet to 12 feet below the surface of the ground to protect the water from frost, but in the United Kingdom a depth of from 2 feet 6 inches to 3 feet has been found to be sufficient even in very severe frosts.

Water, especially when soft, causes the interior of cast-iron pipes to become incrusted with nodules of iron, which reduce the effective diameter of the pipe and so diminish its capacity. This action is greatly retarded and in some instances entirely prevented by the application to the pipes, soon after they have been cast, of the coating introduced many years ago by the late Dr. Angus Smith, a process now nearly always employed.

It was at Southport that I witnessed the bursting of a main pipe, the only occurrence of the kind that I have seen during a period of forty years, of which a considerable portion has been spent amongst waterworks. Owing to the introduction of a new supply of water, the original main pipe was charged with water at a higher pressure than it had been intended to bear, with the result that several fractures occurred. I happened to be standing on one of

the roads at a little distance from the town when I heard a sound, and looking in the direction whence it came, saw in a field near by a black column rise vertically in the air for about forty feet in height. A girl who happened to be working in the field put her hands to her ears and fled, probably thinking she had seen Satan himself, but the column soon became clear, the black colour having been caused by the peat carried up with the water.

Having traced the water from its source to the door of the consumer, we now enter into another branch of the subject. Up to this point the water has been entirely under the control of the company or local authority by whom it is provided, but from the moment it enters the consumer's communication pipe, or where the communication pipe is the property of the water supplier, from the moment the water reaches the premises of the consumer, it comes under his control, subject only to such regulations and supervision as the Legislature has given the water supplier power to make and to exercise.

When water was supplied on the now almost obsolete "intermittent service," under which a town was divided into a number of districts into each of which in succession the water was turned for only one or two hours a day, the water suppliers paid but little attention to the fittings within the houses of the consumers, because, however great the quantity of water wasted through defective fittings, the waste could only last for the short time during which the water was turned on in each district, and it ceased altogether during the night.

About the year 1831 the system of "constant service," by which is meant a supply of water available from the pipes of the water suppliers at any moment throughout the day or night, was introduced into this country by the late Mr. Thomas Hawksley, at Nottingham, and it soon became evident that if a constant service was to be maintained the fittings within the houses of the consumers must be adapted to the new conditions and be placed under regulation and supervision. Suitable regulations were therefore formulated, and have since been improved and modified to meet modern requirements. These regulations, which are mainly directed to the use of proper pipes, taps and other fittings, and to service cisterns so constructed as to prevent a continuous flow and consequent waste of water, do not in any way limit the use of water by a consumer, who is at liberty to take as much as he requires whether by day or by night, nor does their strict enforcement inflict any hardship on the consumer, to whom good water fittings kept in a proper state of repair are in the end more economical than cheaper and inferior fittings requiring the frequent attendance of the plumber.

About five years ago, I had occasion to obtain statistics relating to the consumption of water in sixteen towns (including Southport) in England, containing an aggregate population within the district supplied of rather more than five millions of people, and found that the average quantity of water consumed in those towns for domestic purposes was 18¾ gallons per head per diem, showing what can be effected by good management and a careful observance of proper regulations for the prevention of waste without imposing any restriction on the quantity of water legitimately used. The figures which I have quoted as water for domestic purposes include the unmetered trade supplies and that comparatively small amount of waste which cannot be prevented, but do not include the water supplied by meter for trade purposes, the amount of which varies greatly in different towns, but being paid for by the consumer according to the quantity used may be disregarded when comparing the management of waterworks undertakings.

Some soft waters, more especially those derived from moorlands, have an injurious action on lead pipes and lead-lined cisterns, and are liable to cause lead poisoning in sensitive persons drinking the water, but this action is now commonly prevented by bringing the water into contact with lime before distribution.

In certain instances of public supplies, the hardness of the water is reduced by one of the several softening processes now in use, but it more frequently happens that the softening is effected by those consumers who require soft water for boiler or other trade purposes.

A few words with regard to the water supply of the town in which the Meeting of the British Association is now being held may not be out of place, the more especially when it is borne in mind that the rapid growth of its population during the last half century could not have taken place but for the introduction of a supply of good water.

The Southport Waterworks Company, by whom water was originally brought to Southport, was established under the authority of an Act of Parliament passed in the year 1854. Water was first obtained from a well sunk at Scarisbrick, about five miles south-east of Southport, a source which was practically superseded by another well which was a few years later sunk at the Aughton pumping station near Ormskirk. As the population to be supplied increased in numbers, the Company subsequently sank a third well, and constructed the still larger Springfield pumping station near Town Green, about nine miles south-east of Southport, and it is from the Aughton and Springfield wells, both sunk into the Bunter Beds of the New Red Sandstone formation, that the present excellent supply of water is derived. At each pumping station the water is raised by a pair of beam rotative steam-engines into two covered service reservoirs situate on the summit of Gorse Hill, near Ormskirk, at an elevation of 260 feet above ordnance datum, or in other words, above the mean level of the sea. From this reservoir the water is brought through two main pipes to Southport and Birkdale, which places have from the commencement of the undertaking had the advantage of a constant service. The late Mr. Thomas Hawksley acted as engineer to the company from its formation until his death in 1893, and I subsequently acted in that capacity until the transfer, under the powers of the Southport Water (Transfer) Act, 1901, of the undertaking of the company to the Southport, Birkdale, and West Lancashire Water Board, consisting of representatives of the Corporation of Southport, the Urban District Council of Birkdale, and the Rural District Council of West Lancashire.

The advances in recent years in chemical science, and the application of the science of bacteriology to the examination of water, have led to the condemnation of waters which a few years ago would have been deemed to be perfectly suitable for a town supply. Whilst fully appreciating the advantages to be derived from the most careful examination of water supplied for domestic consumption, I cannot but think that we are sometimes unnecessarily alarmed by the results obtained. Taking a broad view of the subject, and looking to the healthy condition of towns which have for many years been supplied with water from sources now regarded with suspicion, I venture to think that the teachings of chemistry and bacteriology are as yet but imperfectly understood, and that in the future it will be found that some waters now considered of doubtful character are perfectly good and wholesome. I am well aware that the expression of these views may call forth the indignation of some of my friends amongst eminent chemists and bacteriologists to whose opinions on such subjects I feel bound to pay deference. A Royal Commission has recently recommended that a Government department be established and endowed with enormous powers of interference with the action and discretion of the bodies entrusted by Parliament with the responsibility of the administration of water supplies, and it behoves those bodies to give careful consideration to that recommendation, and to take such steps as may be necessary to check any attempt to give effect to a proposal which may result in committing them to the carrying out of unreasonable requirements, possibly involving needless expenditure, at the bidding of a Department from whose dictum they may have no appeal.

Although a matter only indirectly connected with water supply, I think it may be of scientific interest to this Section to have brought to their notice the case of the River Rede in Northumberland, which takes its rise in the Cheviots. At a place called Catcleugh, about four miles below the source of the Rede, its waters are diverted by the Newcastle and Gateshead Water Company for the supply of their district. The gathering-ground above the point of diversion is about 10,000 acres in extent, and the quantity of water taken is ascertained by means of a gauge, and registered continuously by a recording instrument. An inspection of the diagrams taken during periods in which there was no rainfall shows a daily variation in the volume of water flowing down the river. For example, during a period of eight days (June 9 to 16, 1899) without interruption by rain,

the gradual rise and fall of the river was almost regular, day by day, the maximum flow occurring about 9 a.m., and the minimum about 9 p.m., the difference between the two amounting to nearly 10 per cent. of the total quantity passing down the river at the time of minimum flow. Various suggestions as to the cause of this phenomenon have been made, but I am unable to give any satisfactory explanation. It occurs in winter as well as in summer, and may take place daily throughout the year, though it cannot be observed except during dry periods. It may well be that a similar phenomenon occurs in other rivers, but has escaped observation owing to the absence of recording gauges.

THE INTERNATIONAL GEOLOGICAL CONGRESS.

THE ninth gathering of the International Geological Congress was held this year in Vienna. After a preliminary series of excursions through different parts of Austria-Hungary the members assembled in the rooms of the University on Thursday, August 20, when the meeting was inaugurated by the Archduke Rainer and the Minister of Public Instruction. According to the programme prepared by the committee of organisation, each alternate day was to be devoted to the reading and discussion of papers on given subjects of general interest, while the intervening days were given up to excursions in the neighbourhood of the imperial city. After the formal opening of the congress, the afternoon of the first day was spent, under the presidency of Mr. Emmons, of the United States Geological Survey, in receiving a miscellaneous group of communications, including a paper on the Laccolites of the Aar-massif by Prof. Baltzer, and an account of the recent volcanic eruptions of Martinique and St. Vincent by Mr. E. O. Hovey, illustrated by an excellent series of photographic lantern slides. The next day of discussion (August 22) was dedicated to the crystalline schists, under the chairmanship of Prof. Zirkel in the morning and Prof. Loewinson-Lessing in the afternoon. Until the various communications are in print and can be studied and compared, it is hardly possible to say how far they have advanced our knowledge of the subject. The speakers on this and subsequently on the other selected subjects of discussion showed a prevailing tendency to dwell on the local peculiarities of the regions most familiar to them, and rather to lose sight of the general principles to which local observations should properly lead. The crystalline schists of Germany, Austria, the Alps, Finland and North America were all brought into review, so that a sufficiently wide basis was provided for satisfactory generalisation. The third day (August 24) for the reading of papers, under the presidency of Sir Archibald Geikie in the forenoon and Prof. Heim in the afternoon, was spent in listening to essays by various geologists on the important phenomena embraced under the general designation of "overthrusts." MM. Lugeon and Haug described the structures displayed in the Alps, Prof. Uhlig those of the Carpathians, Mr. Bailey Willis those of the United States. In an interesting discussion Prof. Heim indicated that he surrendered the so-called "double-fold" of the Glärnish, as originally advocated by him, and now admitted that the structure implied a gigantic overthrust. Prof. Rothpletz, who has long maintained this view, also took part in the debate, which at times became lively from the energy of the speakers and the difficulty which they found in confining their exuberance within the limits of time prescribed by the council. Though the doctrine of overthrusts was admitted, considerable divergence of opinion appeared as to the true nature and origin of the structure.

Wednesday (August 26) was dedicated to a consideration of the geology of the Balkan peninsula and the East, under the presidency of Prof. Barrois in the forenoon and Prof. Tschernyschew in the afternoon. An interesting and important series of papers was read, in which the present state of our knowledge of these regions was detailed by those geologists to whom the recent advance of that knowledge has mainly been due.

On Thursday (August 27) the morning was taken up in the reception of miscellaneous communications in four different rooms of the University. As this extensive building includes a large number of rooms separated from each other by staircases and passages, and as no adequate system of placards was adopted to guide the members to these various meeting-places, much time was lost in trying to find them, and in some instances the search was abandoned in despair. The afternoon was devoted first to the reception of the reports of the various Commissions appointed by the congress at previous meetings. A satisfactory statement was made by Prof. Beyschlag as to the progress of the international geological map of Europe. Sir Archibald Geikie gave in the report of the Commission on lines of raised beach in the northern hemisphere and also that of the Commission on international cooperation in geological research. On his proposal it was agreed to form a small committee for the purpose of collecting information from different countries with a view to combined effort in those branches of inquiry which are not purely geological but require the services of other sciences. The first number of the "Palæontologia Universalis" was laid before the meeting by M. Oehlert, who was warmly congratulated on the successful launching of this enterprise. The report of the Commission on glaciers was presented by M. Finsterwalder. The recommendation of the committee appointed to consider the Spendiaroff prize was unanimously adopted, that the prize should be awarded to Prof. Brögger, of Christiania. The last official act of the congress was to choose the next place of meeting, which, by a majority, was fixed to be Mexico.

A very unpleasant impression was made on a number of members of the congress by the action of the Vienna committee of organisation in regard to the next meeting place. So far back as March last the general secretary wrote to Dr. Bell, acting director of the Geological Survey of Canada, asking whether an invitation could be sent from Canada to hold the next meeting of congress there, and assuring him that many Austrian geologists would be very pleased to visit that country and would be happy to support the invitation at the approaching Vienna meeting. No mention was made in that letter, or in any subsequent communication, that applications had been sent to any other country. Dr. Bell replied in the same month of March that he cordially welcomed the proposal and would do all in his power to further its acceptance. The Geological Survey and the Royal Society of Canada warmly supported it, and eventually the Government authorities took it up and Parliament actually voted 25,000 dollars towards the necessary expenses of the meeting. Dr. Bell was commissioned to proceed to Vienna and personally invite the congress to hold their next session in Canada. On arriving in Vienna, however, he found that, unknown to any one in Canada, the committee had also been simultaneously in treaty with Mexico, and without writing to know what was being done in Canada had inserted in the official programme an invitation which had in response been received from Mexico. He soon saw that though the committee could not bind the congress, they had practically decided the question in favour of Mexico so far as their votes and influence could go. The Canadian authorities naturally feel indignant at such treatment, and it will excite no surprise if they are in no hurry to renew their invitation should the visit to Mexico fail of accomplishment.

Excursions have always formed a prominent part of the work of the geological congress, and this year they have been organised on a greater scale than ever before. Not only was there a diversified series set on foot before the meeting and another after it, but half the time of the congress in Vienna was devoted to excursions in the neighbourhood. Whether these miscellaneous parties contribute as much as might be desired to the enlargement of the geological experience and knowledge of the congressists, they at least have one excellent result inasmuch as they bring together scientific friends who have seldom a chance of meeting each other and, likewise, enable them to make the personal acquaintance of men with whose writings they may have been long familiar. Indeed, it may be asserted that the fostering of such personal acquaintance is perhaps the most practically valuable part of the work of the congress. For the enlightenment of the excursionists an admirable Livret Guide to Austrian geology was drawn up by Dr. Teller. Of this publication an account will be given in another issue of NATURE.

NOTES.

PROF. GRAHAM KERR has just received a letter from Mr. J. S. Budgett in which the latter announces that he has solved the important problem of the development of Polypterus. The letter is written from southern Nigeria and dated August 28. It appears that Mr. Budgett has been able to fertilise a large quantity of eggs of *Polypterus senegalus*, and that the early development is "astoundingly frog-like"—segmentation being complete and fairly equal, and the process of invagination resembling that of the frog's egg. Prominent neural folds are formed which arch over in the normal fashion. Mr. Budgett had already made three expeditions to various parts of tropical Africa in his endeavour to obtain material for studying the development of Polypterus, and zoologists will rejoice that his efforts have been at last attended with success. The Crossopterygians have been for some time the most important vertebrate group awaiting the investigation of the embryologist, and the results gained by Mr. Budgett in the working out of his material in the laboratory will be looked forward to with the greatest interest by all vertebrate morphologists.

A MOVEMENT is in progress for erecting a memorial of James Watt, and at a meeting recently held it was decided that the form the memorial should take should be an institution for scientific research, and an appeal is now being made for funds to carry out the project. Mr. Andrew Carnegie, who is the secretary for America, has promised a subscription of 10,000*l.* towards the object.

THE Bombay University Syndicate announces that the subject selected for the Dr. Theodore Cooke memorial prize for 1905 is "Electric Traction and the Application of Electricity to the Requirements of Cities in India." Competitors for the prize should be graduates in engineering of the University of Bombay of not more than seven years' standing.

THE second International Congress of Philosophy is to be held in September of next year in Geneva.

THE fourth International Congress of Psychology will, it is stated, meet in Rome in the spring of 1905, instead of in the autumn of 1904, as had been arranged.

DR. LOUIS PARKES has been appointed to succeed the late Prof. Corfield as consulting sanitary adviser to H.M. Office of Works.

THE forty-eighth annual exhibition of the Royal Photographic Society opens to-day at the New Gallery, Regent Street. The exhibition will remain open until October 31.

FURTHER trials on the electric railway at Zossen have resulted in a speed of nearly 114 miles an hour being attained.

AN exhibition of the pathological specimens which have been added to the St. George's Hospital Museum during the past year will take place at the museum from October 1 to 17.

THE death is announced of Mr. Washington Teasdale, of Leeds, at the age of seventy-three. He was a fellow of several scientific societies, and president of the Leeds Astronomical Society.

A REUTER telegram from Santiago de Cuba announces that a shock of earthquake, the most violent since 1885, occurred there on the morning of September 19, and lasted fifteen seconds.

THE death, at the advanced age of eighty-five, is announced of Dr. Alexander Bain, who for twenty years occupied the chair of logic in the University of Aberdeen, and was a voluminous writer on language, logic, psychology, and kindred subjects.

IT is stated by Reuter that the private subscriptions towards Captain Bernier's projected North Pole expedition amount to 12,000*l.*, of which Lord Strathcona has given 1000*l.* It is also stated that the Canadian Government will probably build and equip the vessel for the expedition.

A PROVINCIAL sessional meeting of the Sanitary Institute will be held at the University of Birmingham on Saturday next, September 26. A discussion on some practical considerations in connection with modern methods of treating sewage will be opened by Prof. A. Bostock Hill and Mr. J. E. Willcox.

THE Colonial Economic Committee of Berlin announces that the utility of the gutta-percha discovered by the expedition which was undertaken to New Guinea under the leadership of Herr Schlechter has so far been established that the gutta-percha from the low-lying country may be regarded as suitable for cable purposes as an admixture, and, if carefully obtained, be fit for cables in a pure condition. Large quantities of gutta-percha have been obtained from New Guinea, and are at present being tested, the Secretary of State for the Imperial Post Office having granted a large sum of money for the purpose. It is proposed by the Colonial Economic Committee to establish a gutta-percha enterprise for the education of the native population of New Guinea in the cultivation of gutta-percha and its winning. This will take the form of a fresh expedition under Herr Schlechter for a period of three years. Assistance will be given by natives of Borneo and others familiar with the question of rubber production.

A SUCCESSFUL journey through eastern Mongolia (supplementing a more extended journey accomplished last year by Mr. Campbell, Chinese Secretary of the British Legation) has, says a Peking correspondent of the *Times*, just been completed by Mr. Claude Russell and Mr. Hicks Beach. The party left Peking on July 20, and, passing through Jehol, struck north to the Manchurian Railway at Tsitsihar, which was reached in forty-eight days. Their route lay east of the Khingan Mountains, the distance covered, 1000 miles, being to a considerable extent, so far as is known, through country not previously visited by any European. The travellers rode on ponies, with pack mules for their baggage. They had four servants, but no escort. They met with unfailing courtesy from all classes, both Mongols and Chinese. The country is thinly peopled, but is being gradually colonised by Chinese from within the Great Wall.

A BRITISH and International Aëronautical Exhibition, organised by the Aëronautical Institute, was opened at the Alexandra Palace on Thursday last. Among the exhibits are a model balloon, and kites and specimens of balloon accessories sent by the German Government, examples of Mr. S. F. Cody's kites and his gear for flying them, various flying machines either full size or in model form, and the large machine which Dr. Barton is constructing. In connection with the exhibition three competitions are to be held, silver and bronze medals being awarded to the two winners in each. The first is for kites, and in judging consideration will be taken of the way in which the kite leaves the ground, the manner in which it ascends, its steadiness, the time required to let out the whole mile of wire or string, the altitude attained, and the

rapidity and manner of descent. The second competition is also for kites, and is organised with a view of ascertaining the best and safest form of aëroplane for man-lifting kites and dynamic flying machines. The third competition is for parachutes.

IN the *Atti della Fondazione Scientifica Cagnola* (vol. xviii.), Prof. Grassi gives an excellent survey of our present knowledge of malaria. He describes fully its epidemiology and prophylaxis, and the morphology and development of the malaria parasite. In the latter connection he introduces some new terms. The asexual parasites producing the febrile attacks are named "monogonia," the developmental forms in the mosquito "amphigonia," while the recurrent attacks of fever which occur at long intervals after infection are regarded as being due to parthenogenetic parasites, which develop from the non-flagellating (female) sexual cells, or gametocytes.

THE first volume of reports of the Sleeping Sickness Commission of the Royal Society has just been issued. In report No. 1 Dr. Aldo Castellani describes his discovery of the presence of a trypanosoma in this disease (see NATURE, lxviii., p. 116). Report No. 2 is a "progress report" by Lieut.-Colonel Bruce, F.R.S., and Dr. Nabarro, who have continued the work of Dr. Castellani, and they confirm his discovery of the presence of a trypanosoma in the cerebro-spinal fluid of sleeping-sickness. In every one of forty cases examined the trypanosome was found, even in the early stages. In fifteen cases of other diseases the trypanosome was not observed, so that the parasite is not present in the cerebro-spinal fluid of the general population. In the blood also of sleeping-sickness the trypanosome is practically always to be met with. In six individuals suffering from fever, but presenting no symptoms of sleeping-sickness, trypanosomes were also detected in the blood but not in the cerebro-spinal fluid. The question arises whether the trypanosome found in the blood of these six cases was the same species as that present in sleeping-sickness. Morphologically there are certain differences between the two, but the results of inoculation experiments are up to the present indefinite. The distribution of sleeping-sickness in Uganda is striking, the disease occurring only in a belt of country fifteen miles wide on the northern shores of the Victoria Nyanza. In this district a tsetse fly (identified as *Glossina palpalis* by Mr. Austen, of the British Museum) was observed to be very abundant, and the question is raised whether this fly conveys the infection in sleeping-sickness, just as one does in the tsetse disease of horses, &c., which is also due to a species of trypanosoma. Flies, freshly caught, were allowed to bite a monkey, and in five days trypanosomes were found in its blood, showing that the flies do convey trypanosome infection, though whether the sleeping-sickness species it is not yet possible to say. The report concludes with the clinical histories of a number of cases of the disease, and is illustrated with ten plates.

WE have recently received meteorological "Yearbooks" (1) from Dr. H. Hergesell, director of the service of Alsace-Lorraine, containing hourly observations for Strassburg and summaries at various other stations, for the year 1899; and (2) from Dr. P. Berghaus, containing hourly observations for Bremen, and rainfall statistics at a few stations. The observations and results of both "Yearbooks" are carefully prepared according to the uniform system adopted for all the States of the German Empire.

DR. G. HELLMANN has published a rain chart of the Prussian provinces of Hessen-Nassau and Rheinland, including Hohenzollern and Oberhessen, together with a discussion of the rainfall statistics for the last ten years. This work is the eighth of the valuable series prepared by him at the request of the Berlin Meteorological Department, to which we have before referred in our columns. The tables contain mean annual values of rainfall, monthly percentages of those values, the greatest falls in short periods, and other useful information.

IN a paper read before the Royal Society of New South Wales, Mr. H. C. Russell clearly disproves a somewhat common belief that a wet season in England is followed by a wet season in Australia. A diagram illustrating the paper shows that, although sometimes heavy rains in England will be followed next year by heavy rains in Australia, they seldom do so. Mr. Russell finds that, from 1880 to 1885, and from 1894 to 1901, for instance, rain was abundant in England, while Australia was suffering a severe drought.

A PAPER read before the South Staffordshire and East Worcestershire Institute of Mining Engineers by Mr. F. G. Meachem deals with underground temperatures. The mean increase in temperature, deduced from the summary of the results collected by the British Association committee and published in 1882, was 1° F. for a descent of 64 feet. Since 1882 other important observations have been made, from which it appears that the highest rock-temperature obtained at a depth of 4580 feet (Calumet and Hecla Copper-mines, Lake Superior) is 79° F., the temperature at a depth of 105 feet being 59° F. The difference of temperature in the column of 4475 feet of rock was 20° F., averaging 1° F. for every 224 feet. The average annual temperature of the air where the observations were made is 48° F., and that of the air at the bottom of the shaft is 72° F. The mean increase obtained by the observations of Mr. H. A. Wheeler at other mines in the Lake Superior district in 1886 was, however, 1° F. in 100·8 feet. Mr. Meachem has made various temperature-tests at Hamstead Colliery extending over several years, and all observations show an increase of temperature in undisturbed strata of 1° F. for every 110 feet of descent beyond 65 feet from the surface. It has been found that the temperature of the undisturbed strata at the pit bottom, 1950 feet below the surface, is 66° F. This was ascertained by inserting a maximum and minimum thermometer, protected by a metal case, into a bore-hole driven 10 feet into freshly-cut coal. The hole was closed with clay and left for various periods from one to fourteen days. Repeated observations led to the result stated. It is concluded that by sinking larger shafts and introducing more efficient ventilating machinery, miners will be able to do as much work at a depth of 3000 feet as is now done at a depth of 1000 feet, and that mining engineers will be able to reach any depth at which coal is likely to be found in this country and work the same.

WE have received the second fasciculus (with plates 13–24) of Dr. E. A. Goeldi's "Album of the Birds of Amazonia" (*Album de Aves Amazonicas*), in course of publication by the Museum Goeldi, at Para. The plates of this part, which, like their predecessors, are coloured, include selected representatives of the Cotingidæ, Psittacidæ, Cœrebidæ, Picidæ, Formicariidæ, Cuculidæ, Dendrocolaptidæ, Cracidæ, &c., and likewise depict those extremely characteristic South American birds, the trumpeter, seriema, horned screamer, ruddy tinamu, and rhea. The latter bird, it may be mentioned, is commonly known by Europeans in Brazil as the emeu (ema), while it may also be noticed that the native name anhuma might conveniently be adopted in ornithological literature for the screamers. The plates

depict, so far as possible, the birds in their natural surroundings, and although in some perhaps a trifle too gaudy, the colouring appears to be very true to nature. When complete, the book should be invaluable to all interested in the birds of Brazil.

ANOTHER illustrated work recently to hand (although the cover is dated 1902) is part x. of the atlas of the section devoted to Crustacea in "Illustrations of the Zoology of the *Investigator*," by Major Alcock and the late Mr. A. F. McArdle. This part includes plates lvi.–lxvii., the majority of which illustrate crabs, although some crawfishes are also figured. In the absence of the text, fuller notice is difficult.

THE Boston (U.S.A.) Society of Natural History is to be congratulated on the decision to publish an annual summary of the work done on the land mammals of North America. The part just issued, dealing with the years 1901 and 1902, forms No. 3 of the Society's *Proceedings*, and is compiled by Messrs. Miller and Rehn. With the aid of such annual summaries naturalists in other countries may hope to keep abreast of American work in this department of zoology.

WE have received the second part of vol. xiv. of the *Natural History Transactions of Northumberland, Durham, and Newcastle*. It contains the presidential addresses for the years 1901 and 1902, both of which set an excellent example in that they deal exclusively with local subjects. The committee records with regret the determination of the Tyneside Naturalists' Field Club to terminate its connection with the Society, which has existed since the year 1864; this feeling of regret will, we think, be widespread, especially as it will involve in the near future a severance of the *Joint Transactions* of the two bodies.

ARTICLE two of vol. xvii. of the *Journal* of the College of Science of Tokyo contains an account of a worm (*Ceratocephale osawai*) which, at certain seasons, appears in swarms in the Gulf of Tokyo and the rivers debouching therein, after the manner of the palolo worms of the South Pacific and the Atlantic. Instead, however, of belonging to the Eunicidæ, the Japanese species, which is regarded by its describer, Mr. A. Isuka, as new to science, is referable to the Lycoridæ. According to the experience of the fishermen, which is confirmed by Mr. Isuka's personal observations, the Japanese "palolo" swarms during the months of October and November, usually in four periods of a few days' duration each. The swarming season always takes place when the moon is either new or near the full, and invariably occurs in the evening just after flood-tide. On the occasion of the author's observation, the height of the swarm did not last more than a couple of hours, the worms after this apparently sinking to the bottom exhausted.

THE collections of plants made by Mr. J. N. Rose in Mexico and Central America have not only added a number of new types, but have yielded several plants which are likely to be of horticultural value. In an account, the third which has appeared in the *Contributions* from the United States National Herbarium, attention is directed to two new bulbous species of Polianthes, and a Crinum. Of the genus Argemone the author has obtained eleven species, including the three well-known cultivated species of which wild specimens are rare, even in herbaria.

THERE is very considerable difficulty in obtaining information concerning the botany of Siam, and the reason for this appears to be that no collectors have attempted to work the country systematically. Mr. F. N. Williams has written a short article on this subject in the current number of the *Journal of Botany*, in which he enumerates the few collections of Siamese plants which he has discovered in the Kew Herbarium. Almost as little known is the algal vegetation of the Shetland Isles, for which the only records date back to the year 1845. A list of the marine algæ collected by Mr. Börgesen—together with those previously recorded—is contributed by him to the same journal.

THE growth of canker-areas on trees has been attributed by some investigators to frost, and by others, including Hartig, to the ravages of the fungus *Nectria ditissima*. The suggestion made some years ago that bacteria were the cause of disease has not met with much support from pathologists. In the *Bulletin International de l'Académie des Sciences de Cracovie*, Mr. J. Brzeziński adduces fresh evidence in favour of this view so far as apple, pear, and hazel trees are concerned. After unsuccessful attempts to set up disease in sound tissues by infection with Nectria, the author sought for the origin of disease in the bacteria which are abundant in the wood elements. It was not difficult to get pure cultures, and after inoculation with the bacteria discoloration and destruction of the tissues soon followed. Canker spots were not produced, but it is probable that they would not develop in the space of time during which the experiments were conducted.

A REPORT has recently been issued by the Foreign Office giving the result of inquiries made by His Majesty's ministers as to the navigable inland water-ways in France, Belgium, the Netherlands, Germany, and Austria-Hungary. The reports are necessarily statistical, but at the same time contain a great deal of useful information. Each of the above countries has expended out of State funds during the past twenty-five years very large sums in improving the inland navigation either by deepening and improving the natural rivers, or, where this was not practicable, by canalising them, or by the construction of new water-ways. Mr. Hugh O'Beirne, who drew up the report relating to France, has arrived at the conclusion that, taking into consideration the cost of improving the water-ways, which varies from 14,924*l*. to 64,516*l*. per mile, it would have been cheaper and more advantageous to have constructed railways. Mr. Robinson, the reporter for the Netherlands, directs attention to the use of petrol motors for moving the boats, and says that the number of small steamers and tugs employed on the water-ways has immensely increased in Holland, and that water transport seems to be on the verge of a revolution owing to the introduction of the cheap, small and practical petroleum motors which can be fitted to almost every description of craft.

A NEW edition—the third—of "The Figures, Facts and Formulæ of Photography" has just been published by Messrs. Dawbarn and Ward, Ltd. The work has been considerably enlarged, and now has an index.

WE have received a copy of the map and report on the auriferous quartz reefs of Cue and Day Dawn in the Murchison Goldfield of Western Australia, by Mr. W. D. Campbell (*Bulletin* No. 7 of the Geol. Survey, W.A.). The reefs lie in areas of granite, diorite and amphibolite.

THE ninth edition of the well-known "Bloxam's Chemistry," revised and rewritten by Prof. J. M. Thomson, F.R.S., and Mr. A. G. Bloxam, has been published by Messrs. J. and A. Churchill. The work retains its characteristics

as a convenient, though necessarily condensed, account of essential points in inorganic and organic chemistry, and it will doubtless remain a popular volume of ready reference for students.

MESSRS. C. GRIFFIN AND CO. have published a second edition of the late Dr. Alder Wright's work on "Animal and Vegetable Fixed Oils, Fats, Butters, and Waxes," edited and partly rewritten by Mr. C. A. Mitchell. The scope of the work has been extended in the direction of the requirements of practical chemists, more details being given of analytical methods and processes for detecting adulteration of individual oils. The systematic description of tests for adulteration occupies 222 pages, and consists almost entirely of new matter.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. A. F. Putz; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Dr. S. Carew; a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mr. Frank Ree; a Getulian Ground Squirrel (*Xerus getulus*) from Morocco, presented by Mr. D. Seth Smith; two Green Lizards (*Lacerta viridis*), European, presented by Mr. R. E. McLaren; a Chimpanzee (*Anthropopithecus troglodytes*, ♂) from West Africa, two Suricates (*Suricata tetradactyla*) from South Africa, an Indian Coucal (*Centropus rufipennis*) from India, deposited.

OUR ASTRONOMICAL COLUMN.

THE ROTATION PERIOD OF SATURN.—In No. 3900 of the *Astronomische Nachrichten*, Mr. W. F. Denning gives a *résumé* of his observations of the white spots which have been visible on Saturn since July 1; out of thirty-two observing nights only seven were recorded as giving "good seeing." Mr. Denning finds it difficult to reconcile the rotation period observed with that usually given, *i.e.* 10h. 15m., but finds that a period of 10h. 39¼m. agrees with the observations much better. As the mean of many observations of seven of the markings, he obtains the period 10h. 39m. 21·1s., so that if the bright spot discovered by Prof. Hall in December, 1876, near to the equator of Saturn, really represented, in its period of 10h. 14m. 23·8s., the rotation of that part of the planet, there is a difference of 25 minutes between the equatorial and the north temperate currents, the latter being the slower; this is in accordance with the Jovian phenomena, where the north temperate markings take 5½ minutes longer for one rotation than do the equatorial markings.

A collection of the observations, made by various observers, of Barnard's large white spot indicates a rotation period of 10h. 38m. for that region of the planet.

NEWLY DETERMINED STELLAR RADIAL VELOCITIES.—From spectrograms obtained at Potsdam with the spectrograph No. iv., in conjunction with the 32·5cm. refractor, Prof. Vogel has determined the radial velocities of β Arietis, ω Ursæ Majoris, and ϵ Ursæ Majoris. From measurements of the magnesium line at λ 4481, he has found the relative velocity in the line of sight of the components of β Arietis to be between 60 and 70km., of ω Ursæ Majoris about 45km., and of ϵ Ursæ Majoris about 15–20km. (*Astronomische Nachrichten*, No. 3898).

REPORT OF THE CAPE OBSERVATORY.—In his report of the Cape Observatory for the year 1902, H.M. Astronomer, Sir David Gill, refers to several additions and improvements of the instrumental equipment.

The new 24-inch Zeiss objective prism, presented to the observatory by Dr. Frank McClean, F.R.S., is now ready for mounting, and has a refracting angle of 11¼°.

The oppositions of Uranus, Saturn, Jupiter, and Neptune were observed with the heliometer, and 476 observations of α Centauri were made in connection with a redetermination of the parallax of that star undertaken by Messrs. Cookson and Lowinger.

Two hundred and eighty successful spectra of stars ranging in magnitude from 3·5 to 5·5 were obtained with the 24-inch "Victoria" telescope fitted with the "Grubb" objective prism.

In connection with the astrographic chart work 522 triple charts have now been taken, and 434 plates, containing 248,921 stars, have been completely measured up to date.

The geodetic survey of South Africa is being carried out despite climatic difficulties, but the determination of the Anglo-German boundary in south-west Africa has been delayed by the imperative necessity for giving the workers a rest and a change of climate; the whole of the triangulation is, however, complete.

LIVERPOOL ASTRONOMICAL SOCIETY.—The first annual report of this society shows that a successful session has been held. The Society possesses a fine 5-inch equatorial by Cooke and Sons, of York, a 3-inch transit instrument, a sidereal clock, and a valuable library.

Amongst the papers read during the session, and summarised in the report, may be noted the presidential address, entitled "The Nebular Hypothesis," by Mr. W. E. Plummer; "Sun-spots and Terrestrial Magnetism," by Father Cortie, S.J. (a vice-president); and an account of a visit to the Yerkes Observatory by the Rev. R. Killip, secretary of the Society.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A SCHOOL of electricity is to be established in connection with the Harris Institute, Preston. The cost will be defrayed out of a legacy of 2000*l.* left for the purpose of advancing mechanical and electrical engineering by the late Mr. J. Billington Booth, of Preston. Of the bequest, 1000*l.* will be devoted to the electrical engineering department, which will be under the superintendence of Mr. G. E. Gittins.

FROM the calendar for the session 1903–4 of the Bristol University College we learn that, excluding medical students, there were 285 day students during the session 1902–3, and 751 evening students. The subscriptions to the sustentation fund for the same year amounted to more than six hundred pounds; a special fund of 5500*l.* has been completed, and amongst other amounts from various persons and public bodies, the Bristol Town Council has contributed five hundred pounds for fifteen free studentships.

Science announces that Prof. J. Mark Baldwin, of Princeton University, has been called to a new chair in philosophy and psychology in the Johns Hopkins University, where it is proposed to organise a university department in these subjects. Dr. E. W. Scripture, assistant professor of experimental psychology at Yale University, has resigned and is succeeded by Dr. Charles H. Judd. Dr. Scripture is spending the year at Leipzig, where he is carrying on researches on the analysis of speech by means of gramophone records, under the auspices of the Carnegie Institution.

As is customary at this time of the year, we have recently received a number of prospectuses of technical institutions, and to some of them reference has already been made in these columns. The polytechnics of London appear to try, year by year, to make their courses of study more and more attractive to practical workmen as well as increasingly useful. The workshops in them are excellently equipped, and the practical demonstrations and lectures in connection therewith should prove of great benefit in supplying workmen with a knowledge of the scientific principles upon which their particular branches of technology are based. It is gratifying to observe a tendency towards specialisation on

the part of the various polytechnics, and a growing disposition to give prominent attention to the industries in their immediate neighbourhood. Thus at the Northampton Institute in Clerkenwell there are, in addition to many other classes, a department of electrochemistry to meet the needs of the men in the numerous workshops in the district engaged in the electroplating industry, and a horological department for the large numbers employed in clock and watch making. At the Borough Polytechnic there are, besides numerous other courses of study, a special school of bakery and confectionery managed by the Association of Master Bakers and Confectioners, and a branch institution at Bermondsey is concerned with leather manufacture in all its branches. Some other polytechnics, though not perhaps specialised yet to the same extent as those mentioned, have numerous trade classes; at the Battersea Polytechnic, for example, the prospectus shows that mechanical and electrical engineers, men in the building trades, and those employed in technical applications of chemistry, can all find classes designed to meet their requirements.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 14.—M. Bouquet de la Grye in the chair.—The simplicity of the spectra of the kathode light in gaseous compounds of nitrogen and carbon, by M. H. **Deslandres**. The kathode ray spectra of carbon monoxide, carbon dioxide, and acetylene have been studied. In the luminous part already known, and in the first half of the ultra-violet region (λ 400 to λ 300), the kathode light gives nearly the same spectrum as the light from the positive pole, but in the second half of the ultra-violet (λ 300 to λ 200) it gives a characteristic spectrum, a new band spectrum in addition to the five band spectra of carbon already known, characterised by a remarkable simplicity in the arithmetical relations of the bands.—The action of a trace of water on the decomposition of the alkaline hydrides by acetylene, by M. Henri **Moissan**. Dry acetylene gas only reacts with potassium hydride at a temperature of 42° C. or higher; if the gas, however, contains a trace of water, the reaction can take place at the ordinary temperature. This is attributed to the disengagement of heat which occurs when the reaction is started at any one point, which determines a rise of temperature to more than 42°, after which the combination becomes total.—On equations of differences possessing a fundamental system of integrals, by M. Alph. **Guldberg**.—Description of a localised storm, by M. Jean **Mascart**.—On the resistance of *Gasterosteus aculeatus* to changes of osmotic pressure in the surrounding medium, by M. Michel **Siedlecki**.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physicomathematical section), part iv. for 1903, contains the following memoirs communicated to the Society:—

June 27.—Ed. **Riecke**: On the nearly-saturated current in an air-space bounded by two concentric spheres. W. **Voigt**: Contribution to the theory of light for active crystals. On specific optical properties of hemimorphous crystals. Ph. **Furtwängler**: On the construction of a certain *Klassenkörper* (domain).

July 11.—O. **Wallach**: Researches from the Göttingen University Chemical Laboratory, xii. (1) On the transformation of cyclic ketones into bases of nitrogenous ring-systems; (2) on a new cyclic base from methylheptenone; (3) on the behaviour and constitution of menthenone. J. **von Braun**: Contribution to our knowledge of tetravalent oxygen.

July 25.—Ed. **Riecke**: On nearly-saturated currents between two parallel planes.

NEW SOUTH WALES.

Linnean Society, July 29.—Dr. T. Storie Dixson, president, in the chair.—The continental origin of Fiji, by Mr. Walter G. **Woolnough**. Part ii., petrology. The rocks now described fall chronologically into two groups:—(1) a Palæozoic, or even older group, of quartzites, slates, jointed tuffs, granites and quartz-diorites; and (2) a Cainozoic group of andesites, olivine-andesites akin to basalts, "soap-stones," and molluscan and coral limestones.—The bacterial origin of the gums of the arabin group, by Dr. R. Greig **Smith**. x. The pararabin gum of Sterculia. The gum of *Sterculia diversifolia* consists of a mixture of arabin and pararabin. The arabin is produced by *Bact. acaciae*. Another organism, *Bact. pararabinum* n.sp., was isolated from the gummed fruits, &c. Upon solid media and in solutions containing saccharose, dextrose, levulose, galactose, mannite or glycerine, a slime was formed. By appropriate treatment this yielded a pararabin gum which was soluble in dilute acids and insoluble in dilute alkalies. It was not hydrolysed by boiling 5 per cent. sulphuric acid, but by treatment with concentrated sulphuric acid the carbohydrate was converted into arabinose and galactose. The bacterium did not secrete invertase, and in solutions of saccharose formed carbon dioxide, ethyl alcohol, succinic, acetic, butyric and formic acids.—Australian fungi, new or unrecorded, decades v.–vi., by Mr. D. **McAlpine**. A new genus of Hyphomycete is proposed, to include a form parasitic upon the flowering stems of *Lobelia gibbosa*, Labill.; also eighteen species, referable to thirteen genera. *Phoma lobeliae*, B. and Br., and *Seynesia banksiae*, Henn., are recorded.

THURSDAY, OCTOBER 1, 1903.

MRS. MARCET REDIVIVA.

Die Schule der Chemie. Erste Einführung in die Chemie für Iedermann. By Wilhelm Ostwald. Part i., General Considerations. Pp. vii+186. (Braunschweig: Friedrich Vieweg und Sohn, 1903.) Price 4.80 marks.

PROF. OSTWALD is an ingenious man; in his own language, the attribute might be expressed by the adjective "schlau." Having, as he tells us in his preface, published volumes of the greatest importance, and of the widest range, on physical chemistry for the use of investigators in the domains of chemistry and physics, and having next written his work on elementary chemistry for the ordinary student commencing the study of the subject in universities or Polytechnika (a work of which an excellent English translation by Dr. Findlay has been brought out), he now makes an attempt in this very elementary work to reach a larger public, and has written this most amusing book for the use of youngsters about ten to thirteen years of age. The plan adopted is to introduce by means of dialogue some chemical facts concerning hydrogen, oxygen, water, nitrogen, air, and carbon and its oxides, and incidentally to consider the nature of pure substances and mixtures, including solutions, the phenomena relating to change of state, and the behaviour of gases with alteration of pressure and temperature. All these subjects are treated in a philosophical manner, and his own views are incidentally, and one might almost say insidiously, introduced, so as to set the young mind on what he considers to be the right track.

Beginning with the notion of a "Stoff," or "stuff"—a convenient word, inasmuch as the word "Substanz," or "substance," from its derivational point of view, by no means accords with the views of the author—the properties of a stuff—sugar—are considered, and the pupil is made to reject the idea of a "substance" by subtracting properties, and recognising that there is no underlying entity. "You must rid yourself of the idea," the pupil is told, "that there is anything underlying the properties of a thing, which is more real or important than the properties themselves. Formerly, before science had progressed, people held such notions, and our language still retains expressions which almost force us to accept the notions. But when once that error is recognised, it can be avoided." To which the pupil replies that he is afraid that he will have difficulty in getting rid of the old views. "But," replies the teacher, "when you know more chemistry, you will see that you have to do only with the properties of stuffs, and never with their real nature; so that you will forget the incorrect method of expression."

Later on, in talking about the melting point of ice, the teacher defines it as "that temperature at which solid and liquid can exist beside each other"; and the pupil asks, "Then, who made this law?" The teacher answers, "The word *law* is only a way of speaking. It has been found that stuffs behave like this, and they have been compared to obedient pupils who always do what they are told. In science the word law means only that we find that things are related to each other in a certain way; and that is expressed in a general form."

In discussing change of state, the teacher refers to the term "state of aggregation," and explains it by the conception of atoms. He elucidates the word "hypothesis," but declines to accept the atomic hypothesis as an "explanation" of states of aggregation, and suggests the word "Formarten," and this leads to the consideration of differences between the states of solid, liquid, and gas. Having got the pupil to infer that liquids when cooled become solid, and solids when heated melt at definite temperatures, the pupil asks, "What determines these temperatures?" "That is a stupid question. You should rather ask: To what other properties do they show that they are related? It is just as if you were to ask: why are there camels? All that you can ask is, what are the properties of these animals, and how are these properties connected with those of other animals?"

Talking of the combustion of a candle and its disappearance, the pupil says, "But it really vanishes before my eyes." "Yes," says the teacher, "it becomes invisible. But can't it change into something invisible?" "There are no invisible things," says the pupil. "Oho!" replies the teacher. "No," says the pupil, "ghosts and goblins don't exist." "Even they are said to be sometimes visible," answers the teacher. "But can you see the air?" "Hum—no," says the pupil. "But the air is changed by burning. I don't see how." And so the formation of an invisible gas is brought out, and the method of determining its weight.

In considering heat and light produced by combustion, their absence of weight is remarked, and the pupil guesses that they are "forces." The teacher corrects, and explains that what used to be known as force is now known as energy, and that it is defined as "what causes things to change." Stuffs contain chemical energy when they can act on each other and form new stuffs, and part of their chemical energy takes the form of heat or light, and sometimes of electrical or mechanical energy. The pupil is made to throw out suggestions on the conversion of one form of energy into another, and his own energy is traced to the chemical energy he takes in as food. "But I am often hungry, even when I do nothing," says the pupil. And it is explained that his temperature has to be maintained, and that if he likes he can produce light by rubbing two pieces of sugar together, and electricity by rubbing sealing-wax with a cloth. In this way an idea is given of transformation and equivalence of energy.

Compounds and elements are next considered, and the pupil asks the natural question, "Are the constituents actually in the compound or not?" "You haven't considered your question. A compound is not a bag or a box in which something can be contained.

If you mean by 'in' that the constituents can be got out again by appropriate means, then they are 'in.' But you mustn't suppose that the constituents are locked up in the compound, somehow or other, with all their properties."

So far, it might be supposed that this system does not differ from the "heuristic" system which has been so much in evidence lately. But that is not so. There is no attempt made to prove anything exhaustively, or to let the pupil do so; as a rule, the experiment is made by the teacher, and the pupil is sometimes allowed to repeat it. A little later, in considering the classification of certain elements, the pupil remarks, "But it appears to me not very scientific to take anything on trust that I can't prove." To which the teacher answers, "You will be able to prove this, when you know more chemistry."

Teleological "explanations" are conspicuous by their absence. Yet when the pupil inquires, "Why have most chemical stuffs such a nasty smell?" he is told, "If they hadn't, we shouldn't notice them, and we should have our skin hurt and get a cold in the head." This is not quite consistent.

That the cost of an article depends on the amount of work put into it is illustrated in the case of aluminium, the compounds of which, such as clay, have almost no value, while the metal is costly. The pupil inquires, "Can the work be got out of the aluminium again?" "Yes," says the teacher, and shows the pupil the reduction of iron oxide by means of powdered aluminium.

The pupil is constantly afraid that he will not be able to retain in his head all that he is taught. But he is comforted by being assured that he will have to go over the subject again, and that he really knows a good deal. These little remarks are very natural, and the answers are most judicious. But we agree with the pupil when he says "Chemistry is a frightfully big subject!" Indeed, he is told that no one man knows all about oxygen, in reply to a remark, flattering to the teacher, "But surely you know all about this!" Much is in writing, however; and he then asks, "Is everything in these books right?" "Most of it," he is assured; and what is best about scientific books is that no one intentionally tries to deceive.

The action of iron oxide in accelerating the evolution of oxygen from potassium chlorate is likened to that of oil on a rusty machine, or of a whip on a horse. And so catalytic phenomena are introduced. There are many such digressions, and often the teacher lets them go on to a certain point, and then harks back to the actual subject of the lesson.

The pupil is introduced to the idea of mass-action after he has made the natural remark, "But iron is stronger than hydrogen, and takes the oxygen from it." "First iron was stronger than hydrogen, and afterwards, hydrogen stronger than iron. That's surely a contradiction." "The contradiction is owing to your looking at the reason of chemical changes as a mechanical power or force; such a force has never been proved to exist or measured." And when pressed, the teacher fences thus, "A man can carry a good lot of water; but a larger quantity of water can carry a man." "So you mean, chemical change depends on which stuff is present in largest quantity." "That's about it; but we must go back to hydrogen." And the digression closes.

The laws of recurrence and of continuity are illustrated and formulated; the existence of allotropic forms of carbon is referred to the difference in their content of energy, and the source of all terrestrial energy, except that of the tides, is traced to the sun, due attention being paid to the reciprocal action of plants and animals.

One admirable feature of the work is that the pupil is allowed to fall into all kinds of traps. For example, he calculates the conversion of the Fahrenheit into the centigrade scale in every conceivable wrong manner before he finds the right use of the "32"; and after he has seen experiments on the compressibility of air and the observations have been written down, he is made to find the law. The method is so good that it is worth quoting. "Suppose you have ten apples: some in your pocket, some in your hand. Call the number of apples in your pocket t, and those in your hand h. Now you know you can calculate t if you know h, and h if you know t. Why is that?" "Because I know that together they make 10." "You see then $t+h=10$; and you can calculate t if you know h, and *vice versâ*." "That's neat. But I could have done that without a formula." "Yes; but only because the formula is so simple. Now try if your pressures and volumes can be calculated as simply." "Let me see:—$75+100=175$; $62.5+120=182.5$; $60+150=210$. No; the sum is always getting bigger." "The sum formula doesn't fit, then. You might have seen that you can only add like things, such as apples to apples: you can't add a pressure to a volume." "What sort of formula can it be, then?" "If p gets bigger, v gets smaller. What kind of combination of p and v will give that result?" "Probably a whole lot." "Quite true; but not many simple combinations. Try the simplest you can think of, besides the sum." "Perhaps the product. If one factor gets smaller, the other must get larger, so as to make the same product." And so he gets it out.

It must be allowed that this is excellent teaching. The whole book is so lively and conversational, and withal so amusing, that it well deserves reading by those of an older generation. It is probably likely to be more useful to teachers than to pupils, for it will serve them as a guide. As the publishers say in their preface, the standpoint from which the book is written is the most modern one; some, perhaps, may consider it too modern, and that some of the doctrines expounded are as yet not in general circulation, and perhaps never will attain universal consent. That is a matter of opinion, and, of course, the author believes that they will. Anyhow, he has taken advantage of the lessons of all missionaries—get hold of the children, and the doctrines will spread. And if an attractive book can help their dissemination, this is one.

W. R.

EXPERIMENTAL EMBRYOLOGY.

Lehrbuch der vergleichenden Entwicklungsgeschichte der wirbellosen Thiere. By Profs. E. Korschelt and K. Heider. Allg. Theil, Erste Lief., Erste und Zweite Auflage. Pp. x+538. (Jena: Fischer, 1902.) Price 14 marks. Zweite Lief., Erste und Zweite Auflage. Pp. 539 to 750. (Jena: Fischer, 1903.) Price 5.50 marks.

ZOOLOGISTS who are already acquainted with the "special" part of Profs. Korschelt and Heider's "Comparative Embryology" will have been anxiously looking forward to the publication of the present volume; we are sure that they will in no wise be disappointed. At present we have only a first instalment, but even this contains an enormous amount of matter, including, as it does, a review of all the recent work on the physiology of development, besides a complete history of the sexual cells.

The latter portion, we may as well say at once, should have come first. Logically, the phenomena of what Roux has called "Vorentwickelung" are more closely related to descriptive than to experimental embryology; and if the order of the first and second portions had been reversed, the authors would have been able to include under a common discussion the kindred problems of ontogeny and heredity.

Of this second portion we have no space to treat at length. It must suffice to say that the student will find here an excellent *résumé* of all that is known on the structure, maturation, and fertilisation of the germ-cells. Criticism is hardly called for; but the definition of the mammalian placenta (p. 292) is out of date, and we should have liked to have seen a less fragmentary account of the maturation phenomena in plants. On the other hand, the difficult subject of maturation is treated with remarkable lucidity, while the attitude of the authors towards the vexed questions of qualitative reduction, and, in the next chapter, the individuality of the centrosome, is admirable in its judicial impartiality.

By far the most important part of the book, however, is the first section—that dealing with the work of the new school of experimental embryologists. The problems at issue are sharply defined in an introductory preface. As the authors rightly remark, ontogeny consists of a series of changes in which every stage is —in the strictest sense of the word—a cause of that which immediately follows. The business of the experimenter is to analyse the phenomena, to determine what is due to external, what to internal factors, and, in respect to the latter, how much is attributable to the initial structure visible or invisible of the ovum, how much to the mutual interaction of the parts that are successively developed.

With this object in view the ground is first cleared by a discussion of the external factors, beginning, quite rightly, not only from a logical, but from a historical point of view, with the pioneer work of Pflüger on the influence of gravity on the segmentation of the frog's egg. An account of the subsequent, and consequent, work of Born, Roux and Hertwig naturally follows. Next are described the effects of heat, light, and physical and chemical changes in the gaseous and liquid environment, and lastly, a little out of their proper place we think, the few experiments that have been made to determine the influence of electricity and magnetism, and of mechanical disturbances on the course of development.

It is a pity that the authors have not introduced at this point a critical summary of the results. It is of the first importance to decide whether these external conditions constitute a series of "specific" or merely "indifferent" causes. Hertwig's artificial production of monsters by heat and salt solutions would have made an apt text for an interesting essay on "Abhängige Differenzirung," and would have served to carry on the reader to the next chapter, "Das Determinationsproblem," in which we are taken straight to the heart of the "Streitfrage" of modern embryology.

While the restoration of the eighteenth century doctrine of preformation to a prominent place in embryological literature dates from His's theory of "Organbildende Keimbezirke," the attempt to gauge its worth experimentally begins with Roux's work on the production of half-embryos from a single blastomere of the frog's ovum. Roux's results, or rather his interpretation, were wholly in favour of this doctrine; their value has, however, been diminished by Hertwig's criticism and Herlitzka's work on the newt. The Amphibia, indeed, together with Amphioxus, the Teleostei, and the Cœlenterata, stand, so far as the "regulative" capacity of their ova are concerned, at one end of a series, at the other extreme of which are forms, the Ctenophora and Mollusca, the isolated blastomeres of which are incapable of developing into anything but partial larvæ. The intermediate position is occupied by the Echinoderms and Ascidians; here the segmentation of such blastomeres is partial, but a whole larva is ultimately formed. Any general theory, therefore, of the necessary predetermination of the parts of the organism in the cytoplasm of the ovum is out of the question. A similar criticism, based on the pressure experiments of Driesch (Echinus) and Hertwig (Rana), is applicable to the nucleus, and, of course, cuts at the root of the "Mosaik-Theorie."

The failure of the attempt to demonstrate a preformed, though invisible, structure in the ovum throws us back on epigenesis, and compels us to search for the internal causes of ontogeny in the mutual interaction of the parts as they are formed. To deduce such interaction, however, from the known functions of cells is a very different matter; but such facts as are significant for the purpose are brought together in the third chapter under the heading of "morphogenetic cellular processes."

The general discussion of the whole problem is reserved for a separate appendix. The authors display a commendable caution in reviewing the theories of Weismann, Hertwig, and Driesch. This caution, indeed, is characteristic of the whole book, and will certainly win the approbation of every embryologist who is content to say with the authors, "wir werden die Speculation nie entbehren können, aber es wird die Aufgabe sein, das ihr zu Grunde liegende Beobachtungsmaterial möglichst zu erweitern."

THE STUDY OF ECONOMICS.

The New Cambridge Curriculum in Economics. By Alfred Marshall. Pp. 34. (London: Macmillan and Co., Ltd.) Price 1s. 6d.

"IN the United States of America, in particular, and in Germany, the subjects of Economics and Political Science are commonly represented by a strong and numerous staff, and afford the main route by which large numbers of students obtain University Honours. . . . England, on the other hand, which long held undisputed leadership in Economics, has suffered in recent years from the lack of adequate provision for the study of that subject at the Universities."

From all sides evidence is forthcoming of attempts to remedy this defect. There is a widespread revival of interest in the subject-matter of economics, and a corresponding determination on the part of its teachers to seize the opportunity to place the subject on firmer and broader foundations in the schools. Development has taken place in several directions. The "monarchical" supremacy of Mill was broken up in the 'seventies by Jevons, Cliffe Leslie, Bagehot and others. In 1890, Prof. Marshall published the first edition of the first volume of his "Principles." In the last three decades of the nineteenth century economics lost much of its insularity on the one hand, and gained in human interest on the other. The work of economists in Germany, Austria, and the United States broadened the horizon and tested the conclusions of the native researcher by an appeal to a richer experience. The advent of the working-classes to political power and the influence of a cheap Press kept social questions ever prominent, and ideas of material well-being, efficiency and comfort occupied an increasing part of economic reflection. The writings of Mr. Charles Booth, Mr. Sherwell, the Rowntrees, Mrs. Bosanquet, and other investigators have recently enjoyed a wide currency in various pure and diluted forms, and have driven many to study economics in a systematic fashion. Municipal enterprise has had a similar effect. With all these writers and students the ruling motive has been the desire to lessen poverty and to improve the quality of human life. In the book before us, Prof. Marshall voices this practical aim in a significant passage:—

"The motto of Sidgwick's 'Political Economy' is: 'Things are in the saddle and ride mankind.' What had made men become economists, in three cases out of four, was the belief that in spite of our growing command over nature it is still things that are in the saddle, still the great mass of mankind that is oppressed—oppressed by things. The desire to put mankind into the saddle is the mainspring of most economic study."

But not only has there been a quickening of interest in the condition of the people at home. The sense of imperial responsibility has deepened. Schemes of federation, sentimental and economic, have filled the air. The competition of advancing rivals has made itself felt in our markets. We have been driven to ask with Sir Robert Giffen, Is the central force of the Empire, the power to hold it together, increasing as rapidly as the Empire generally? It would be fatal while widening the circumference to weaken the centre; to fix the spokes in a rottening hub. The Empire drains the home country of valuable administrative energy of which it never has too much for high social efficiency. And in business, managers of elastic minds, wide outlook, and great organising power, in command of large masses of capital are still relatively scarce.

It is unnecessary to point out how the controversy of the last few months has impressed impartial observers with the complexity of practical economic problems, and with the urgency of studying these problems in an atmosphere uncharged with the passion of parties. The people are suddenly confronted with political choices of international moment, and their instructors are too often politicians and pressmen whose hastily acquired information displays all the symptoms of indigestion. Can the universities do something to provide the nation with more capable administrators for central and municipal government, and for the diplomatic and consular services? Can they train men for the supreme positions in the industrial and commercial world? Prof. Marshall's booklet tells us that the University of Cambridge has answered in the affirmative by instituting a new honours school in economics and associated branches of political science, and it supplies us with the ideas which have guided the Senate in framing the curriculum. This is not the place to make detailed comparisons with the similar courses newly arranged in the Universities of London, Birmingham, and Victoria. Speaking broadly, the Cambridge curriculum makes its appeal to advanced students who will be called upon to decide main questions of policy in politics and industry rather than to subordinates who wish to be equipped in the technique of administration and business. It is theoretical and scientific rather than practical and professional. Only shallow thinkers will infer that, on this account, it is out of touch with reality. Prof. Marshall is under no illusion on this point. His little book is a plea for a training which, while it fits a man for his duties as a citizen, never loses sight of the practical demands made upon the employer and the civil servant in these strenuous days. Prof. Marshall himself is his own best argument, for these pages mirror the wisdom and fairness and humility and idealism of a life devoted to economic study.

T. J.

OUR BOOK SHELF.

A Treatise on Electromagnetic Phenomena and on the Compass and its Deviations Aboard Ship. Vol. ii. By Commander T. A. Lyons, U.S. Navy. Pp. vii+582. (New York: Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 25s. 6d. net.

SOME forty years ago there appeared the second edition of the "Admiralty Manual for Deviations of the Compass," and as the compass is "the soul of the ship," so the teaching of that manual remains the soul of the numerous works on the subject which different maritime countries have since published, albeit that chapters on cognate subjects may have been added thereto. Naturally America has provided her quota, and this book is her latest contribution.

This second volume of the treatise, which is devoted to the "compass and deviations aboard ship," can hardly be fully mastered until after reading the first volume, but it is in a great measure complete in itself, especially to those who have already some knowledge of terrestrial magnetism. All will agree with the author of this book when he insists upon the necessity for every navigator knowing as much as possible about his compass and that magnet—his ship—which is ever in antagonism to the earth, which does its best to direct the compass to magnetic north.

Of the five parts into which this volume is divided, part ii. treats of the manufacture of the liquid compass (the only kind in use in the U.S. Navy), giving in full detail the principles of magnetism and mechanics connected with its construction and use afterwards.

In part iii. the ship is shown to be a magnet by experimental magnetic surveys of ships illustrated by diagrams. The physical representation of the theory of the deviation of the compass is fully given, but decided exception must be taken to the instructions for determining the position of the compass after the ship is launched. It is then too late, and the experienced Superintendent of Compasses and the constructors should long before have agreed upon a place for it in the ship's drawings, and afterwards worked in harmony to keep iron fittings at a proper distance.

Part iv. treats of the mathematical theory of the deviations of the compass, and here, as in other of the mathematical investigations he gives, the author gives valuable assistance to those who are not skilled mathematicians by "filling up those gaps in the sequence of the formulas that often yawn forbiddingly."

On the question of compensation of the deviations of the compass, to which part v. is devoted, we have the least satisfactory part of the book. Thus the formula for correcting the heeling error with spheres in place is very convenient in practice, but not mathematically correct. The instructions for compensating the secondary part of the quadrantal deviation known as coefficient E by spheres are incorrect. Again, the residuary quadrantal deviation, after compensation, is described as "practically constant the world over"; but this is certainly not so in the example given of the "Machias," where, between Aden and Pechili Strait, the quadrantal deviation differed nearly 3°, as might be expected where soft iron correctors are placed near the long powerful needles of the Ritchie compass. Further, the Flinders bar will not compensate any important part of the heeling error due to soft iron as here proposed.

There is much to recommend this book to the student, both as regards the mathematical treatment of the subject and for its numerous explanatory diagrams. Its weak point lies in the parts relating to the application of theory to practice, which require modernising and a careful revision. E. W. C.

Comité international des Poids et Mesures. Procès-Verbaux des Sciences. Deux. Série. Tome ii. Session de 1903. Pp. 170. (Paris: Gauthier-Villars, 1903.)

THE *Procès-Verbaux* recently issued by the Comité international des Poids et Mesures refers to their meeting at Paris in April last. The committee included Dr. W. Foerster (president), Prof. P. Blazerna (secretary), Dr. Benoit (director of the bureau), and MM. Arndsten, D'Arrillaga, de Bodola, Egoroff, Gautier, Hasselberg, and von Lang. Their proceedings mainly had reference to the work at their bureau (Pavillon de Breteuil, Sèvres, Paris) for the current year, including the consideration of the annual expenses of the committee (100,000 francs).

The committee lament the death of their distinguished colleague, Prof. A. Cornu, on April 12 last, and also of Dr. H. von Wild, September 5, 1902, an honorary member of the committee. They announce the unanimous election on the committee of M. E. Mascart, and of Dr. A. Chappuis as an honorary member. Count de Macedo (Portugal), Dr. A. Michelson (United States), and Mr. H. J. Chaney (Great Britain) were unable to attend the present meeting.

During the past year the verification of length standards at the bureau included standards for the Board of Trade, the Education Department, the National Physical Laboratory, and other authorities in England. On the application of the British Government, indeed, an important work was undertaken by the committee, that of the graduation and verification of a new linear standard of the metre and yard, a standard made of iridio-platinum, X section.

Although the scientific work of the bureau last year does not appear to have covered a wide field, it has followed important paths, as in some investigations (Appendix iii.) as to the linear expansion by heat of platinum, iron, nickel, steel, glass, and quartz, and the results reported by the committee are now probably among the most authoritative of such thermometric investigations. Dr. C. E. Guillaume also adds (Appendix i.) an essay on the theory of the alloys of steel and nickel, and M. E. Sauvage (Appendix ii.) an account of an international series of screw-threads, based on metric measure, as formulated at a congress held at Zürich in 1898–1900, a series which appears to be now adopted for engineering purposes in France.

Flora of the Island of Jersey. By L. V. Lester Garland. Pp. xv+205. (London: West, Newman and Co., 1903.)

ALTHOUGH in most parts of the country a botanist can generally make a goodly collection of plants within a day's journey of his residence, there is always a desire to visit those localities in the British Isles which have a special flora of their own. Such are the Scotch mountain ranges, the counties of Devon and Cornwall, and by no means the least interesting to the southerner, the Channel Islands. On these visits it is a great boon to have a flora which will give the information where certain plants may be sought. For Guernsey and the adjacent islands of Alderney and Sark, Mr. Marquand has published records, and no less welcome is the compact little book which Mr. Lester Garland has compiled on the flora of Jersey. The book presents one essentially new feature, since the system adopted is that of Engler. Some excuse is offered for the innovation, but there can be no question that Engler's system is bound to supplant that of the "Genera Plantarum," and considerable credit is due to the author for acting up to his convictions. In conformity with this change some of the generic names have been altered, and Erucastrum, Lobularia, and Parentucellia take the place of others more familiar; for the same reason *Tillaea muscosa*, L., becomes *Crassula Tillaea*, Lester. No trouble has been spared to test uncertain or critical species and records, and the notes on these are sound and practical; also distinction is made between native plants and aliens. The genus Centaurea serves to illustrate the author's caution and care; he declines to split up *Centaurea nigra* into uncertain varieties, queries *Centaurea scabiosa*, accepts *Centaurea scabra*, and classes the species cyanus, paniculata, calcitrapa, solstitialis among the aliens. The last few pages are devoted to an account of the geographical distribution and affinities of species, and these complete a book which, in addition to its convenient form, is to be recommended for its extremely practical and scientific value.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Radium and the Geological Age of the Earth.

AT various times since the appearance of Mr. W. E. Wilson's suggestion (NATURE, July 9) that the presence of radium in the sun might enter as an important factor in contributing to solar radiation, I had intended directing the attention of geologists to the direct application of this suggestion to the views entertained as to the extent of geological time. Absence from home led me to defer doing so.

Prof. Darwin has in a large measure anticipated my remarks (NATURE, September 24) by pointing out that the age of the sun can no longer be determined from dynamical considerations if supplies of energy from radio-active bodies go towards maintaining solar temperature. It will have to be shown, indeed, that such bodies do not enter even as a small ingredient into solar stuff (see Mr. Wilson's letter), or else that they do not retain their heat-generating properties at high temperatures. So far as experiments go—especially on the radio-active emanations—the latter contention seems improbable.

The gross dynamical supply of solar heat must no longer be regarded as affording a major limit both to solar age and geological time.

But there was one other good argument from the physical side opposed to the geological estimate of the earth's age: that derived from the observed gradient of temperature from the earth's surface inwards. Prof. Perry has pointed out (NATURE, Jan. 3, 1895) that an increase of conductivity towards the interior would lead to extension of Lord Kelvin's minor limit of time since the *Consistentior Status*. Quite equivalent to increased supplies from the interior would be a source of supply of heat in every element of the material. The establishment of the existing gradient of temperature inwards may, in fact, have been deferred indefinitely during the exhaustion of stores of radium and similar bodies at greater or shallower depths. In fact, we find these bodies here; the only question is as to how much of them exists, or at one time existed, in the earth's interior.

The remaining physical objection (that based on tidal retardation) being condemned for good reasons, it would appear that the estimates derived from physical speculations are now subject to modification in just the direction which geological data required. The hundred million years which the doctrine of uniformity requires may, in fact, yet be gladly accepted by the physicist. J. JOLY.

Trinity College, Dublin, September 26.

Some Overlooked Zoological Generic Names.

IN the course of my reading, I have found a few generic names of animals which have been overlooked in the preparation of the invaluable "Index Zoologicus," recently published by the Zoological Society of London. It may be as well to direct attention to them, so that zoologists may take note of them, and avoid duplicating them for other animals. They are:—

Callobombus, Dalla Torre, Cat. Hymenop., x. p. 503 [nom. emend.].

Cephalacanthus, Lapworth, tenth Ann. Rep. U.S. Geol. Surv., p. 641 [nom. præocc.].

Fiorentinia, Dalla Torre, Cat. Hymenop., x. p. 334.

Helenia, Walcott, *Proc.* U.S. Nat. Mus., 1889, p. 39 [not Helena, Hartm., 1881].

Holmia, Matthew, 1890 (subg. of Olenellus).

Isoxys, Walcott, tenth Ann. Rep. U.S. Geol. Surv., p. 625.

Leptomitus, Walcott, *Bull.* U.S. Geol. Surv, 1886, p. 89.

Linnarssonia, Walcott, *Amer. Journ. Sci.*, 1885, p. 114.

Olenoides, Meek, *cf. Amer. Journ. Sci.*, 1888, p. 165.

Protopharetra, Bornemann, *Geol. Zeitschr.*, 1883, p. 274.

Protocaris, Walcott, *cf. Bull.* U.S. Geol. Surv., 1886, p. 148.

Protospongia, Salter, *cf. Bull.* U.S. Geol. Surv., No. 30, p. 90. [I suppose Protospongia, Kent, 1880, is different.]

Authorities will differ as to whether Helenia should be changed because of Helena. I think it should not; the difference of a letter is enough to constitute it a distinct name. T. D. A. COCKERELL.

Colorado Springs, Colorado, U.S.A.

Height of the Atmosphere Determined from the Time of Disappearance of Blue Colour of the Sky after Sunset.

THE extreme height of our atmosphere has been determined heretofore from the observation of meteors, which begin to glow when the friction becomes sufficiently intense to vaporise the materials of which they are composed. This method is very satisfactory from most points of view, and will perhaps continue to be used by astronomers. Nevertheless, I think it worth while to direct attention to another method, which is more simple, and which, I believe, will be found equally accurate. It consists in observing with the naked eye the gradual disappearance of the *blue* colour of the sky as darkness comes on. It is surprising how accurate a person of good sight can make this observation when the atmosphere is perfectly clear. The time of sunset should be noted, and the time of the last sensible blue of the sky. With the data in the Nautical Almanac a simple computation by spherical trigonometry gives the depression of the sun at the instant the blue fades out into black, and we at once calculate the height of the illuminated particles overhead. The following are the results of some observations taken by the writer at Annapolis, Md. :—

1903.	Height.	Remarks.
August 10 ...	125 miles ...	A trace of blue remaining.
,, 21 ...	130 ,, ...	Blue just vanishing.
,, 22 ...	133 ,, ...	Sky just black.
,, 23 ...	135 ,, ...	Blue has disappeared.
,, 24 ...	132 ,, ...	Blue vanishing.

Average height, 131 miles.

The uncertainty of this value will probably be between five and ten miles.

The instant the blue disappears from the sky is a little indefinite, owing to the gradual thinning out of particles in the upper air sufficiently dense to reflect blue light which can be seen by the eye against a black night sky, but I have not found this indefiniteness so great as might be expected. It does not seem to lead to greater uncertainty in the height of the atmosphere than the method depending on meteors.

Prof. Newcomb, in his "Popular Astronomy," p. 397, says that, from observations taken at Richmond and Washington during the meteoric shower of November 13, 1867, "the general result was that they (the meteors) were first seen at an average height of 75 miles, and disappeared at a height of 55 miles. There was no positive evidence that any meteor commenced at a height greater than 100 miles. It is remarkable that this corresponds very nearly to the greatest height at which most of the brilliant meteors are ever certainly seen. These phenomena seem to indicate that our atmosphere, instead of terminating at a height of 45 miles, as was formerly supposed, really extends to a height of between 100 and 110 miles."

According to Lord Rayleigh's theory the blue colour of the sky is due to reflection of sun-light from minute particles of oxygen and nitrogen in the upper layers of our atmosphere. This theory receives its most striking confirmation from the long duration of the blue colour after sunset, showing the great height of the particles which scatter the blue light. There can, I think, be very little doubt that our atmosphere extends to a height of about 130 miles.

Washington, D.C., September 1. T. J. J. SEE.

The Lyrids of 1903.

BEING absent I did not see the letter on the Lyrids of 1903 at the time of its appearance in NATURE of July 23. The Lyrid maximum occurred this year, it would seem, on the night of April 22, or a day later than an important display observed by Mr. Denning on April 21, 1901. The night of April 22 happened to be overcast here. There was a fair amount of meteoric activity seen by the present

writer and other observers on the night of April 19, several brilliant meteors having been observed. If the computed time of the maximum for that night be correct, viz. 10h. 30m., it would not, of course, have been possible for observers situated near the longitude of Greenwich to witness the display in its entirety.

The Lyrid activity on the night of April 21, judging from Mr. Alphonso King's letter, appears to have been somewhat exceptional, and scarcely inferior to that observed on April 22 It may be interesting to note that the well-known continental observer, Prof. A. A. Nijland, states that the night of April 19, as well as that of April 20, was almost constantly and entirely overcast, and that not a single Lyrid was observed at Utrecht in 1903, though the night of April 21 was both clear and moonless. This negative result might have been anticipated from the forecast which appeared in NATURE last April. JOHN R. HENRY.

Dublin, September 21.

Glow-worm and Thunderstorm; also Milk.

IN the *Daily News* of July 14 is printed an observation by a Mr. Haswell, of Handsworth, which bears the marks of genuineness, that during a thunderstorm a glow-worm extinguished its light for a second or a second and a half before each flash, relighting at an equal interval after the flash. May I ask if this has been noticed by anyone else?

It may also be worth while for someone to examine whether radium can assist milk to turn sour, or can otherwise influence organic processes of that kind.

OLIVER LODGE.

ILL-HEALTH OF THE RAND MINERS.[1]

THE two official reports described in the footnote are not pleasant reading; it seems that the War Office is not the only culprit with regard to South African affairs, for the waste of life among the Transvaal miners from disease and accidents may fairly be described as appalling. But here, as in the case of the War Commission, the Briton is not afraid to wash his dirty linen in public, and for this he must be commended. The remedy for an ill will be discovered most speedily, if the symptoms are proclaimed widely and discussed freely.

The first document tells us that the death-rate among the natives employed at the mines on the Rand is 42 per 1000, which is extremely high. To see exactly what this figure means, we should compare it with the mortality rate of males of like age and occupation in this country; and no one can say that too favourable a case is taken if we choose, as a standard, the Cornish miner, who notoriously is a great sufferer from the ills which pertain to work below ground. Unfortunately, the official report does not state the mean age of the Rand miners, but it may be fairly assumed that the majority are young, and probably no great error would be made if their ages were taken as ranging from 25 to 35. In the years 1890–92 the mean annual death-rate of Cornish tin miners of 25 to 35 years of age was 8.06 per 1000, and for the men of 35 to 45 it rose to 14.32 per 1000. In brief, the death-rate of the natives employed at mines on the Rand is five times as much as that of the Cornish miners for the life-period 25 to 35, and nearly three times that of the men in the life-period 35 to 45.

The endeavour to cast some of the blame upon the natives themselves by saying that they fail to take ordinary common-sense precautions is ungenerous on the part of the author of the report. In matters of hygiene, the natives must be regarded as children and treated as such. The blame for the ill-health of the native must in the main lie at the door of the British employer. It is satisfactory, however, to learn that the present heavy death-rate on the Rand is regarded as exceptional.

The second document is a Blue-book containing the report of a Commission appointed by Lord Milner to inquire into the disease commonly known as miner's phthisis. Judging by the facts and figures brought forward, the inquiry has taken place none too soon. The Commissioners report "that the disease prevails to a very great extent, and that a high mortality is due to it." Carefully prepared medical evidence shows very plainly that the malady is silicosis pure and simple, a dust disease. The miner inhales sharp, angular particles of quartz, and these cause such irritation that the lung tissue undergoes a change and gradually becomes incapable of carrying on its respiratory functions. At the end of a few years, often only six or seven, so large a proportion of the lungs is rendered useless that the man dies. The age at death of many of the victims is only about 35 years. In the majority of cases there is no tubercular phthisis added to the silicosis. As might be expected, the men working rock drills are the greatest sufferers; and especially in places where the holes are bored upwards without any water.

The remedies suggested by the Commissioners are sprays and jets of water to prevent and keep down the dust, and some of the witnesses advocate the use of respirators, which are already being employed to a certain extent. The Commissioners are of opinion that experience is needed before deciding how water can be best applied.

Though dust is the worst evil affecting the miner on the Rand, it is not the only one. Analyses show undesirable proportions of carbonic oxide in what is called "normal mine air under ordinary working conditions." This noxious gas is generated mainly by the dynamite and other explosives, but also in some cases by heat acting upon the lubricant during the compression of the air used for working the drills. Mine-managers are often unaware of this latter source of danger. Mr. E. Hill, in a paper read before the American Institute of Mining Engineers, puts the matter very plainly by saying, "Workmen at the front, instead of receiving pure, cool air from the exhaust of the drills or other machines, breathe a foul, stupefying, and sometimes fatal, mixture."

The Transvaal Commissioners deserve much credit for the painstaking inquiry which they have made, and the lessons taught by it should be taken to heart by English mine-owners, for both Dr. Ogle and Dr. Tatham in their well-known reports have pointed out, that the Cornish tin miner is a great sufferer from his dust-producing occupation.

"Report of the Miners' Phthisis Commission, 1902–1903, with Minutes of Proceedings and Minutes of Evidence." Pp. 147 folio and 7 appendices. (Pretoria, 1903.)

PHOTOGRAPHY AT THE NEW GALLERY.

THE forty-eighth annual exhibition of the Royal Photographic Society is, in general arrangements, much like its predecessors, and shows very little evidence of this being the jubilee year of the Society. In the scientific and technical division the only difference that we notice is the reappearance of several exhibits that have been seen before, and the presence of a few isolated frames of examples from the Society's own collection. We understood that the Society's fine historical collection was to have been on view in its entirety, and feel much regret that advantage has not been taken of this opportunity for its display.

The fact that many of the exhibits are old and already well known gives especial value to the present

collection, and that value would have been much enhanced if the scientific section had been subdivided into definite sections, and the order in the catalogue had corresponded to the order on the walls, as we have previously advocated. But the student will be well repaid for the trouble that is imposed upon him of sorting out the exhibits for himself.

Telephotography, or, as we prefer to call it, large-image photography—for the only function of a telephotographic lens is to enlarge the image before it falls upon the sensitive surface, and whether the original image is small by reason of the distance of the object or because of its size makes no difference—is better represented probably than ever before. The well known "Mont Blanc," by M. Fred. Boissonnas, is on view again, also an early telephotograph by the late Prof. W. K. Burton, of interest because of its age. But the most striking and new applications of this kind of work are shown by M. Fred. Boissonnas of enlargements of telephotographs. He gives several examples in sets of three:—(1) a photograph with an ordinary lens; (2) with a telephotographic lens; (3) an enlargement of the latter, the proportional sizes being approximately as 1 : 5 : 24. Thus a measurement of one inch on the first becomes two feet on the last, and the detail, vigour and general quality of the enlargements are surprising, and demonstrate the fine quality of the image given by the telephotographic lens.

The gradual changes that take place during rapid movement or slow development are well represented by three new series. Sixteen radiographs showing the various stages in the incubation of a pigeon's egg, by Mr. M. W. Martin, enable one to trace the process very clearly, the first appearance of blood vessels and of the beak being quite marked, and the final packing of the two parts of the shell together ready for removal from the nest by the old bird fitly completes the series. Mr. Martin also exhibits a beautifully made series of forty radiographs illustrating the evolution of the common frog, appropriately finishing with an old frog which has broken its leg. The life-history of a splash is well shown by Mr. A. C. Banfield in a series of thirty-six photographs.

Colour work is not so much in evidence as it was at the last two or three exhibitions. We have no opportunity of judging whether any appreciable advance has been effected, because in no case is the original object shown with the photograph. For this reason many of these exhibits have no value, for we do not need at the present day any proof that photographs in colour can be produced.

Photomicrography is well represented. The student will probably be specially interested in Mr. Spitta's "small garden spider," ×20, taken with a 50mm. planar, as a fine example of low-power work; the fourteen photographs of test objects, ranging up to a magnification of about 4300, also by Mr. Spitta, and Mr. Albert Norman's series of photographs of different bacilli.

We have not space to do more than mention the fact that the exhibition includes astronomical and spectroscopic photographs, as fine a series of photographs from balloons as, probably, has ever been brought together, photographs of many kinds of animals, birds, reptiles, insects, fishes, flowers, and plants; photographs in mines and quarries and dark factories, illustrations of waves and ripples and lightning, and many splendid reproductions by many different processes. The science of photography itself is represented by photomicrographs of film sections by Mr. Edgar Senior, including multiple films, and a Lippmann's colour photograph showing a very large number of layers of deposit due to the stationary waves, and Mr. Watkins's demonstrations of the validity of his time method of development.

NOTES.

THE fund established by Mrs. Elizabeth Thompson, of Stamford, Connecticut, "for the advancement and prosecution of scientific research in its broadest sense," now amounts to 26,000 dollars. As accumulated income will be available in January next, the trustees desire to receive applications for appropriations in aid of scientific work. Preference will be given to those investigations which cannot otherwise be provided for, which have for their object the advancement of human knowledge or the benefit of mankind in general, rather than to researches directed to the solution of questions of merely local importance. Further particulars can be obtained from the secretary of the Board of Trustees, Dr. C. S. Minot, Harvard Medical School, Boston, Mass., U.S.A. It is intended to make new grants in January, 1904. Decided preference will be given to applications for small amounts, and grants exceeding 300 dollars will be made only in very exceptional circumstances. The following list of grants for 1902 has not previously been recorded:—125 dollars to Dr. F. T. Lewis, Cambridge, Mass., for investigation of the development of the vena cava inferior; 150 dollars to Prof. Henry E. Crampton, New York, for experiments on variation and selection in Lepidoptera; 100 dollars to Prof. Frank W. Bancroft, Berkeley, Cal., for experiments on the inheritance of acquired characters; 250 dollars to Prof. John Weinzirl, Albuquerque, N.M., for investigation of the relations of climate to the cure of tuberculosis; 300 dollars to Prof. H. S. Grindley, Urbana, Ill., for the investigation of the proteids of flesh; 300 dollars to Dr. Herbert H. Field, Zürich, Switzerland, to aid the work of the Concilium Bibliographicum (an additional grant of 300 dollars was made June, 1903); 250 dollars to Dr. T. A. Jaggar, Cambridge, Mass., for experiments in dynamical geology; 50 dollars to Prof. E. O. Jordan, Chicago, Ill., for the study of the bionomics of Anopheles; 300 dollars to Dr. E. Anding, Munich, Bavaria, to assist the publication of his work, "Ueber die Bewegung der Sonne durch den Weltraum"; 300 dollars to Prof. W. P. Bradley, Middletown, Conn., for investigations on matter in the critical state; 300 dollars to Prof. Hugo Kronecker, Bern, Switzerland, for assistance in preparing his physiological researches for publication; 300 dollars to Prof. W. Valentiner, Heidelberg, Germany, for observations on variable stars.

PROF. VON BEHRING is reported to have brought before the Medical Congress at Cassel some new conceptions regarding tuberculosis. The fundamental idea of his theory is that tuberculosis in animals and in man represents different varieties of the same disease, and that it is transferable by the agency of tuberculous milk; in these respects he is in direct opposition to Prof. Koch. He distinguishes between adults and infants, maintaining that the former may as a rule safely partake of unsterilised milk, while infants are particularly liable to infection from that source, and he holds that infection may take place many years before the disease becomes manifest. Prof. Behring is now engaged in experiments upon new-born animals with the view of testing the possibility of rendering them immune against tuberculosis by supplying them with a suitable solution of tuberculous virus in the food. He is further inclined to believe that the milk of cows which have been rendered immune contains prophylactic elements which it will be practicable to employ in the treatment of the disease in human beings.

THE death is announced of M. A. Certes, formerly president of the French Zoological Society. M. Certes carried out numerous delicate researches on bacteria, and presented several memoirs to the Paris Academy of Sciences.

ON the invitation of the leading engineering societies of the United States, it has been decided that the next autumn meeting of the Iron and Steel Institute shall be held in New York on October 24–26, 1904. After the meeting there will be an excursion to Philadelphia, Washington, Pittsburg, Cleveland, Niagara Falls, and Buffalo, returning to New York on November 10. Arrangements will also be made for a visit to the St. Louis Exhibition.

THE death is announced of Mr. John Allen Brown, who was the author of numerous papers on geological and anthropological subjects, and of a volume "Palæolithic Man in North-west Middlesex."

THE trials on the electric railway between Zossen and Marienfeld, near Berlin, have been continued during the past week, and on September 26 a speed of 118 miles an hour was attained, as against 114 miles recorded last week.

IT has been decided to hold the American Conference on Tuberculosis at Washington on April 4–6, 1905, and not at St. Louis in 1904, as previously arranged. This course has been adopted so that the American meeting shall not clash with the International Congress on Tuberculosis to be held in Paris next year.

WE learn from *La Nature* that M. Dybowski, the Inspector-General of Colonial Agriculture, has just been appointed by the Minister of French Colonies to undertake a mission to Senegal and French Guinea to study the conditions existing in these possessions with a view to future enterprise in the direction of agricultural colonisation.

THE Harben lectures for 1903 will be given under the auspices of the Royal Institution of Public Health in King's College, London, by Prof. Ferdinand Hueppe, of Prague, on October 8, 12, and 15. The subjects for the respective days are:—(1) the etiology of infectious diseases from the standpoint of natural science; (2) hygienic lessons to be derived from the serum treatment; and (3) tuberculosis.

Two violent shocks of earthquake were felt on the night of September 22 at Blidah at an interval of three seconds. The total duration is estimated at fifteen seconds. The direction was from the south-east to the north-west. A slight shock lasting from four to five seconds was felt at Algiers at the same time. Two earthquake shocks also occurred in the Canaries on September 22, and caused cracks in the walls of several houses.

M. DE LA VAULX made a balloon ascent from St. Cloud, Paris, at 7 p.m. on Saturday, September 26, and reached Hull at 11 o'clock on the following morning. The balloon started with a favourable wind, and reached the Channel at 1 a.m. on September 27, crossed it in an hour and fifty minutes, and passed over the Thames at 5 a.m. almost midway between Greenwich and Chatham. As the balloon skirted the Wash four hours later it was evident that the wind was changing. From there the voyage to the Humber occupied an hour and fifty minutes. When nearing Hull it was seen that the journey could not be continued without danger of being blown out to sea, so a descent was made at 11.40 six miles north-east of Hull.

A COMMITTEE has been appointed by the Cunard Steamship Company to investigate the application of marine turbines to steamers, with special reference to the suitability of this class of engines for the two great vessels which are to be built under the agreement with His Majesty's Government. The Admiralty is represented by Engineer Rear-Admiral Oram, Deputy-Engineer-in-Chief of the Navy, and he will be assisted by Engineer Lieutenant Wood as secretary of the committee. Sir William White, late Director of Naval Construction, has also consented to give his assistance. Ordinary marine engines powerful enough to propel the projected Cunarders at 25 knots would be so excessively heavy that the comparative lightness of marine turbines would be a considerable advantage if their trustworthiness could be demonstrated. The questions of steam consumption and fuel economy of the turbines will also be investigated.

IN a letter to the *Times* (September 15), Mrs. Garrett Anderson, M.D., gives a valuable analysis of the data published in the "Report of the Metropolitan Asylums Board" respecting the 1901–2 epidemic of small-pox, in order to discuss the evidence there afforded upon (1) the protective influence of infant vaccination and the limits of its duration; (2) the necessity for systematic revaccination at school age; (3) the cost to the ratepayers of the method now employed. In the epidemic of 1901–2, 9659 persons were admitted to the small-pox hospitals, of whom 1663 died, equal to 17·1 per cent. Disregarding all doubtful cases, in 1901, 264 vaccinated persons under twenty contracted small-pox, of whom 175 were between fifteen and twenty, that is, they had reached an age when the protective power of infant vaccination is seriously weakened. In 1901 there were no deaths of vaccinated children, whereas there were 65 deaths of unvaccinated children under ten. In 1902 there were no deaths of vaccinated children, but 337 deaths of unvaccinated children under seven. Among vaccinated children up to fifteen years of age who contracted the disease, the mortality did not exceed 1·7 per cent. at different age periods, while among the unvaccinated it was not less than 32 per cent. From fifteen to thirty years of age the mortality is 4·8 and 30·4 per cent. respectively among the vaccinated and unvaccinated. Even up to thirty years of age the protective power of infant vaccination is, therefore, still an important factor, but is evidently waning, emphasising the need for revaccination. As regards the cost of the epidemic, Mrs. Anderson points out the great expense the ratepayers have been put to in order to provide hospital accommodation; she estimates that in Battersea every case cost 71*l*. 7*s*. 1*d*. There has to be added to this, of course, the economic loss to the community of the able-bodied through the sickness and death of those attacked.

WE have received from Mr. H. C. Russell No. 7 of his interesting current papers. We are glad to see that the number of these papers is increasing year by year. Up to October, 1902, 105 notices had been recovered, and for the last seven years the number of papers amounted to 703. One of the bottles referred to in the last paper had a drift of 29·2 miles a day; it was thrown overboard in the Socotra Sea on January 28, and found in the Gulf of Aden on February 9, having travelled 350 miles in twelve days. With one exception, this is the most rapid drift on record, so far as this series of observations is concerned. The pamphlet is accompanied by charts illustrating the drift of the bottles.

Symons's Meteorological Magazine for September contains an interesting summary of the British Rainfall Organisation on the occasion of the retirement of Mr. Sowerby Wallis, who has been intimately connected with the undertaking for more than thirty years. Most of our readers are probably aware that the system was commenced by the late Mr. G. J. Symons in 1859, by hunting up old rainfall records and the collection of actual observations. The first results were published for 1860, from the records of 168 stations. In ten years the number of stations reached 1500, and in 1890 3000 stations. Dr. H. R. Mill,

who has undertaken the sole management of the organisation, which is now recognised as of great national value, directs attention to the power of initiation possessed by the founder, as shown by the fact that the page of "British Rainfall" in 1860 hardly differed in arrangement from that at the present day, and states that in all essentials the work will be continued in the straight course which its founder impressed upon it.

IN the *Physical Review* for August, Mr. Edgar Buckingham describes a simple mechanical contrivance for tracing the family of curves which represent the adiabatics of a perfect gas.

VOL. iv. part ii. of the *Bibliotheca mathematica* contains an account of the life and works of the late Prof. P. G. Tait by Mr. Alexander Macfarlane, of South Bethlehem.

MR. FRANZ KERNTLER, of Budapest, has published a short article dealing with the potentials of the forces between elements carrying electric currents, according to Ampère's and allied laws. It is printed by the Pester Lloyd Gesellschaft.

IN the *Physical Review* for July and August, Messrs. E. F. Nichols and G. F. Hull describe experiments for determining the pressure due to radiation. In order to obtain results free from the effects due to the disturbing action of gases, (1) use was made of the most perfect reflecting surfaces to receive the radiation; (2) the action of a beam of constant intensity was studied in gases at different pressures; (3) the apparatus was arranged as a torsion balance, in such a way that the disturbing actions could in large measure be reversed; and (4) ballistic observations were made. It appears that the radiation pressure depends only on the intensity of radiation, and is independent of the wave-length, thus confirming the Maxwell-Bartoli theory within the probable errors of observation.

EAST AFRICAN chamæleons form the subject of an illustrated article by Mr. J. L. Monk in the September number of the *Zoologist*, to which serial Mr. W. W. Fowler contributes a note on what he believes to be an unknown warbler recently observed nesting in Oxfordshire.

IN the August number of the *Victorian Naturalist* Mr. W. Hopkins raises the question whether eels in Australia do not breed in fresh water. Among other facts, it is stated that in a swamp which had been dry for some months swarms of young eels made their appearance after the first rains.

IN the *American Naturalist* for July Dr. C. R. Eastman records a lung-fish with a cutting type of dentition from the Permian strata of Texas. Possibly the divergence from the normal form may be correlated with a change from marine to brackish water conditions, of which there are indications in the Permian; but in any case it is very remarkable in view of the singularly uniform type of dentition presented by the lung-fishes throughout their history. The new species is named *Sagenodus pertenuis*.

THE *Proceedings* of the Philadelphia Academy for June contain a description of a new species of Pleurotomaria from Japan. The shell resembles that of *P. beyrichi* in general form and characters, and if perfect would measure about 3 inches in height. To the same issue Mr. J. P. Moore contributes a long article on polychætous worms from Japan, Kamchatka, and Bering Sea, in the course of which many new forms are named and described; while in the section for July Messrs. Eigenmann and Kennedy have notes on fishes from Paraguay, accompanied by a synopsis of the American representatives of the cichlid group.

ONE of the most remarkable phenomena connected with Mont Pelée, in Martinique, is a gigantic plug of solidified lava which has been thrust up from the summit of the new cone of the volcano. This cone has been built up in the ancient crater-basin (the Étang Sec) to a height of 1600 feet or more, and it is now dominated by the ascending obelisk of lava, of which, through the courtesy of Prof. Angelo Heilprin, we are able to give a picture. The appearance of this mass of rock (as he tells us) was made known by Prof. Lacroix, and it calls to mind some of the pyramidated summits among the South American volcanoes. When first observed it must have been 1000 feet in height, and where implanted it has a thickness of some 300 to 350 feet. The plug has lost 180 feet, but when the photograph was taken (on June 13) it added 800 or 900 feet to the mountain, making the altitude more than 5000 feet. The obelisk terminates in a needle summit, a true *aiguille*. It is

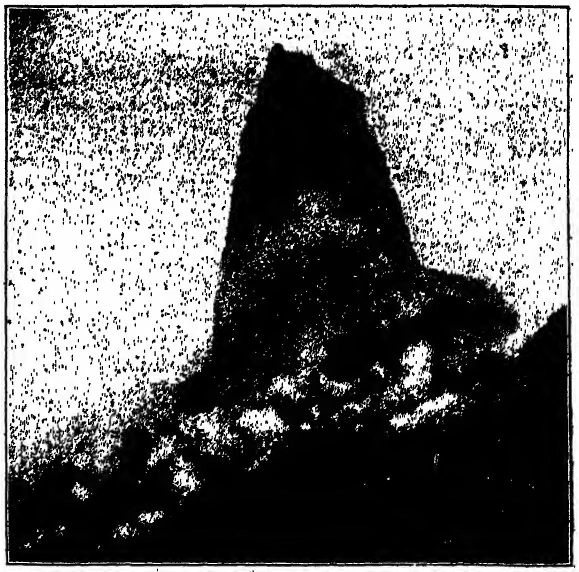

FIG. 1.—The Ascending Obelisk of Mont Pelée. Photograph by Prof. Angelo Heilprin, June 13, 1903, taken from the rim of the crater.

gently curved in the direction of St. Pierre, and on this face it is cavernous and slaggy, giving evidence that explosions have torn away portions of the lava. On the opposite side, the surface is more solid in appearance, and there it is smoothed and even polished, with grooves and striæ, like a slickensided surface—the result, evidently, of attrition when the mass was extruded. No doubt the lava was so rapidly solidified that it was unable to flow away, moving upwards, and receiving accretions to its mass from below. Prof. Heilprin observed that the growth during a period of four days measured six metres. Previously a growth of ten metres in eight days had been recorded by M. Giraud. The volcano was too active to permit of a descent into the crater-hollow; steam and sulphur-puffs were issuing, and avalanches of rock were disrupted from the obelisk. Pelée, as remarked by Prof. Heilprin (*Science*, August 7) was still "ugly."

A NEW map of the world on an equal area projection has been published by Messrs. Darbishire and Stanford, Ltd., Oxford, price 6*d*. net. British possessions are coloured red,

and the principal areas where corn, rice, and other food stuffs are at present grown are indicated by shading.

MESSRS. WATTS AND CO. have published for the Rationalist Press Association, Ltd., a carefully revised, popular edition of "Supernatural Religion. An Inquiry into the Reality of Divine Revelation." The new edition runs to 920 pages, and is issued at 6s. net.

DR. ADOLF MARCUSE, Privat-docent at the University of Berlin, having taken charge of the section of geographical surveying in the "Geographischen Jahrbuch," edited by Prof. Wagner, asks astronomers, geographers, and explorers to send him papers or other publications containing results of which notice should be taken.

AT the request of teachers of chemistry in secondary schools, Messrs. J. and A. Churchill have published separately, at 2s. 6d. net, the chapters on general chemistry contained in the "Elementary Practical Chemistry" of Dr. Clowes and Mr. J. B. Coleman. In its present form the book provides a really good course of experimental chemistry, in which the broad principles of the science are gradually presented to the student.

DR. F. BASHWORTH has prepared a pamphlet of thirty pages, published by the Cambridge University Press, containing "A Historical Sketch of the Experimental Determination of the Resistance of the Air to the Motion of Projectiles." The pamphlet gives a general survey of the author's experiments and results, which have extended over many years, and for which he devised his chronograph, and shows their relationship to other investigations.

A NEW edition of Dr. Alfred Russel Wallace's book, "The Wonderful Century. The Age of New Ideas in Science and Invention," has been published by Messrs. Swan Sonnenschein and Co., Ltd. The book has been revised and largely rewritten. Among the most important changes may be mentioned the addition of a chapter on electricity, of four chapters on astronomy, and the omission of the long chapter on the vaccination question which was included in former editions. In its new form the book provides an excellent survey of the development of science during the nineteenth century.

THIS year's issue of "Chemical Handicraft," the illustrated catalogue of chemical apparatus and reagents manufactured and sold by Messrs. John J. Griffin and Sons, Ltd., is attractively arranged and very complete. Among new apparatus we notice vessels of quartz glass scheduled on pp. 45–6. These vessels may be treated in the blowpipe flame without previous warming, and, whilst hot, be plunged into cold water without being fractured. Teachers of chemistry should find this catalogue of assistance in ordering the apparatus necessary for their laboratories and lecture-rooms.

WE have received copies of the first three *publications de circonstance* of the Conseil Permanent International pour l'Exploration de la Mer, published by MM. Høst & Fils, of Copenhagen. The first booklet is a preliminary communication, by Dr. C. G. Joh. Petersen, on how to distinguish between mature and immature plaice throughout the year; the second, by M. Martin Knudsen, deals with the standard-water used in the hydrographical research until July, 1903. The third is a larger book of 107 pages, and includes ten compendious monographs on the literature of the ten principal food fishes of the North Sea, illustrated by ten plates, and preceded by a useful index.

THE Tuesday evening popular science lectures at the Royal Victoria Hall, Waterloo Bridge Road, have been the means of creating scientific interest and activity among many people who have attended them. Many men of science have given their services as lecturers at the hall, and have helped to make known the work that is being carried on there. An appeal is now being made for subscriptions to assist the committee to meet the expenditure of 3000*l.* for alterations which had to be undertaken in order to make the building fireproof to the satisfaction of the London County Council. Donations should be sent to Miss Emma Cons, honorary secretary, Royal Victoria Hall, London, S.E.

THE additions to the Zoological Society's Gardens during the past week include two Sacred Baboons (*Papio hamadryas*), two Variegated Jackals (*Canis variegatus*), two Spotted Hyænas (*Hyaena crocuta*), a Striped Hyæna (*Hyaena striata*), a Lion (*Felis leo*), a Leopard (*Felis pardus*), an Abyssinian Duiker (*Cephalophus abyssinicus*), three Somali Ostriches (*Struthio molybdophanes*) from Somaliland, presented by Mr. William Northrup McMillan; a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Mr. A. G. Turner; two Pig-tailed Monkeys (*Macacus nemestrinus*) from Java, presented by Mr. Eussens; an Otter (*Lutra vulgaris*), British, presented by Miss Boughey; two Gold-fronted Finches (*Metoponia pusilla*) from India, presented by Mr. H. C. Harper; two Black Salamanders (*Salamandra atra*) from Switzerland, presented by Mr. W. C. Worsdell; three Indian Chevrotains (*Tragulus meminna*), nine Starred Tortoises (*Testudo elegans*) from India, a Mayotte Lemur (*Lemur mayottensis*), a Fringed Gecko (*Uroplates fimbriatus*), six Green Geckos (*Phelsuma madagascariensis*), twelve Blackish Sternotheres (*Sternothoerus nigricans*), a Sharp-nosed Snake (*Lioheterodon madagascariensis*) from Madagascar, four Angulated Tortoises (*Chersina angulata*) from South Africa, fourteen Stink-pot Terrapins (*Cinosternum odoratum*), two Prickly Trionyx (*Trionyx spinifer*) from North America, a Spiny-tailed Mastigure (*Uromastix acanthinurus*) from North Africa, three Cuban Snakes (*Liophis andrae*) from Cuba, a Merrem's Snake (*Rhadinoea merremi*) from Brazil, deposited.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN OCTOBER:—

Oct. 5. 13h. 48m. to 17h. 0m. Transit of Jupiter's Sat. III. (Ganymede).

6. Partial eclipse of the moon.
   5h. 32m. Moon rises obscured by the penumbra.
   6h. 7m. Last contact with the penumbra.

10. 8h. 18m. to 9h. 11m. Moon occults α Tauri (Aldebaran, Mag. 1·1).

15. Venus. Illuminated portion of disc=0·188, of Mars =0·907.

18. 9h. 41m. Minimum of Algol (β Persei).

" 15h. 0m. Mercury at greatest elongation (18° 13′ W.).

" 19h. 0m. Mercury in conjunction with moon, Mercury 1° 57′ N.

19–22. Epoch of Orionid meteoric shower. (Radiant 91°+15°).

21. 6h. 30m. Minimum of Algol (β Persei).

22. Saturn. Polar diameter =15″·7. Minor axis outer ring=13″·62.

24. 3h. Mars in conjunction with Uranus, Mars 1° 13′ S.

" 12h. Venus at greatest brilliancy.

31. 7h. Jupiter in conjunction with moon, Jupiter 3° 39′ S.

REPORT OF THE PARIS OBSERVATORY FOR 1902.—In his report of the Paris Observatory for 1902, M. M. Lœwy, the director, describes in detail the various important series of observations made at that observatory.

In announcing that the last two volumes of the "Catalogue de l'Observatoire de Paris" are ready for publication, M. Lœwy gives a detailed account of the circumstances which led to the inception and prosecution of the work necessary for the publication of such a complete stellar catalogue.

For the determination of the latitude of the Paris Observatory, 6530 measures of the absolute polar distances of fundamental stars were made with the large meridian circle during the year, and, in accordance with Sir David Gill's proposals, 5063 observations of reference stars for the astrographic chart were made.

The observations for the redetermination of the difference of longitude between Paris and Greenwich were completed, and the concordance between the observations of the Paris and Greenwich observers in the first series, which has been completely reduced, is very striking.

504 photographs of the moon for the "Atlas Photographique de la Lune," of which the sixth section has been published, were taken with the large equatorial coudé. A 6-inch grating, for use with the smaller equatorial coudé, has been ordered from America, and when this is received it is proposed to carry out, systematically, similar researches in solar physics to those which are already prosecuted in England and America.

In connection with the "International Astrographic Chart and Catalogue" fifty-six plates for the chart and twelve for the catalogue were secured; the printing of the catalogue for zone +24° was completed, and it contains the positions of 64,264 stars, whilst the publication of zone +23° was commenced and the section 0h. 4m. to 6h. 20m. completed. Altogether the positions of 21,855 stars were completely measured for the catalogue, and the magnitudes of 35,630 stars belonging to zone +23° were determined during 1902.

THE RIGIDITY OF PIERS FOR MERIDIAN CIRCLES.—In No. 3902 of the *Astronomische Nachrichten*, Prof. G. W. Hough, of the Dearborn Observatory (U.S.A.), discusses in detail the relative merits of brick and stone piers as supports for meridian circles. It will perhaps be remembered that in the last report of the superintendent of the United States Naval Observatory it was stated that since the substitution of a brick pier for the marble pier that was formerly used, the previously reported changes in azimuth of the 6-inch Repsold meridian circle had entirely disappeared. The experience of Prof. Hough is opposed to the principle contained in that statement, viz. that brick piers are superior to stone for this purpose.

By a table of comparative expansions he shows that those of granite, sandstone, &c., approximate more nearly than that of brick to the expansion of iron, and therefore, with iron fastenings, a stone pier will ensure a greater rigidity of the instrument in regard to the pier; from the same table it is seen that brass fastenings are far more likely to produce lack of rigidity than those made of iron.

RECENT PAPERS ON METEORITES.

THROUGH the courtesy of Prof. Henry A. Ward, of Rochester, New York, we are able to reproduce for our readers a photograph which gives a good idea of the form and dimensions of the large mass of meteoric iron lying at a place called Ranchito, near Bacubirito, in the province of Sinaloa, Mexico. The existence of the mass was made known to the scientific world by Prof. Barcena more than a quarter of a century ago, and, later, its dimensions were recorded by Prof. Castillo; but until after the visit of Prof. Ward there had been no published information as to the particulars of the occurrence. Prof. Ward, who is greatly interested in meteorites, travelled from the city of Mexico to Bacubirito, an extremely long, arduous, and expensive journey, for the special purpose of examining the meteorite *in situ*. It was found by him to be lying at the place specified, but to have only one end projecting from the ground. Twenty-eight labourers were employed by him to excavate round the mass and make it possible to determine the complete form. After two days' work not only had this been done but, through removal of the support from one side, the large mass had been made to turn itself over. It is 13 feet 1 inch long, 6 feet 2 inches wide, and 5 feet 4 inches thick. Its irregularity of form and the character of the surface are manifest from Fig. 1. The mass is estimated to weigh

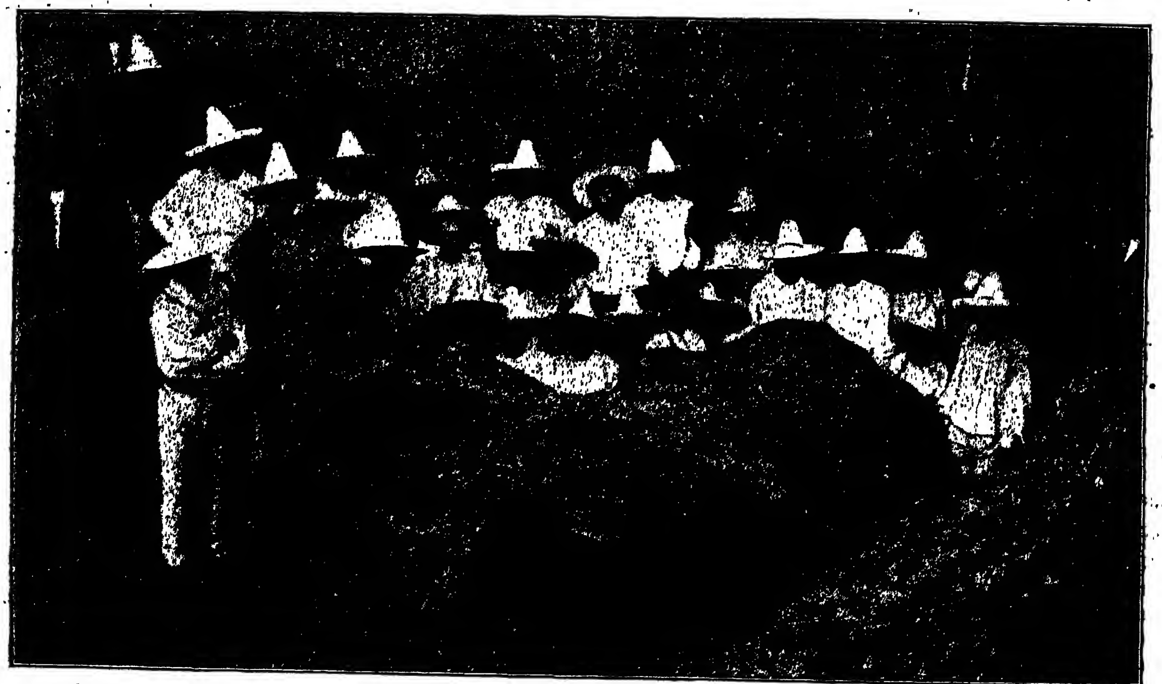

FIG. 1.—The Meteoric Iron of Bacubirito, Sinaloa, Mexico.

50 tons (the specific gravity having been determined to be 7·69), and it is probably at least as large as the big mass brought some years ago from Greenland to the United States by Lieutenant Peary. After these two, the next largest known meteorite in the world is that of Chupaderos, which has lately been removed to the city of Mexico and found to weigh 15¾ tons. A polished face of the Bacubirito iron, when etched, shows very distinct Widmänstätten figures. According to a chemical analysis made by Prof. Whitfield the percentage of nickel (and cobalt) is 7·2. The time of fall of the mass is unknown. The meteorite is described by Prof. Ward in the *Proceedings* of the Rochester Academy of Science (vol. iv. p. 67, 1902).

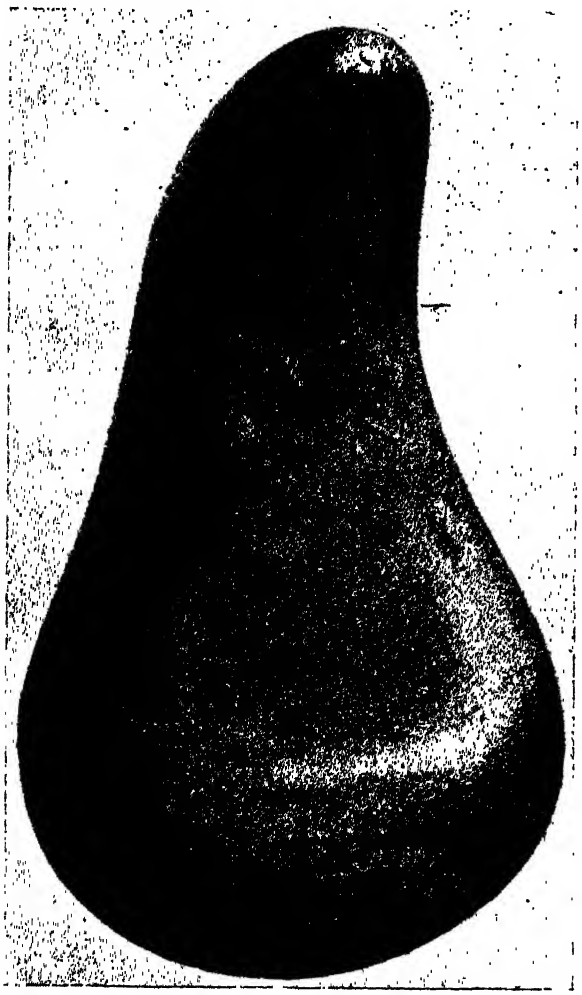

FIG. 2.—The Boogaldi meteorite, N.S.W. Showing "drip" from the underside, tail end. Length 5 inches, width 3 inches; weight 2057·5 grms. Sp. gr. 7·85.

In the *Journal* and *Proceedings* of the Royal Society of New South Wales, vol. xxxvi. pp. 341–359, Prof. Archibald Liversidge, F.R.S., of Sydney, gives descriptions of four meteorites, all from New South Wales, one of them a meteoric iron, the other three meteoric stones. The meteoric iron, though not actually observed to fall, was found shortly after that event; it was noticed in January, 1900, that the ground had been torn up on a hard ridge near Boogaldi Post Office; the furrow was followed, and a small pear-shaped mass of iron was found slightly embedded in the ground; it had come from the north-west, and its path must have been inclined at only a small angle to the horizon. It weighed 4½ lb., and has a specific gravity of 7·8. The surface is formed by a skin of fused oxide, which has been arranged in waves with transverse furrows by the motion through the air (Fig. 3); part of the fused oxide has accumulated at the thin end of the meteorite, and part of it has doubtless been blown off at that part (Fig. 2). A polished section, when etched, shows well-marked Widmanstätten figures; only one or two specks of troilite are visible on the etched face. Chemical analysis of the metallic sawdust obtained on cutting the meteorite shows that the nickel and cobalt amount to 8·5 per cent. In addition to the chemical elements normally present in meteorites, Prof. Liversidge found small quantities of arsenic, gold, and either platinum or some other member of the platinum group.

The places of fall of the meteoric stones were (1) Barratta, near Deniliquin; (2) Gilgoin, near Brewarrina; (3) Eli Elwah, near Hay; the falls were not actually observed. The stones are all remarkable for their size. In the case of Barratta, about 2 cwt. had been found on a previous

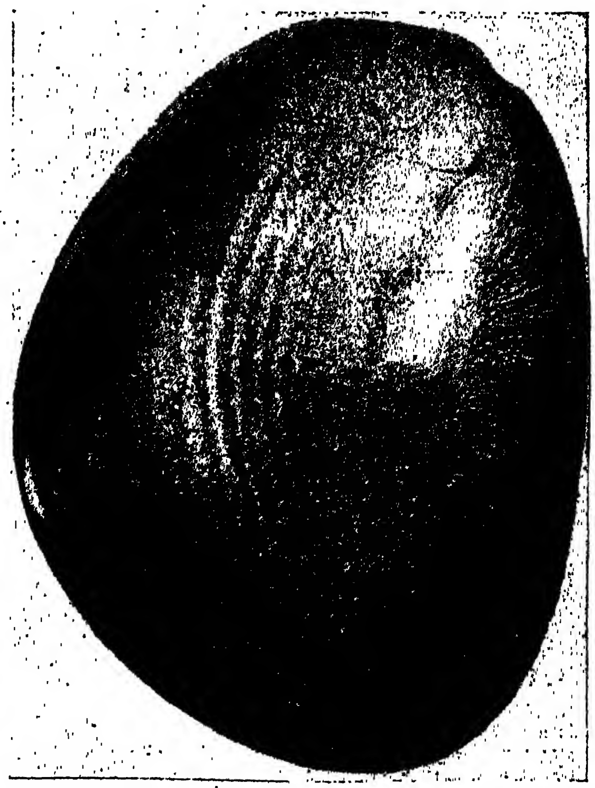

FIG. 3.—The Boogaldi meteorite, N.S.W. Showing waves formed in the fluid skin at the forward end; the right hand side was the lower one during flight. Enlarged two diameters.

occasion many years ago; two other stones have lately been found weighing 31½ lb. and 48 lb. respectively. The Gilgoin stones weigh 67½ lb. and 74½ lb., and the Eli Elwah stone 35½ lb. All these stones have a chondritic structure; the specific gravities range from 3·39 to 3·86. The paper is illustrated with no fewer than twelve plates.

In the *Publications* of the Field Columbian Museum (Geological Series, vol. i. pp. 283–315) Dr. O. C. Farrington gives an account of various meteorites. The first of them is from Long Island, Phillips County, Kansas, of the structure of which Dr. Weinschenk gave a minute description several years ago. The meteorite, which belongs to the chondritic kind, was not observed to fall, and must have been in the ground some time before it was found. Fragments having a total weight of 1244 lb. have been recovered; it is therefore the largest meteoric stone which has yet been met with. The larger fragments can be closely fitted together, and the original form of the mass is thus reproduced. The directive character of the pittings and furrows is very suggestive of the exterior of the Goalpara stone,

Chemically, the meteorite is remarkable for its high percentage (6·3) of chromium sesquioxide. Dr. Farrington suggests that a small portion may be present as a constituent of the olivine, and the rest as part of the chromite. The author next enters into a discussion of the relations of the various meteoric stones which have been found in Ness County and other parts of north-western Kansas; he infers that Prairie Dog Creek, Long Island, Oakley, Jerome, and Franklinville belong to distinct falls, and that Wellmanville may be part of the Franklinville fall, and Kansada part of either the Franklinville or the Jerome meteorite. Another meteorite described is one from Los Reyes, forty miles from Toluca; this is an iron, and its characters are similar to those of other masses found nearer Toluca; there is no reason to believe that the mass has been transported by man from the latter locality. The Los Reyes mass may belong either to a distinct fall or indicate a wide spreading of the Toluca shower. In the same paper an account is given of the structure of the meteoric iron found in the Hopewell Mounds of Ohio; one of these is a small, unwrought mass weighing about five ounces, the others are worked specimens, namely, a part of a head and ear ornament, some celts, and a number of beads; they were all found associated with a single human skeleton near an altar of one of the mounds; the iron, when etched, shows Widmanstätten figures, which have been bent and distorted by hammering. Finally, Dr. Farrington states that the tænite extracted from the Kenton County meteorite was found on analysis to consist of 80·3 parts of iron and 19·7 parts of nickel (and cobalt).

THE BRITISH ASSOCIATION.

SECTION F.

ECONOMIC SCIENCE AND STATISTICS.

OPENING ADDRESS BY EDWARD W. BRABROOK, C.B., F.S.A., V.P.S.S., PRESIDENT OF THE SECTION.

IT is a coincidence, which has great interest for me personally, that the honour of being President of this Section has fallen to me in the last year of my engagement in the public service. I am now in the sixty-fifth year of my age and the thirty-fifth of my connection with the Registry of Friendly Societies, and in a few months the guillotine of the Order in Council will fall, and the Department and its present head will be severed. The consequences are not so tragic as they sound, for the Department will at once find a new head, and the old head will contrive to maintain a separate existence. I therefore meet the stroke of fate with cheerfulness; for I am strongly of opinion that the arrangements for retirement from the Civil Service of the country are as wise as they are liberal. It is a good thing that the place of a man whose ideas have grown old and become fixed, and whose long service indisposes him to entertain new ones, should be taken by a younger man anxious to make his own mark on the administration of his department. Again, the prospect of promotion opened up by the limited term of service of the older men is a distinct inducement to able and ambitious young men to devote themselves to their country's service. I have lately had occasion to give minute and careful attention to one branch of this important question, and the study of the whole subject which has thus been rendered necessary has strongly confirmed the conviction I previously entertained that the system of retirement which now prevails greatly tends to promote the efficiency of the Civil Service and the interests of the country. I do not apologise for saying this much on a subject into which I was led by an observation that concerns me personally, for the means of securing efficiency in the public service is an important economic question.

The coincidence to which I refer tempts me to choose as the principal subject of the Address which I am permitted and enjoined to deliver to the Section on this occasion that small corner of the great field of Economics in which I have been a day labourer for so long, and I am not able to resist the temptation. My piece of allotment ground, if I may so call it, is that which is devoted to the cultivation of thrift, or of economy in the popular rather than the scientific sense. The temptation is strengthened by the circumstance that that subject has rarely been treated by my predecessors. Sir Robert Giffen in his Address of 1887 referred to it, and Sir Charles Fremantle in 1892 treated it at somewhat greater length. In old times, when the Chair of this Section was more frequently occupied by the practical statesman than by the professed economist, there were passing allusions to it by Henry Fawcett in 1872, William Edward Forster in 1873, and Sir Richard Temple in 1884; but in more recent years the accomplished economists who have presided over this Section, notably my immediate predecessor, have delivered luminous and memorable Addresses on the broad principles of Economics, the application and potency of its doctrines, and their serviceableness to mankind, with a comprehensiveness of view that is only attainable as the result of deep study, and a brilliancy of exposition that belongs to philosophic insight. I may here, in passing, express the satisfaction we all feel that at Cambridge, where we are to meet next year, proficiency in Economics and Political Science is now fully recognised as qualifying for academical honours.

I have spoken of the subject of Thrift as a small corner of the great field of Economics; and relatively to the broad field itself it is so; but it is a subject that deals with large figures and intimately affects large numbers of people. The 2000 Building Societies in Great Britain and Ireland have 600,000 members and sixty-two millions of funds; the 28,000 bodies registered under the Friendly Societies Act have 12,000,000 members and forty-three millions of funds; the 2000 co-operative societies have 2,000,000 members and forty millions of funds; the 600 trade unions have more than a million and a half members and nearly five millions of funds; in the 13,000 Post Office and other savings banks there are more than 10,000,000 depositors and more than 200 millions invested; so that upon the whole in nearly 50,000 thrift organisations with which the Registry of Friendly Societies has, in one form or other, to deal there are twenty-seven millions of persons interested and 360 millions of money engaged. These figures, however, possess no significance other than that they are very big. Many individuals are necessarily counted more than once, as belonging to more than one society in one class, or to more than one class of societies. Some portion of the funds of Friendly Societies is invested in savings banks, and therefore is counted twice over. Some of the co-operative societies, as, for example, the wholesale societies, have for capital the contributions of other societies, which thus are also counted twice over. On the other hand, the aggregate, large as it is, is necessarily defective. It includes only bodies which are brought into relation with the Registry of Friendly Societies in one or other of the functions exercised by that department. It does not include, therefore, many co-operative and other bodies which are registered under the Companies Act, nor the Industrial Assurance Companies which are regulated by the Assurance Companies Act, nor does it include the great body of Friendly Societies which are not registered at all. Among these shop clubs hold a prominent position, and these are very numerous. The Royal Commissioners of thirty years ago thought that the unregistered were then commensurate with the registered bodies; and as one result of the legislation which the Commissioners recommended has been to diminish the applications for registry made by such societies as are subjected by it to the necessity of a periodical valuation of assets and liabilities, there seems no reason to think that unregistered societies are relatively now any fewer than they were then.

It would seem, then, that the figures we have cited are well within the mark, and that, used for the mere purpose of indicating the magnitude of the interests involved, they may be relied upon as not over-estimating it. The observation just made leads to the question, why should there be so many unregistered societies? Why, indeed, should there be any unregistered societies? The National Conference of Friendly Societies, which consists wholly of registered bodies, has just passed a resolution recommending the enactment of a law that all societies should be compelled to register. Why not? I think it will not be difficult to find the real answer to these questions. It was given as long ago as 1825 by a Committee of the House of Commons in these wise words:—"It is only in consideration of advantages conferred by law that any restrictive interference can be justified with voluntary associations established for lawful

and innocent purposes. It is for the individuals themselves to determine whether to adopt the provisions of the statute, which offers them at the same time regulation and privilege, or to remain perfectly unfettered by anything but their own will, and the common or more ancient law against fraud or embezzlement," which common or more ancient law was strengthened in 1868 by the Act known as Russell Gurney's Act. "For your Committee apprehend that although the Act of 1793 appears to begin by rendering lawful the institution of Friendly Societies, there neither was at that time nor is now any law or statute which deprives the King's subjects of the right of associating themselves for mutual support."

Upon this principle the Legislature has hitherto proceeded. Registration is voluntary. The subscriptions of the members are voluntary. The conditions of membership are such as the rules framed by the members themselves impose. They have full authority to alter those rules from time to time. Those conditions may, if the members so please, imply that the subscriptions are to be small and the benefits large. They may provide for investment of funds on any security they think fit so long as it is not personal security. They may provide for the periodical division of the funds so long as they make it clear that all claims existing at the time of division are first to be met. Up to this point the registered society and the unregistered are hardly distinguishable. What, then, are the obligations consequent upon registry? There is the making an annual return and the making a quinquennial valuation; but the action to be taken by the society upon the result of the valuation is wholly in the discretion of the members. The valuer may demonstrate beyond doubt that the society in order to save itself from disaster must increase the subscriptions of the members or diminish their benefits; but neither he nor the Registrar can enforce the recommendation. The society has its destinies wholly in its own hands. Then, again, the Act contains certain provisions for the protection of members. Individual members have the right to inspect the books of the society, to receive copies of its balance sheets and valuations, and so forth. A certain number of the members have the right to apply to the Registrar to appoint an inspector into the affairs of the society or to call a special meeting of the members. The inspector can only report—there is no action which the Registrar can take upon his report if the members disregard it. The special meeting will in no way differ from an ordinary meeting called by the society itself, except that it may choose its own chairman. The Registrar cannot in any way control its proceedings. Even these things he cannot do of his own motion without being set in action by a competent number of the members. If a society becomes insolvent, members may in like manner apply to him to wind it up: he may see that a readjustment of contributions and benefits would set the society on its legs again, and may suspend his award of dissolution to enable the society to make that readjustment, but he can do no more. If the society refuse to make it, he has no option but at the end of the period of suspension to issue the award. Here again he may have the fullest knowledge that a society is hopelessly insolvent, yet he can do nothing unless a competent number of the members call in his aid. I confess that I think the Legislature might have gone further in this respect and conferred upon the Registrar, or at any rate upon some public authority, the power to deal compulsorily with cases of hopeless insolvency, and if necessary to appoint a receiver, as such cases are not infrequently complicated with fraud carried on in circumstances which make it difficult for a competent number of the members to join in an application to the Registrar. However that may be, taking the legislation as it stands, it embodies to the fullest extent the principle laid down by the Committee of 1825.

The surrender of freedom which a Friendly Society is called upon to make in order to obtain the privileges of registry, which are not inconsiderable, is therefore exceedingly small; yet it is sufficient, as we have seen, to keep out of the registry office a large number of societies. It seems not improbable, looking back on the history of legislation on the subject—and the observation is a curious one—that unwillingness to register has been closely connected with actuarial considerations. Thus, in the year 1819, an Act was passed which provided, among other things, that the justices should not confirm any tables or rules connected with calculation until they had been approved by two persons at least known to be professional actuaries or persons skilled in calculation; but that was repealed in 1829. Again, in 1846 an Act was passed which provided, among other things, that every registered society should make a quinquennial valuation; but that was repealed in 1850 before a single quinquennial period had arrived. It was not until a quarter of a century after 1850 that this most salutary provision again found a place in the statute book, and the experience of the last twenty-eight years has shown how valuable it is, and how much it is to be regretted that the Act of 1846 was not allowed to remain in force. Again, the Act of 1850 provided for the discrimination of societies into two classes: those which were simply registered and those which were certified. These latter were to obtain the certificate of a qualified actuary that their tables of contribution were sufficient for the benefits they proposed to insure. Very few certified societies were established, and that Act was repealed in 1855. The experience of the Legislature has not been favourable therefore to endeavours to impose upon Friendly Societies by Act of Parliament conditions of actuarial soundness.

If, however, the voluntary principle is abandoned, and all societies are to be compelled to register, it is obvious that there must be a recurrence to the policy of imposing such conditions. At present a registered society may be as unsound as it pleases, and so may an unregistered society. Unless registry is to imply something more than that, there can be no reason for any compulsion to register. For what does compulsion mean? It means prosecuting, fining, and sending to prison all persons who associate themselves together for the lawful and innocent purpose of mutual support in sickness and adversity without registration; and that, obviously, cannot reasonably be done unless abstinence from registration is shown to be a moral offence; that is to say, unless the conditions of registration are such that a registered society shall be necessarily a good one, and an unregistered society necessarily a bad one. We must begin, at any rate, by devising model tables and insisting that every society shall adopt them. Are they not ready to hand? Did not my lamented colleague, Mr. Sutton, prepare a Blue Book of 1350 pages full of them? That is true; but it is also true that in the brief introductory remarks which he addressed to me at the beginning of that report he observed, with great force, that the adoption of sufficient rates of contribution is not enough to secure the soundness of a society. Those rates are derived from the average experience of all classes of societies—some exercising careful supervision over claims for sick pay, others lax in their management—and it is upon care in the management, rather than upon sufficiency of rates, that the success of a Friendly Society mainly depends. If the members administer the affairs of their society with the same rigorous parsimony and watch over the claims for sick-pay with the same vigilance which a poor and prudent man is compelled to exercise in the administration of his own household affairs, the society will be more than solvent, even though they do not pay as high a contribution as the model tables exact. If they neglect these precautions, there is no model table which will rescue them from ultimate insolvency. In Mr. Sutton's happy phrase, it is the personal equation of the members and of their medical adviser that tells the most on the prosperity or the failure of a society. Your compulsory registration will impose unfair conditions on the well-managed societies, and will do nothing to prevent the inevitable collapse of those which are badly managed. Registration tells for a great deal while it is voluntary and free; but if you make it compulsory, and add to it conditions that you suppose will tend to soundness, you will inevitably do more harm than good. It is, of course, of vital importance that adequate rates of contribution should be charged for the benefits proposed to be ensured; but if these are imposed by authority, the management of the societies must also be undertaken by the same authority. It is a curious observation, which has been borne out by experience, that in poor societies the claims for sickness are relatively less than in rich ones. M. Bertillon, the eminent French statistician, has shrewdly remarked: "The truth is, that friendly societies, when they grant sick-pay, attach less weight to the text of their rules than to the state of their funds. If the society is rich, it grants relief

more freely than if it is poor. Thence, and thence only, it comes that the great English societies, which are often very old and generally rich, give more days' pay than the French societies, for example, which are bound to a rigorous economy." Without necessarily assenting to all that M. Bertillon says, it is easy to see that if the State were unwise enough to say that such-and-such rates would be sufficient, it would encourage laxity of management, and accept a responsibility that does not belong to it.

I may now proceed to show that the present voluntary system, unscientific as it may be supposed to be, works very well on the whole. Its most useful feature is the valuation, for a society which disregards the lessons of one valuation finds itself pulled up sharply by the results of a second. A deficiency that is frankly faced by an increase of contributions, a reduction of benefits, or a levy, or by all three together, will probably not only disappear, but be succeeded by a surplus; but a deficiency that is disregarded not only grows at compound interest, but increases by the continued operation of the causes which produced it. It is to be remembered that a valuation deficiency or surplus, as the case may be, in a Friendly Society is always hypothetical. It means this in the case of deficiency—if you go on as you are going and do not modify your contracts you will ultimately be in a deficiency of which this is the present value. In the case of surplus it means—if you go on as you are going and do not allow your prosperity to tempt you to recklessness you will probably have enough to meet all your engagements, and this much over together with its improvements at interest.

When Friendly Societies are considered in their economic aspect, they appear to be an excellent application of the principle of insurance to the wants of the industrial community. Sickness may come upon a working man at any time, and may disable him from work for an indefinite period. In such an event, if he had nothing to rely upon but his own savings accumulated while he was at work, they would before long be exhausted, and he would be left in distress. By combining with a number of others who are exposed to the same risk, he can fall back upon the contributions to the common fund which have been made by those who have escaped sickness. It is an essential part of every contract of insurance that the contributions of all who are exposed to an equal contingent risk are equal; but the benefits are only derivable by those of the number in whose experience the contingent risk becomes actual, and they receive more than they have paid, the deficiency being made up out of the contributions of those who have escaped the contingent risk.

This really seems too elementary a proposition to be worth stating, but it is the fact that the principle of insurance is so little understood that many members of Friendly Societies look upon themselves as having performed an altruistic and charitable act in joining a society when they have been fortunate enough not to make claims upon it through sickness. Several intelligent witnesses before Lord Rothschild's Committee on Old-age Pensions, representing large and well-managed societies, actually urged upon the Committee that the members of Friendly Societies were more deserving of old-age pensions than other people because they subscribed for the benefit of others and not of themselves.

Another economic point of view in which Friendly Societies call for consideration is that of their relation to the Poor Law. The old Act of 1793, which was the day of elaborate preambles to statutes, affirmed that the protection and encouragement of such societies would be likely to be attended with very beneficial effects by promoting the happiness of individuals, and at the same time diminishing the public burthens. The public burthen at which this was pointed was no doubt the Poor Law, which was then administered in a very different manner from that which has prevailed since the great reform of 1834, and one of the items of encouragement which the Legislature provided for the societies was that their members should not be liable to removal under the Poor Law until they had actually become chargeable to their respective parishes. This exemption was no doubt of great value at that time, when the law of settlement bore very severely upon the poor.

It appears to me that the proper relation of the Friendly Societies to the Poor Law is a negative one. The main object of the societies should be, as indeed it is, to keep their members independent of the Poor Law. They have done so with great success. The returns which have more than once been presented to Parliament of persons receiving relief who are or have been members of Friendly Societies have frequently been shown to be untrustworthy. The number of actual members of such societies who seek relief is small absolutely, and still smaller relatively to the population. It was therefore not without regret that I observed the passing of an Act in 1894 which empowered Boards of Guardians to grant relief out of the poor rates to members of Friendly Societies, and if they thought fit to exclude from consideration of the amount of relief to be granted the amount received by the applicant from his Friendly Society. That Act has just been followed in the natural course of events by a bill for taking away from the Guardians their discretion in the matter, and requiring them to grant full relief to the applicant in addition to the weekly sum, not exceeding five shillings, which he receives from his Friendly Society. In other words, they are to provide a pauper who is a member of a Friendly Society with a free income of five shillings a week more than they would grant as adequate relief to a pauper who was not a member of a Friendly Society, however deserving in other respects that pauper might be. Poor-law relief, instead of being a painful and deplorable necessity, is elevated into a reward of merit in the one case, in which that merit has been displayed by joining a society. A kind of old-age pension is provided for the member, but instead of being an old-age pension without the taint of pauperism, it is a condition of obtaining it that the man must become a pauper. This seems to me to be topsy-turvy legislation. The very bodies the aim and proud boast of which it should be that their members never are paupers have been contented to claim for their members the rank of privileged paupers.

The discussion of the subject of old-age pensions which has now been proceeding for the last twelve or thirteen years has had one good effect in bringing under the consideration of the Friendly Societies the practical methods by which they can obtain these pensions for themselves. The impression that some day and somehow the State would provide pensions for everybody, or at least for everybody who is thrifty, has had a bad effect; but the wiser members of the societies have seen that it would be a good thing to substitute for their present plan of continuing sick-pay to the end of life a plan of insuring a certain annuity after a given age. For this purpose they have had to overcome a natural reluctance on the part of the members to lock up their savings in the purchase of deferred annuities, and they have done so with some success, several thousands of persons having agreed to subscribe for these benefits. It is anticipated that the report of Mr. Alfred Watson on his investigations into the sickness experience of the Manchester Unity of Oddfellows will add force to this movement by showing how great a burden old-age sickness at present is, and how slight an additional sacrifice would secure a deferred annuity. It need hardly be said that it is more desirable that the members generally should do this for themselves than that they should get the State to do it for them.

Registered Friendly Societies are becoming more popular and more wealthy under the present system. The number of returns from societies and branches increased from 23,998 on December 31, 1891, to 26,431 on December 31, 1899, and 27,005 on December 31, 1901; the number of members from 4,203,601 to 5,217,261 in eight years, and to 5,479,882 in ten years; the amount of funds from 22,695,039*l*., or 5*l*. 8*s*. per member, to 32,751,869*l*., or 6*l*. 5*s*. 6*d*. per member, after eight years, and 35,572,740*l*., or 6*l*. 9*s*. 9*d*. per member, after ten years. It is necessary to observe, however, that some of the numerical increase is due to greater completeness in the later returns. The increase in ratio is not affected by this. It may be worth noting that, on the average, the proportion of members under fifty years of age to those above that age is as 81 to 19; and that of the total aggregate receipts per annum, 73 per cent. goes in benefits, 11 per cent. in management, and 16 per cent. is added to capital. The average annual contribution per member is 1*l*. 1*s*. 6*d*.

Up to this point I have referred merely to the Friendly Society of the ordinary type, the sick club and burial fund. Societies of the collecting group, while registered under the

Friendly Societies Act, are also regulated by a separate Act, and it is convenient therefore to consider them apart. They insure burial money only. They are only 46 in number, having increased from 43 in 1891. They have as many as 6,678,005 members, an increase from 5,922,615 in 1899 and 3,875,215 in 1891; but among these each individual above the age of one year in every family is counted separately, and the majority, therefore, are young children. Their funds are 5,973,104*l*., or 17*s*. 11*d*. per member, having increased from 5,207,686*l*., or 17*s*. 7*d*. per member, since 1899, and from 2,713,214*l*., or 14*s*. per member, since 1891. These societies therefore show progress like the others.

The collecting societies do a similar business to that of the Industrial Assurance Companies, of which the Prudential is the type. Their ostensible reason for existence is to answer that instinct of human nature which makes even the poorest desire that the burial of the dead should be attended with some degree of ceremony; but strong as that instinct may be, it does not prompt the poor to seek out the office of the society and pay their premiums there. They have to be solicited by canvassers and waited upon by an army of collectors at their own homes; and the maintenance of this army and the general cost of management absorb nearly half the contributions, so that the poor insurer pays double the net price for his insurance. There is reason to believe, moreover, that these societies are largely used for speculative insurances by persons who have no real insurable interest in the lives insured. So long ago as 1774 an Act was passed for the purpose of checking this sort of gambling in human life; but as it only makes the policy void, the insurer takes the risk of the society repudiating the contract, knowing that its doing so would discredit it and spoil its business.

A number of other classes of societies are capable of being registered under the Friendly Societies Act, such as cattle insurance societies, benevolent societies, working men's clubs, and societies for any purpose the registry of which the Treasury may specially authorise. The formation of cattle insurance societies on a large scale was contemplated by an Act of 1866, when the cattle plague was at its height; but in practice only small pig clubs and similar societies in Lincolnshire and the neighbouring counties have been registered under this head. Benevolent societies are defined as societies for any benevolent or charitable purpose, and might therefore comprise all the charitable institutions of the United Kingdom, but in fact the registered benevolent societies are few. Working men's clubs—frequently called working men's clubs and institutes—were first brought under the operation of the Friendly Societies Act of that day by Sir George Grey as Secretary of State in 1864, and were then societies for purposes of social intercourse, mutual helpfulness, mental and moral improvement, and rational recreation. They are still so defined by law; what they are in fact has been revealed by the provisions of the Licensing Act, 1902, as to the registration of clubs. Rules have been submitted to the Registry Office, and we have been advised that we have no discretion to refuse to register them as rules for carrying out the excellent purposes just defined, providing for the supply of intoxicating liquors to members and their friends at hours when the ordinary licensed houses are compulsorily closed, for keeping the club open every night until midnight, and on nights when there are balls until six o'clock in the morning, and for other incitements to intemperance. I hope that it will not be long before an enactment is passed that the registry of a club under the Licensing Act shall vacate its registry under the Friendly Societies Act. Such clubs have nothing to do with thrift or with insurance; they are rather instruments of extravagance, improvidence, and dissipation.

Some of the specially authorised purposes are also wide of the mark, which upon the *ejusdem generis* rule should, I think, be pointed with strictness in the direction of provident insurance; but there has always been a desire liberally to extend the benefits of the Friendly Societies Act with a view to the encouragement of societies having praiseworthy objects which for want of means or some other reason are not registered as companies. The large majority of specially authorised societies are Loan Societies, and though these may in some cases be fairly good investments for those who lend, they are of doubtful benefit to those who borrow. An exception must be made to this statement with respect to the Agricultural Credit Societies, many of which have been established in Ireland by the exertions of Sir Horace Plunkett, and have been pecuniarily assisted by the Congested Districts Board. It is a feature of these societies that they not only lend money to the small farmer, but see that he spends it on improvements to his farm; and also that there is no division of profit among the members.

The returns from all societies under the Friendly Societies Act other than Friendly Societies proper increased from 557 in 1891 to 1308 in 1899, and 1449 in 1901; the number of members from 241,446 in 1891 to 610,254 in 1899, and 649,491 in 1901; and the amount of funds from 594,808*l*. in 1891 to 1,528,064*l*. in 1899, and 1,686,656*l*. in 1901. Here, again, great allowance has to be made for the want of completeness in the returns of the earliest date.

Allied to Friendly Societies, but having special regulations under other Acts, are shop clubs and workmen's compensation schemes. In a vast number of large industrial establishments the men have their own sick club, sometimes assisted by the employer; and in a few the employer makes it a condition of employment that every workman shall join the club. Where this is done it is now enacted, not only that the club shall comply with the requirements of the Friendly Societies Act as to registry, but also with other conditions of more stringency. As yet only a few clubs have been able to satisfy all the requirements of the Shop Clubs Act, 1902. The workmen's compensation schemes provide an alternative to the general scheme of compensation to injured workmen contained in the Act of 1897, and have enabled the employers and workmen in several large industries to enter into mutual arrangements by which the workman gains an equivalent to the compensation which the Act would give him, and enters into partnership with the employer for obtaining other benefits. According to the returns, these schemes have hitherto resulted very favourably to the workmen, and it seems a pity there are not more of them.

The sentiment of which I have spoken, that it is desirable to extend the benefits of the Friendly Societies Acts to societies for good objects, even though those objects may not be purposes of provident insurance, is expressed in the statute of 1834, which allowed of "any purpose which is not illegal," and in that of 1846, in which the definition of a Friendly Society was made to include the frugal investment of the savings of the members for better enabling them to purchase food, firing, clothes, or other necessaries, or the tools, implements, or materials of their trade or calling, or to provide for the education of their children or kindred. Under these Acts the Rochdale Equitable Pioneers and a number of other Co-operative Societies were registered, and in 1852 an Act was passed specially dealing with these bodies under the name of Industrial and Provident Societies. They were made corporate bodies by an Act of 1862, and are now regulated by the Industrial and Provident Societies Act, 1893. The societies that may be registered under that Act are societies for carrying on any industries, businesses, or trades specified in or authorised by their rules, whether wholesale or retail, and including dealings of any description with land.

This definition indicates pretty clearly the manner in which Co-operative Societies have worked out their own evolution. The expression "Industries" denotes the productive form of society, a form which has always embodied the ideal of co-operation when the combined labour of the members should be engaged in the production of commodities. The expression "Businesses" indicates the recognition of the Legislature that Co-operative Societies ought to cover a wider range than was allowed by the words "labour, trade, or handicraft" in the Act of 1876, and includes banking, assurance, and the like. The expression "Trades" denotes the distributive form of society, a form in which co-operation has gained its greatest successes. The permission to carry on these functions "wholesale" as well as retail points to the system of super-association, or co-operation between societies, which has attained phenomenal proportions in the co-operative wholesale societies of Manchester and of Glasgow, and exists in a smaller degree of development in other societies. The authorising of "dealings of any description with land" relates not merely to a considerable number of land societies, but is also an indication of the great extent to which societies for other purposes have applied their profits and

some of their capital to the excellent work of providing homes for their members. It is also to be observed that many societies are both distributive and productive.

What have these societies done for their members? They have reduced the price of the necessaries of life and have thus enabled persons of limited means to enjoy some of its luxuries; they have provided a remunerative investment for small savings; they have done much to put an end to the practice of giving and taking long credit; they have done as much as in them lies to ensure the purity of commodities; they have discountenanced (though, perhaps, not with all the success that might have been hoped for) the practice of taking commissions and commercial bribery generally; they have raised the standard of comfort and have helped many members to obtain the coveted possession of a house of their own; they have devoted a share of their profits to educational purposes with excellent results. Some of the productive societies, by the practice of giving a bonus to labour, have improved the economic position of the workman and contributed to the efficiency of his work. On the other hand, co-operative societies generally have not been so successful as was expected in realising some of the aspirations of the founders of co-operation; commercial failure has not been unknown among them; losses have occurred, though the simple organisation of the societies has made it easy to deal with them by adjustments of the capital account; they have not always had the best of managers, and have sometimes failed to give their confidence where it was deserved, and given it where it was not. In many places they have had to contend with opposition from the traders to whose business and profits their success was unfavourable. Taking all things into consideration, the progress they have made is surprising.

Comparing the returns for the United Kingdom for the years ending December 31, 1891, and December 31, 1901, the increase in number of societies was from 1597 to 2175; in number of members from 1,136,907 to 1,929,628; in amount of funds from 16,545,138*l*. to 40,824,660*l*.

It has been observed that the Co-operative Societies are largely undertaking the work of providing houses for their members; and to that it may be added that the Friendly Societies are more and more tending to adopt the practice of lending money to members on mortgage as one of the most remunerative forms of investment open to them. The Building Societies, which were established for that purpose only, are still carrying on the same work, and the combined operation of all three ought to produce a material effect on the prosperity and well-being of the industrial population. Building Societies alone advance as much as 9,000,000*l*. a year on mortgage.

Building Societies have passed through a crisis. The incorporated societies reached their highest point of prosperity in 1887, when their capital amounted to fifty-four millions; by 1894 it had fallen to below forty-three millions. The Building Societies Act, 1894, required of societies a fuller disclosure of the real state of their affairs than had previously been called for. The result was to show that, apart from the special scandal caused by the fraudulent proceedings of the Liberator Society, there were hitherto undisclosed elements of weakness in the management of Building Societies that justified the withdrawal of the public confidence that had been reposed in them. The properties in possession before the passing of the Act of 1894 were not less than 7,500,000*l*.; they are now less than 3,000,000*l*. This points to the fact that the early prosperity of Building Societies had led to the establishment of more societies than the public demand called for, with the consequences that societies competed against each other, and that in the stress of competition and the anxiety to do business they accepted unsatisfactory securities, which must lead to loss upon realisation. From this point of view the effect of the Act of 1894 has been wholly salutary. Year after year the societies have reduced their properties in possession. The evils which they dreaded from the disclosure of the facts have not arisen. At this day it may be said that the societies as a whole have regained the position they held in public confidence, for the members now know the worst. They know, too, that where the blight of properties in possession still infests the business the managers are resolutely endeavouring to diminish its effect.

I need hardly repeat what has so often been said of the economic value of a sound Building Society. The man who by its means gets a stake in the country mounts many steps on the social ladder. When he has paid off the mortgage on his own dwelling-house, and so liberated himself from the obligation to pay principal and interest, either in the form of repayment annuity or of rent, what is to prevent him from buying in the same manner, as an investment, another house with the income thus set free, and so on?

There are still sixty-eight Building Societies which remain under the operation of the Act of 1836, having been established before 1856, and not having availed themselves of the option of taking upon themselves the responsibilities and the privileges of the Acts of 1874 and subsequent years. One society (the Birkbeck) stands by itself, as, although its business as a Building Society is considerable—the new advances granted on mortgage last year having been for 120,000*l*.—its main operations are those of a deposit bank, and it keeps the far greater part of its funds in investments on liquid securities. The other societies are pursuing the even tenor of their way, just as they have done for the last fifty years, and show on the average an increase of business from year to year. But the great body of Building Societies are those which are incorporated under the Acts of 1874 to 1894, exceeding 2000 in number. They have so far recovered from the effects of the depression that their assets are now forty-eight millions, being midway between the low-water mark of 1894 and the high-water mark of 1887. That and the fact that they have in about seven years reduced their properties in possession by about 60 per cent. leads to the inference that they are now, speaking generally, in a fairly healthy condition, and that many years of usefulness are still to be expected for them.

The Friendly Societies Registry also registers and receives returns from trade unions. These useful and necessary bodies have, I think, been rather cruelly treated, not only in past days, but also in more recent times. Without going back to the bad old times when six poor agricultural labourers were sentenced to seven years' transportation for forming a trade union, or even to the time when they were refused the protection of the law for the funds they had accumulated, because, forsooth, they were for an illegal purpose, it will be sufficient to mark the unexpected change that has been worked in their position since the Act of 1871 purported to render them legal. Registry under that Act authorised the trustees of a trade union to hold land not exceeding one acre, vested the property of the union in them, authorised them to sue and be sued on behalf of the union, limited their liability, made the treasurers and officers accountable to them or to the members, and enabled them to take summary proceedings against any person misapplying their funds. But it did not create the unions corporate bodies, and did not enable any Court to entertain legal proceedings for enforcing their contracts with their members, recovering contributions due from a member, or recovering from the union benefits due to a member or other person, or for enforcing any agreement between one trade union and another, even where any such contracts or agreements were secured by bond. It was commonly thought that the effect of all this would be that the unions, having none of the privileges of incorporation, would escape the liabilities which affect corporate bodies; and so much was this the general opinion that the Duke of Devonshire and other members of the Royal Commission on Labour made a minority report in which they suggested that the law in this respect should be altered.

It has recently been determined that, although unions are not corporate bodies, they are responsible for the acts of their agents as much as if they were. I do not presume to question the propriety of this decision as a matter of law, nor even to say that it is a decision which is contrary to equity; but only to point out that its result upon the individual member of a trade union, who gave no mandate to its agents to do any illegal or injurious act, but handed over his savings to the trustees of the union, relying on the stringency of the provisions of the Act as to misapplication of funds, is very serious and was unexpected. The contributions of workmen to their trade union represent an amount of self-sacrifice and self-denial that is not readily gauged or measured or understood by persons in easier circumstances of life. Their object, which is primarily to provide the sinews of war in any conflict that may be necessary to secure their material welfare, and secondarily to provide sick and funeral and pension and out-of-work

benefits against the ordinary ills of life, is one that ought to appeal most strongly to the sympathies of the economist. If it is the fact that trade unions make mistakes, as most people do, those mistakes will be much fewer and less mischievous when full legislative recognition and protection are afforded them than they were under the old *régime* of suspicion and repression.

Loan Societies under the Act of 1840 are societies for lending sums of money not exceeding 15*l.* to the industrious classes upon terms of a deduction of interest at the time of granting the loan and a corresponding weekly repayment fixed to commence at such a time that the rate of interest earned by the society shall be about 12 per cent. per annum; another instance of the experience which always faces the poor man that he has to pay for any small accommodation he wants a higher relative price than the man has who wants more. These societies are of two types: the Friends of Labour Loan Societies, existing mainly in the metropolis, having two classes of members, investing and borrowing, but limiting the subscriptions of the one class to the 15*l.*, which is the statutory limit of the loans to the other class; and what may be called the proprietary loan societies, existing mainly in Yorkshire, making their loans to non-members, and consisting of a small number of persons who contribute the whole of the capital, the holding of each proprietor sometimes amounting to several hundreds of pounds.

The Registry of Friendly Societies has for one of its functions that of granting to societies which are exclusively for purposes of science, literature, and the fine arts certificates exempting them from local rating. Though there can be no question that these certificates are of great value to many excellent institutions, such as public libraries, picture galleries, museums, and scientific and learned societies, which would find the liability to pay rates, in these days when rates have increased and are increasing so largely, a serious deduction from the scanty means at their command for maintaining their useful operations, yet I have very grave doubts whether on economic grounds any such exemption from rates is capable of being defended. The benevolent people who subscribe to maintain these buildings for the public good increase the burden upon the small ratepayer to the extent to which they fail to contribute their share. The Act of 1843 has more than once been scheduled in Bills for repealing exemptions from rating, but those Bills have not been passed, and the Act is still in force.

There only remains to consider the case of Savings Banks, which are brought in connection with the Registry of Friendly Societies by the Acts which confer upon that office exclusive and final jurisdiction in the settlement of disputes, and effectually oust the jurisdiction of the Courts of Law. Under these Acts many thousands of disputes have been settled by my predecessors, my colleagues, and myself, and at the present time an average of three appointments every week during the busy time of the year has to be made to hear the parties. We see much of the seamy side of life in these cases—many family and other quarrels of a sordid character are brought to light—and it has been noted as a curious fact that persons guilty of fraud or embezzlement seem frequently, but most unwisely, to select the Savings Bank as the securest receptacle for their ill-gotten gains. On the other hand many pathetic and touching instances of thrift and self-sacrifice have been brought under our notice, and much evidence has been accumulated as to the great value to the poor of these excellent institutions. As compared with the several self-governing bodies to which I have already directed attention, the Savings Bank may not unfairly be described as the elementary form of organisation for thrift. The depositor entrusts his money to it for mere safe custody and accumulation, and has no voice in the application of it or control over its managers. All he asks is that he may run no risk of losing it. Savings Banks are of three classes: the 230 Trustee Savings Banks of the old type which still remain, and have to their credit an undiminished amount of funds, though there were at one time more than twice as many banks; the Post Office Savings Bank, which is one of the many monuments still extant to the financial genius of Mr. Gladstone, and not less to the administrative skill of the public servants who settled the lines upon which it works, and which has increased the savings of the people more than threefold by bringing almost to every man's door the opportunity of making deposits. I hope that it may meet in its new and splendid home at West Kensington with a continuance and increase of the marvellous success which has hitherto attended it. Thirdly, there are the Railway Savings Banks, which have collected from the workmen employed and from their families nearly five million pounds. It is right to observe that they give a rate of interest exceeding by about 1 per cent. that given by the Trustee and Post Office Savings Banks. It is also to be borne in mind that the deposits in Savings Banks are not drawn wholly from the industrial population, but that many, especially women and children, belonging to other classes make use of the banks. Indeed, the Postmaster-General, in an approximate estimate made some years ago, calculated that women and children constituted 56·per cent. of the whole number of depositors. School Savings Banks and Penny Savings Banks are also to be mentioned as feeders of the ordinary Savings Banks, and as greatly increasing the opportunities of saving afforded to the young, and instilling into them valuable lessons of thrift.

Such is the story the department I am about to leave has to tell of the free and spontaneous efforts of the industrial population to better their condition by means of thrift and economy. It is, I venture to think, one which speaks well for the general body of that population and has great promise for the future of the country. In times of depression, as well as in times of prosperity, the gradual increase of the funds of these various bodies has been maintained; the members have not been compelled by the one, nor tempted by the other, to relax their efforts and their sacrifices.

I ask forgiveness for having detained you so long on so small a branch of the great subjects with which this Section has to deal, and which will be well illustrated in the important papers and discussions that are set down on its programme. The course of events has given to one group of subjects, that has often been considered in this Section, a new and unexpected prominence; and we await with keen interest the teaching which economic science has to offer on the questions of the day.

SECTION H.

ANTHROPOLOGY.

Opening Address by Prof. Johnson Symington, M.D., F.R.S., F.R.S.E., President of the Section.

It is now nearly twenty years since Anthropology attained to the dignity of being awarded a special and independent Section in this Association, and I believe it is generally admitted that during this period the valuable nature of many of the contributions, the vigour of the discussions, and the large attendance of members have amply justified the establishment and continued existence of this Section.

While the multifarious and diverse nature of the subjects which are grouped under the term Anthropology gives a variety and a breadth to our proceedings, which are very refreshing in this age of minute specialism, I feel that it adds very considerably to the difficulty of selecting a subject for a Presidential Address which will prove of general interest.

A survey of the recent advances in our knowledge of the many important questions which come within the scope of this Section would cover too wide a field for the time at my disposal, while a critical examination of the various problems that still await solution might expose me to the temptation of pronouncing opinions on subjects regarding which I could not speak with any real knowledge or experience. To avoid such risks I have decided to limit my remarks to a subject which comes within the range of my own special studies, and to invite your attention to a consideration of some problems arising from the variations in the development of the skull and the brain.

Since the institution of this Section the development, growth, and racial peculiarities of both skull and brain, and the relation of these two organs to each other, have attracted an ever-increasing amount of attention. The introduction of new and improved methods for the study of the structure of the brain and the activity of an able

band of experimenters have revolutionised our knowledge of the anatomy and physiology of the higher nerve centres.

The value of the results thus obtained is greatly enhanced by the consciousness that they bear the promise of still greater advances in the near future. If the results obtained by the craniologist have been less marked, this arises mainly from the nature of the subject, and is certainly not due to any lack of energy on their part. Our craniological collections are continually increasing, and the various prehistoric skull-caps from the Neanderthal to the Trinil still form the basis of interesting and valuable memoirs.

While the additions to our general knowledge of cerebral anatomy and physiology have been so striking, those aspects of these subjects which are of special anthropological interest have made comparatively slight progress, and cannot compare in extent and importance with the advantages based upon a study of fossil and recent crania. These facts admit of a ready explanation. Brains of anthropological interest are usually difficult to procure and to keep, and require the use of special and complicated methods for their satisfactory examination, while skulls of the leading races of mankind are readily collected, preserved, and studied. Hence it follows that the crania in our anthropological collections are as numerous, well preserved, and varied as the brains are few in number and defective, both in their state of preservation and representative character. It may reasonably be anticipated that improved methods of preservation and the growing recognition on the part of anthropologists, museum curators, and collectors of the importance of a study of the brain itself will to some extent at least remedy these defects; but so far as prehistoric man is concerned, we can never hope to have any direct evidence of the condition of his higher nerve centres, and must depend for an estimate of his cerebral development upon those more or less perfect skulls which fortunately have resisted for so many ages the corroding hand of time.

I presume we will all admit that the main value of a good collection of human skulls depends upon the light which they can be made to throw upon the relative development of the brains of different races. Such collections possess few, if any, brains taken from these or corresponding skulls, and we are thus dependent upon the study of the skulls alone for an estimate of brain development.

Vigorous attacks have not unfrequently been made upon the craniometric systems at present in general use, and the elaborate tables, compiled with so much trouble, giving the circumference, diameters, and corresponding indices of various parts of the skull, are held to afford but little information as to the real nature of skull variations, however useful they may be for purposes of classification. While by no means prepared to express entire agreement with these critics, I must admit that craniologists as a whole have concentrated their attention mainly on the external contour of the skull, and have paid comparatively little attention to the form of the cranial cavity. The outer surface of the cranium presents features which are due to other factors than brain development, and an examination of the cranial cavity not only gives us important information as to brain form, but by affording a comparison between the external and internal surfaces of the cranial wall it gives a valuable clue to the real significance of the external configuration. Beyond determining its capacity we can do but little towards an exact investigation of the cranial cavity without making a section of the skull. Forty years ago Prof. Huxley, in his work "On the Evidence of Man's Place in Nature," showed the importance of a comparison of the basal with the vaulted portion of the skull, and maintained that until it should become "an opprobrium to an ethnological collection to possess a single skull which is not bisected longitudinally" there would be "no safe basis for that ethnological craniology which aspires to give the anatomical characters of the crania of the different races of mankind." Prof. Cleland and Sir William Turner have also insisted upon this method of examination, and only two years ago Prof. D. J. Cunningham, in his Presidential Address to this Section, quoted, with approval, the forcible language of Huxley. The curators of craniological collections appear, however, to possess an invincible objection to any such treatment of the specimens under their care. Even in the Hunterian Museum in London, where Huxley himself worked at this subject, among several thousands of skulls, scarcely any have been bisected longitudinally, or had the cranial cavity exposed by a section in any other direction. The method advocated so strongly by Huxley is not only essential to a thorough study of the relations of basi-cranial axis to the vault of the cranium and to the facial portion of the skull, but also permits of casts being taken of the cranial cavity; a procedure which, I would venture to suggest, has been too much neglected by craniologists.

Every student of anatomy is familiar with the finger-like depressions on the inner surface of the cranial wall, which are described as the impress of the cerebral convolutions; but their exact distribution and the degree to which they are developed according to age, sex, race, &c., still remain to be definitely determined. Indeed, there appears to be a considerable difference of opinion as to the degree of approximation of the outer surface of the brain to the inner surface of the cranial wall. Thus the brain is frequently described as lying upon a water-bed, or as swimming in the cerebro-spinal fluid, while Hyrtle speaks of this fluid as a "ligamentum suspensorium" for the brain. Such descriptions are misleading when applied to the relation of the cerebral convolutions to the skull. There are, it is true, certain parts of the brain which are surrounded and separated from the skull by a considerable amount of fluid. These, however, are mainly the lower portions, such as the medulla oblongata and pons Varolii, which may be regarded as prolongations of the spinal cord into the cranial cavity. As they contain the centres controlling the action of the circulatory and respiratory organs, they are the most vital parts of the central nervous system, and hence need special protection. They are not, however, concerned with the regulation of complicated voluntary movements, the reception and storage of sensory impressions from lower centres, and the activity of the various mental processes. These functions we must associate with the higher parts of the brain, and especially with the convolutions of the cerebral hemispheres.

If a cast be taken of the cranial cavity and compared with the brain which had previously been carefully hardened *in situ* before removal, it will be found that the cast not only corresponds in its general form to that of the brain, but shows a considerable number of the cerebral fissures and convolutions. This moulding of the inner surface of the skull to the adjacent portions of the cerebral hemispheres is usually much more marked at the base and sides than over the vault. Since the specific gravity of the brain tissue is higher than that of the cerebro-spinal fluid, the cerebrum tends to sink towards the base and the fluid to accumulate over the vault; hence probably these differences admit of a simple mechanical explanation. Except under abnormal conditions, the amount of cerebro-spinal fluid between the skull and the cerebral convolutions is so small that from a cast of the cranial cavity we can obtain not only a good picture of the general shape and size of the higher parts of the brain, but also various details as to the convolutionary pattern. This method has been applied with marked success to the determination of the characters of the brain in various fossil lemurs by Dr. Forsyth Major and Prof. R. Burckhardt, and Prof. Gustav Schwalbe has made a large series of such casts from his craniological collection in Strassburg. The interesting observations by Schwalbe[1] on the arrangement of the "impressiones digitatæ" and "juga cerebralia," and their relation to the cerebral convolutions in man, the apes, and various other mammals, have directed special attention to a very interesting field of inquiry. As is well known, the marked prominence at the base of the human skull, separating the anterior from the middle fossa, fits into the deep cleft between the frontal and temporal lobes of the brain, and Schwalbe has shown that this ridge is continued—of course in a much less marked form—along the inner surface of the lateral wall of the skull, so that a cast of the cranial cavity presents a shallow but easily recognised groove corresponding to the portion of the Sylvian fissure of the brain separating the frontal and parietal lobes from the temporal lobe. Further, there is a distinct depression for the lodgment of the inferior frontal convolution, and a cast of the middle cranial fossa shows the three external temporal convolutions.

We must now turn to the consideration of the relations

1 "Ueber die Beziehungen zwischen Innenform und Aussenform des Schädels," *Deutsches Archiv für klinische Medicin*, 1902.

of the outer surface of the cranium to its inner surface and to the brain. This question has engaged the attention of experts as well as the "man in the street" since the time of Gall and Spurzheim, and one might naturally suppose that the last word had been said on the subject. This, however, is far from being the case. All anatomists are agreed that the essential function of the cranium is to form a box for the support and protection of the brain, and it is generally conceded that during the processes of development and growth the form of the cranium is modified in response to the stimulus transmitted to it by the brain. In fact it is brain growth that determines the form of the cranium, and not the skull that moulds the brain into shape. This belief, however, need not be accepted without some reservations. Even the brain may be conceived as being influenced by its immediate environment. There are probably periods of development when the form of the brain is modified by the resistance offered by its coverings, and there are certainly stages when the brain does not fully occupy the cranial cavity.

At an early period in the phylogeny of the vertebrate skull the structure of the greater part of the cranial wall changes from membranous tissue into cartilage, the portion persisting as membrane being situated near the median dorsal line. In the higher vertebrates the rapid and early expansion of the dorsal part of the fore-brain is so marked that the cartilaginous growth fails to keep pace with it, and more and more of the dorsal wall of the cranium remains membranous, and subsequently ossifies to form membrane bones. Cartilage, though constituting a firmer support to the brain than membrane, does not possess the same capacity of rapid growth and expansion. The head of a young child is relatively large, and its skull is distinguished from that of an adult by the small size of the cartilaginous base of the cranium as compared with the membranous vault. The appearance of top-heaviness in the young skull is gradually obliterated as age advances by the cartilage continuing slowly to grow after the vault has practically ceased to enlarge. These changes in the shape of the cranium are associated with corresponding alterations in that of the brain, and it appears to me that we have here an illustration of how the conditions of skull growth may modify the general form of the brain.

Whatever may be the precise influences that determine skull and brain growth, there can be no doubt but that within certain limits the external form of the cranium serves as a trustworthy guide to the shape of the brain. Statements such as those by Dr. J. Deniker ("The Races of Man," p. 53) "that the inequalities of the external table of the cranial walls have no relation whatever with the irregularities of the inner table, and still less have anything in common with the configuration of the various parts of the brain," are of too general and sweeping a character. Indeed, various observers have drawn attention to the fact that in certain regions the outer surface of the skull possesses elevations and depressions which closely correspond to definite fissures and convolutions of the brain. Many years ago Sir William Turner, who was a pioneer in cranio-cerebral topography, found that the prominence on the outer surface of the parietal bone, known to anatomists as the parietal eminence, was situated directly superficial to a convolution of the parietal lobe of the brain, which he consequently very appropriately named "the convolution of the parietal eminence." Quite recently Prof. G. Schwalbe has shown that the position of the third or inferior frontal convolution is indicated by a prominence on the surface of the cranium in the anterior part of the temple. This area of the brain is of special interest to all students of cerebral anatomy and physiology, since it was the discovery by the illustrious French anthropologist and physician, M. Broca, that the left inferior frontal convolution was the centre for speech, that laid the scientific foundation of our present knowledge of localisation of function in the cerebral cortex. This convolution is well known to be much more highly developed in man than in the anthropoid apes, and the presence of a human cranial speech-bump is usually easily demonstrated. The faculty of speech, however, is such a complicated cerebral function that I would warn the "new" phrenologist to be cautious in estimating the loquacity of his friends by the degree of prominence of this part of the skull, more particularly as there are other and more trustworthy methods of observation by which he can estimate this capacity.

In addition to the prominences on the outer surface of the cranium, corresponding to the convolutions of the parietal eminence and the left inferior frontal convolution, the majority of skulls possess a shallow groove marking the position of the Sylvian point and the course of the horizontal limb of the Sylvian fissure. Below these two other shallow oblique grooves indicate the line of the cerebral fissures which divide the outer surface of the temporal lobe into its three convolutions, termed superior, middle, and inferior. Most of these cranial surface markings are partially obscured in the living body by the temporal muscle, but they are of interest as showing that in certain places there is a close correspondence in form between the external surface of the brain and that of the skull. There are, however, distinct limitations in the degree to which the various cerebral fissures and convolutions impress the inner surface of the cranial wall, or are represented by inequalities on its outer aspect. Thus over the vault of the cranium the position of the fissure of Rolando and the shape of the cerebral convolutions in the so-called motor area, which lie in relation to this fissure, cannot usually be detected from a cast of the cranial cavity, and are not indicated by depressions or elevations on the surface of the skull, so that the surgeons in planning the seats of operations necessary to expose the various motor centres have to rely mainly upon certain linear and angular measurements made from points frequently remote from these centres.

The cranium is not merely a box developed for the support and protection of the brain, and more or less accurately moulded in conformity with the growth of this organ. Its antero-lateral portions afford attachments to the muscles of mastication and support the jaws and teeth, while its posterior part is liable to vary according to the degree of development of the muscles of the nape of the neck. Next to the brain the most important factor in determining cranial form is the condition of the organs of mastication —muscles, jaws, and teeth. There is strong evidence in favour of the view that the evolution of man from microcephaly to macrocephaly has been associated with the passage from a macrodontic to a microdontic condition. The modifications in the form of the cranium due to the influence of the organs of mastication have been exerted almost entirely upon its external table; hence external measurements of the cranium, as guides to the shape of the cranial cavity and indications of brain development, while fairly trustworthy in the higher races, become less and less so as we examine the skulls of the lower races, of prehistoric man, and of the anthropoid apes.

One of the most important measurements of the cranium is that which determines the relation between its length and breadth and thus divides skulls into long or short, together with an intermediate group neither distinctly dolichocephalic nor brachycephalic. These measurements are expressed by an index in which the length is taken as 100. If the proportion of breadth to length is eighty or upwards, the skull is brachycephalic; if between seventy-five and eighty, mesaticephalic; and below seventy-five, dolichocephalic. Such a measurement is not so simple a matter as it might appear at first sight, and craniologists may themselves be classified into groups according as they have selected the nasion, or depression at the root of the nose, the glabella, or prominence above this depression, and the ophryon, a spot just above this prominence, as the anterior point from which to measure the length. In a young child this measurement would practically be the same whichever of these three points was chosen, and each point would be about the same distance from the brain. With the appearance of the teeth of the second dentition and the enlargement of the jaws the frontal bone in the region of the eyebrows and just above the root of the nose thickens, and its outer table bulges forwards so that it is now no longer parallel with the inner table. Between these tables air cavities gradually extend from the nose, forming the frontal sinuses. Although the existence and significance of these spaces and their influence on the prominence of the eyebrows were the subject of a fierce controversy more than half a century ago between the phrenologists and their opponents, it is only recently that their variations have been carefully investigated.

The frontal sinuses are usually supposed to vary according to the degree of prominence of the glabella and the supra-orbital arches. This, however, is not the case. Thus Schwalbe[1] has figured a skull in which the sinuses do not project as high as the top of the glabella and supra-orbital prominences, and another in which they extend considerably above these projections. Further, Dr. Logan Turner ("The Accessory Sinuses of the Nose," 1901), who has made an extensive investigation into these cavities, has shown that in the aboriginal Australian, in which this region of the skull is unusually prominent, the frontal sinuses are frequently either absent or rudimentary. The ophryon has been selected by some craniologists as the anterior point from which to measure the length of the skull, under the impression that the frontal sinuses do not usually reach above the glabella. Dr. Logan Turner, however, found that out of 174 skulls in which the frontal sinuses were present in 130 the sinuses extended above the ophryon. In seventy-one skulls the depth of the sinus at the level of the ophryon varied from 2 mm. to 16 mm., the average being 5·2 mm., while in the same series of skulls the depth at the glabella varied from 3 mm. to 18 mm., with an average depth of 8·5 mm. It thus appears that the selection of the ophryon in preference to the glabella, as giving a more accurate clue to the length of the brain, is based upon erroneous assumptions, and that neither point can be relied upon in the determination of the anterior limit of the cranial cavity.

The difficulties of estimating the extent of the cranial cavity by external measurements and the fallacies that may result from a reliance upon this method are especially marked in the case of the study of the prehistoric human calvaria, such as the Neanderthal and the Trinil and the skulls of the anthropoid apes.

Statistics are popularly supposed to be capable of proving almost anything, and certainly if you allow craniologists to select their own points from which to measure the length and breadth of the cranium, they will furnish you with tables of measurements showing that one and the same skull is dolichocephalic, mesaticephalic, and brachycephalic. Let us take as an illustration an extreme case, such as the skull of an adult male gorilla. Its glabella and supra-orbital arches will be found to project forwards, its zygomatic arches outwards, and its transverse occipital crests backwards, far beyond the anterior, lateral, and posterior limits of the cranial cavity. These outgrowths are obviously correlated with the enormous development of the muscles of mastication and those of the back of the neck. In a specimen in my possession the greatest length of the cranium, *i.e.* from glabella to external occipital protuberance, is 195 mm., and the greatest breadth, taken between the outer surfaces of the zygomatic processes of the temporal bone, is 172 mm., giving the marked brachycephalic index of 88·21. The zygomatic processes, however, may reasonably be objected to as indicating the true breadth, and the side wall of the cranium just above the line where the root of this process springs from the squamous portion of the temporal bone will certainly be much nearer the cranial cavity. Measured in this situation the breadth of the cranium is 118 mm., which gives a length-breadth index 60·51, and thus represents the skull as decidedly dolichocephalic. The transverse occipital crests and the point where these meet in the middle line to form the external occipital protuberance are much more prominent in the male than in the female gorilla, and the estimate of the length of the cranium in this male gorilla may be reduced to 160 mm. by selecting the base of the protuberance in place of its posterior extremity as the posterior end measurement. This raises the index to 73·75, and places the skull near the mesaticephalic group. At the anterior part of the skull the prominent glabella is separated from the inner table of the skull by large air sinuses, so that on a median section of the skull the distance from the glabella to the nearest part of the cranial cavity is 36 mm. We have here, therefore, another outgrowth of the cranial wall which in an examination of the external surface of the skull obscures the extent of the cranial cavity. Accordingly the glabella cannot be selected as the anterior point from which to measure the length of the cranium, and must, like the zygomatic arches and occipital protuberance, be excluded from our calculations if we desire to determine a true length-breadth index. The difficulty, however, is to select a definite point on the surface of the cranium to represent its anterior end, which will be free from the objections justly urged against the glabella. Schwalbe suggests the hinder end of the supra-glabellar fossa, which he states often corresponds to the beginning of a more or less distinctly marked frontal crest. I have found this point either difficult to determine or too far back. Thus in my male gorilla the posterior end of this fossa formed by the meeting of the two temporal ridges was 56 mm. behind the glabella, and only 24 mm. from the bregma, while in the female gorilla the temporal ridges do not meet, but there is a low median frontal ridge, which may be considered as bounding posteriorly the supra-glabellar fossa. This point is 22 mm. from the glabella, and between 50 mm. and 60 mm. in front of the bregma.

I would suggest a spot in the median line of the supra-glabellar fossa which is crossed by a transverse line uniting the posterior borders of the external angular processes of the frontal bone. I admit this plan is not free from objections, but it possesses the advantages of being available for both male and female skulls. In my male skull the selection of this point diminishes the length of the cranium by 25 mm., thus reducing it to 137 mm. The breadth being calculated at 114 mm., the index is 83·21, and hence distinctly brachycephalic. The length of the cranial cavity is 118 mm. and the breadth 96 mm., and the length-breadth index is thus the brachycephalic one of 81·36.

I have given these somewhat detailed references to the measurements of this gorilla's skull because they show in a very clear and obvious manner that from an external examination of the skull one might easily be misled as to the size and form of the cranial cavity, and that, in order to determine from external measurements the proportions of the cranial cavity, skull outgrowths due to other factors than brain growth must be rigorously excluded. Further, these details will serve to emphasise the interesting fact that the gorilla's skull is decidedly brachycephalic. This character is by no means restricted to the gorilla, for it has been clearly proved by Virchow, Schwalbe, and others that all the anthropoid apes are markedly round-headed. Ever since the introduction by the illustrious Swedish anthropologist Anders Retzius of a classification of skulls according to the proportions between their length and breadth great attention has been paid to this peculiarity in different races of mankind. It has been generally held that brachycephaly indicates a higher type of skull than dolichocephaly, and that the increase in the size of the brain in the higher races has tended to produce a brachycephalic skull. When the cranial walls are subject to excessive internal pressure, as in hydrocephalus, the skull tends to become distinctly brachycephalic, as a given extent of wall gives a greater internal cavity in a spherical than an oval form. In estimating the value of this theory as to the evolutionary line upon which the skull has travelled, it is obvious that the brachycephalic character of the skulls of all the anthropoid apes is a fact which requires consideration.

Although an adult male gorilla such as I have selected presents in an extreme degree outgrowths from the cranial wall masking the true form of the cranial cavity, the same condition, though to a less marked extent, is met with in the human subject. Further, it is interesting to note that the length of the skull is more liable to be increased by such growths than the breadth, since they occur especially over the lower part of the forehead and to a less degree at the back of the skull, while the side walls of the cranium in the region of its greatest breadth generally remain thin.

Few if any fossils have attracted an equal amount of attention or given rise to such keen controversies as the "Neanderthal" and the "Trinil" skull-caps. According to some authorities both these skull-caps are undoubtedly human, while others hold that the "Neanderthal" belongs to an extinct species of the genus Homo, and the "Trinil" is the remains of an extinct genus—*Pithecanthropus erectus* of Dubois—intermediate between man and the anthropoids. One of the most obvious and easily recognised peculiarities of these skull-caps is the very marked prominence of the supra-orbital arches. The glabella-occipital length of the

[1] "Studien über *Pithecanthropus erectus*," *Zeitschrift für Morphologie und Anthropologie*, Bd. i. 1899.

Neanderthal is 204 mm., and the greatest transverse diameter, which is over the parietal region, is 152 mm.—an index of 74·51—while the much smaller Trinil calvaria, with a length of 181 mm. and a breadth of 130 mm., has an index of 71·8. Both these skulls are therefore slightly dolichocephalic. Schwalbe has corrected these figures by making reductions in their lengths on account of the frontal "outworks," so that he estimates the true length-breadth index of the Neanderthal as 80 and that of the Trinil as 75·5. These indices, thus raised about 5 per cent., are considered to represent approximately the length-breadth index of the cranial cavity. A comparison of the external and internal measurements of many recent skulls with prominent glabellæ would, I suspect, show a greater difference than that calculated by Schwalbe for the Neanderthal and Trinil specimens. In a male skull, probably an aboriginal Australian, with a cranial capacity of 1227 c.cm. I found that the glabella-occipital length was 189 mm., and the transverse diameter at the parieto-squamous suture 127 mm., which gives an index of 67·20 and makes the skull decidedly dolichocephalic. The length of the cranial cavity, however, was 157 mm. and the breadth 121 mm. (an index of 77·07 and a difference of nearly 10 per cent.), so that while from external measurements the skull is distinctly dolichocephalic, the proportions of its cavity are such that it is mesaticephalic. It is probable that many skulls owe their dolichocephalic reputation simply to the prominence of the glabella and supra-orbital ridges. An excessive development of these structures is also liable to give the erroneous impression of a retreating forehead. In the Australian skull just mentioned the thickness of the cranial wall at the glabella was 22 mm.; from this level upwards it gradually thinned until 45 mm. above the glabella it was only 6 mm. thick. When the bisected skull was placed in the horizontal position the anterior surface of the frontal bone sloped from the glabella upwards and distinctly backwards, while the posterior or cerebral surface was inclined upwards and forwards. In fact, the cranial cavity in this region was separated from the lower part of the forehead by a wedge-shaped area having its apex upwards and its base below at the glabella.

The cranial wall opposite the glabella is not appreciably thicker in the Neanderthal calvaria than in the Australian skull to which I have already referred, and the form of the cranial cavity is not more masked by this prominence in the Neanderthal than in many of the existing races.

Although the Neanderthal skull is by no means complete, the base of the cranium and the face bones being absent, still those parts of the cranial wall are preserved that are specially related to the portion of the brain which subserves all the higher mental processes. It includes the frontal, parietal, and upper part of the occipital bones, with parts of the roof of the orbits in front, and of the squamous division of the temporal bones at the sides. On its inner or cranial aspect there are markings by which the boundaries between the cerebrum and the cerebellum can be determined. In a profile view of such a specimen an inio-glabellar line can be drawn which will correspond very closely to the lower boundary of the cerebrum, and indicate a horizontal plane above which the vaulted portion of the skull must have contained nearly the whole of the cerebrum.

Schwalbe[1] has devised a series of measurements to illustrate what he regards as essential differences between the Neanderthal skull-cap and the corresponding portion of the human skull. From the inio-glabellar line another is drawn at right angles to the highest part of the vault, and by comparing the length of these two lines we can determine the length-height index. According to Schwalbe this is 40·4 in the Neanderthal, while the minimum in the human skull is 52. He further shows that the frontal portion of the vault, as represented by a glabella-bregmatic line, forms a smaller angle with the base or inio-glabellar line, and that a vertical line from the posterior end of the frontal bone (bregma) cuts the inio-glabellar further back than in the human subject. Prof. King, of Galway, attached special importance to the shape and proportions of the parietal bones, and more particularly to the fact that their mesial borders are shorter than the lower or temporal, whereas the reverse is the case in recent man. This feature is obviously related to the defective expansion of the Neanderthal vault, and Prof. Schwalbe also attributes considerable significance to this peculiarity.

1 "Ueber die specifischen Merkmale des Neanderthalschädels," *Verhandl. der anatomischen Gesellschaft in Bonn*, 1901

Another distinctive feature of the Neanderthal skull is the relation of the orbits to the cranial wall. Schwalbe shows that its brain-case takes a much smaller share in the formation of the roof of the orbit than it does in recent man, and King pointed out that a line from the anterior inferior angle of the external orbital process of the frontal bone, drawn at right angles to the inio-glabellar line, passed in the Neanderthal in front of the cranial cavity, whereas in man such a line would have a considerable portion of the frontal part of the brain-case anterior to it.

From the combined results of these and other measurements Schwalbe arrives at the very important and interesting conclusion that the Neanderthal skull possesses a number of important peculiarities which differentiate it from the skulls of existing man, and show an approximation towards those of the anthropoid apes. He maintains that in recognising with King[1] and Cope[2] the Neanderthal skull as belonging to a distinct species, *Homo Neanderthalensis*, he is only following the usual practice of zoologists and palæontologists by whom specific characters are frequently founded upon much less marked differences. He maintains that as the Neanderthal skull stands in many of its characters nearer to the higher anthropoids than to recent man, if the Neanderthal type is to be included under the term *Homo sapiens*, then this species ought to be still more extended, so as to embrace the anthropoids.

It is interesting to turn from a perusal of these opinions recently advanced by Schwalbe to consider the grounds on which Huxley and Turner, about forty years ago, opposed the view, which was then being advocated, that the characters of the Neanderthal skull were so distinct from those of any of the existing races as to justify the recognition of a new species of the genus Homo. Huxley, while admitting that it was "the most pithecoid of human skulls," yet holds that it "is by no means so isolated as it appears to be at first, but forms in reality the extreme term of a series leading gradually from it to the highest and best developed of human crania." He states that "it is closely approached by certain Australian skulls, and even more nearly by the skulls of certain ancient people who inhabited Denmark during the stone period." Turner's[3] observations led him to adopt a similar view to that advanced by Huxley. He compared the Neanderthal calvaria with savage and British crania in the Anatomical Museum of the University of Edinburgh, and found amongst them specimens closely corresponding to the Neanderthal type.

While yielding to no one in my admiration for the thoroughness and ability with which Schwalbe has conducted his elaborate and extensive investigations on this question, I must confess that in my opinion he has not sufficiently recognised the significance of the large cranial capacity of the Neanderthal skull in determining the zoological position of its owner, or made sufficient allowance for the great variations in form which skulls undoubtedly human may present.

The length and breadth of the Neanderthal calvaria are distinctly greater than in many living races, and compensate for its defect in height, so that it was capable of lodging a brain fully equal in volume to that of many existing savage races and at least double that of any anthropoid ape.

A number of the characters upon which Schwalbe relies in differentiating the Neanderthal skull-cap are due to an appreciable extent to the great development of the glabella and supra-orbital arches. Now these processes are well known to present very striking variations in existing human races. They are usually supposed to be developed as buttresses for the purpose of affording support to the large upper jaw and enable it to resist the pressure of the lower jaw due to the contraction of the powerful muscles of mastication. These processes, however, are usually feebly marked in the microcephalic, prognathous, and macrodont negro skull, and may be well developed in the macrocephalic and orthognathous skulls of some of the higher races. Indeed, their variations are too great and their significance

1 "The Reputed Fossil Man of the Neanderthal," *Journal of Science*, 1864.

2 "The Genealogy of Man," *The American Naturalist*, vol. xxvii. 1893.

3 "The Fossil Skull Controversy," *Journal of Science*, 1864.

too obscure for them to form a basis for the creation of a new species of man. Both Huxley and Turner have shown that the low vault of the Neanderthal calvaria can be closely paralleled by specimens of existing races.

If the characters of the Neanderthal calvaria are so distinctive as to justify the recognition of a new species, a new genus ought to be made for the Trinil skull-cap. In nearly every respect it is distinctly lower in type than the Neanderthal, and yet many of the anatomists who have expressed their opinion on the subject maintain that the Trinil specimen is distinctly human.

Important and interesting as are the facts which may be ascertained from a study of a series of skulls regarding the size and form of the brain, it is evident that there are distinct limits to the knowledge to be obtained from this source. Much additional information as to racial characters would undoubtedly be gained had we collections of brains at all corresponding in number and variety with the skulls in our museums. We know that as a rule the brains of the less civilised races are smaller, and the convolutions and fissures simpler, than those of the more cultured nations, beyond this but little more than that definitely determined.

As the results of investigations in human and comparative anatomy, physiology, and pathology, we know that definite areas of the cerebral cortex are connected with the action of definite groups of muscles, and that the nervous impulses starting from the organs of smell, sight, hearing, and common sensibility reach defined cortical fields. All these, however, do not cover more than a third of the convoluted surface of the brain, and the remaining two-thirds are still to a large extent a *terra incognita* so far as their precise function is concerned. Is there a definite localisation of special mental qualities or moral tendencies, and if so where are they situated? These are problems of extreme difficulty, but their interest and importance are difficult to exaggerate. In the solution of this problem anthropologists are bound to take an active and important part. When they have collected information as to the relative development of the various parts of the higher brain in all classes of mankind with the same thoroughness with which they have investigated the racial peculiarities of the skull, the question will be within a measurable distance of solution.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. DAVID HEPBURN has been appointed professor of anatomy at the University College of South Wales and Monmouthshire, and Dr. T. J. Jehu professor of geology in the University of St. Andrews.

THE distribution of medals and prizes to the students of the Royal College of Science will take place in the lecture theatre of the Victoria and Albert Museum, South Kensington, at 2.30 p.m. on October 8, when an address will be delivered by Prof. Farmer, F.R.S.

EIGHTEEN lectures, open to the public without payment or ticket, will be given at University College, London, during October by professors in the faculties of arts and laws and of science. On October 7 a lecture on "Architectural Evolution," introductory to the work of the School of Architecture, will be given by Prof. F. M. Simpson. Sir William Ramsay will lecture on the gases of the atmosphere, and their connection with radium and its emanations, on October 6.

THE "Education Directory," just published by the Education Committee of the Oxfordshire County Council, shows that the committee has ordered a special survey of the educational conditions of the area over which it has control. Until this inquiry has been held the committee has decided that the higher education of the county shall be carried forward on the lines previously laid down by the Technical Instruction Committee, only modified in so far as last year's Act gives wider powers to the Education Committee.

THE research, statistical and biometric laboratory of University College, London, under Prof. Karl Pearson, offers good opportunities for post-graduate students and research workers in many fields of inquiry. The aim of the department is to give exact training in both observation and computation. Lectures are provided in both elementary and advanced statistics, and the general theory of statistics is so developed as to be of service not only to "biometricians," but to those who propose in the future to deal with social, economic or vital statistics. The training thus gained is far more profitable than any mere examination curriculum for those professions which require powers of careful observation, of original thought, or of accurate computation.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 21.—M. Albert Gaudry in the chair.—Parthenogenesis by carbonic acid obtained with eggs after the emission of the polar globules, by M. Yves **Delage.** It has been shown in previous work by the author that the eggs of the sea urchin are absolutely refractory to the action of carbonic acid. The effect of heat alone, or of shaking alone, gave also negative results, but moderate shaking at 30° C. in presence of carbonic acid was successful in producing the desired result, segmentation taking place in about 60 per cent. of the eggs.—On the production of sugar in the blood during the passage of the latter through the lungs, by MM. R. **Lépine** and **Boulud.** From the experiments described the authors conclude that, during the passage of the blood through the lungs, there is not only a glycolytic, but also a glycogenic process, hitherto unnoticed.—On monodrome functions and differential equations, by M. Edm. **Maillet.**—On the properties and constitution of the manganese steels, by M. Léon **Guillet.** The metallographic and mechanical tests are in perfect agreement with each other, and show that there is great similarity between nickel and manganese steels.—The diagnosis of biliary calculi by preliminary radiography, by MM. **Mauclaire** and **Infroit.**—The germination of orchids, by M. Nöel **Bernard.**

MILITARY TOPOGRAPHY.

Recherches sur les Instruments, les Methodes et le Dessin Topographiques. By le Colonel A. Laussedat. Tome ii., part ii. Pp. 287. (Paris: Gauthier-Villars, 1903.)

THE second volume of Col. Laussedat's exhaustive work on topography, which has just been published, deals with the art of metrophotography as developed in Europe generally and in France in particular; condensing the opinions and experiments of leading men of science, and epitomising their results. Attempts to adapt the principles of natural perspective to topography in France date from the middle of the last century. French methods were adopted by Germany in 1865; Italy followed suit in 1875; and in Austria, Maurer executed a military reconnaissance of some importance (which could have been attained in no other way) in 1887. There has gradually accumulated a large amount of scientific literature in Austria dealing with this subject; and in 1889 the Swiss engineer S. Simon had made a photographic survey of Jungfrau. Russia has been busy for many years in the Trans-Caucasus and in Persia, working on similar methods to those of Switzerland, whilst Greece, Brazil and Madagascar have all contributed results of scientific value towards the development of the art. Spain has been interested since 1863, and in 1899 an "excellent ouvrage" was produced in Madrid by two engineers, Iriarte and Navarro, which seems to have been the most complete work on the subject up to the date of Laussedat.

New Zealand and Australia have not been idle; but amongst our colonies it is to Canada chiefly that we look for the most practical experiments leading to the most noteworthy results in this as in every other branch of topographic art. In the United States as early as 1886, photographic methods for rapid reconnaissance were taught at West Point; but it is to the Canadian experts, Deville and Fleurer, that we owe most of our practical knowledge. A general summary of Canadian results will be found in Wilson's useful work on topographic art.

England and English surveyors alone contribute nothing to the world's knowledge ot this branch of surveying, although of all countries in the world England is probably most interested in its development. Colonel Laussedat, noting that as early as 1869 Colonel J. Baillie proposed that photography should be utilised as an aid to reconnaissance, suggests that the absence of all result may be due to the fact that its military application precluded it from publication—"il est probable que des résultats à la fois curieux et utiles ont pu être obtenus dans un ordre d'idées qui ne se prête pas à la publicité." But he is probably unaware that the preliminary art of topography is as yet undeveloped in England; and that we are still a long way from the scientific consideration of any of its more subtle branches. It is true that in India (where the knowledge of topography is an every day practical necessity) some experiments have been made with the Bridges-Lee instrument (the phototheodolite), but there are good reasons why photography as an aid to surveying should only be applicable in exceptional cases and under exceptional conditions in that country. The ultimate practical value of metrophotography lies in the power which it places in the hands of one accomplished topographer to do the work of many. It is a financial question in the long run, but, as Col. Laussedat does not fail to point out, it is useless in the hands of an amateur. It requires a surveyor (or an artist) of exceptional ability and experience as a topographer to render it effective. Workmen of this stamp are rare anywhere and command good value for their work. In India the simpler form of topography attained by the use of the plane table (which is invariably superior in its final results to those of metrophotography when applied to ordinary country by ordinary workmen) is attained cheaply and satisfactorily; for the native labour of India is cheap, abundant, and specially adapted by nature to this form of art. Metrophotography, therefore, would probably not pay.

The practical application of metrophotography has been well exemplified by Le Bon in India, in aid of archæological research; by Legros as an explorer; by Vallot as a mountaineer (in which direction it is specially useful), and by many other Frenchmen in various ways in different parts of the world, leaving no room for doubt as to its value in exceptional circumstances, and the necessity for its continued development. But Laussedat is at some pains to quote the opinion of the Canadian expert Deville, who proves clearly the limitations of the art, and shows that photographic topography is just as much dependent on accurate preliminary triangulation as any other form of topography. He enters fully into the difficulties which beset the method, both as to the determination of scale and the representation of orographic features by contours.

A variety of new instruments designed to aid in the reduction of photographs to plan are described, and the scientific principles involved in their construction are discussed at length—such as the trirègle of Nicholson, the perspectograph of Hermann Ritter, Hanck's apparatus, and the perspecteur panoramique of Ch. von Ziegler. Some of the problems offered for the consideration of his readers are of considerable mathematical complexity. A good deal has been added to that which has already appeared in vol. i. on the subject of telephotography (which was employed with so much success by engineers during the siege of Paris), and forms a particularly fascinating chapter in this work.

A chapter on balloon and kite flying reconnaissance, with an inquiry into the nature of the instruments used and of their attachments, as well as into the principles involved in determining the scale of the resulting photograph and in the reduction of observations, is interesting; although it is difficult to believe that automatic observations taken from flying kites or balloons can be made valuable for military purposes unless applied to the illustration of positions within which two or three points have been accurately fixed

by one of the ordinary methods of terrestrial survey. The results of the first trial in the kite flying for plan photographic purposes were published in *La Nature* by M. Batut in 1888, so that the experiment is by no means new; but we doubt if this system has ever really added any valuable results to the reconnaissance information obtained by more usual methods in time of war; and it is conceivable that only for military purposes under stringent conditions would such methods be applicable. Stereophotography is the subject which concludes Col. Laussedat's review of instruments and methods. This, indeed, forms a most useful variation on ordinary metrophotographic observations, for it is obvious that the representation of orographic features as effected by this well known process conveys a far more readable impression to the eye of the nature of the country photographed, the rise and fall of undulations, the gradation of slopes, &c., than any flat photograph can possibly convey. It is a branch of photography applied to topography which has received very considerable attention in France, and it promises to become a very valuable aid in the process of reducing landscape photographs to topographical maps in future.

Colonel Laussedat has undoubtedly written a most valuable book—one which will be a standard authority for years on the subjects which he treats so ably. Men of science and experts may not agree as to the practical utility of some of the methods discussed; but they are discussed impartially, carefully, and in almost exhaustive detail, and the reader is left to form his own conclusions. There are yet many countries in the world which are greatly in need of good topographical illustration of the natural features contained in them. There are still vast areas unmapped, if not unexplored. Thus Col. Laussedat's book appears at a most appropriate time, when the demand for topography is the first demand of the administrator, and the necessity for utilising every method which promises to effect a saving of time and expense is paramount. It should find a place in every scientific library with any pretension to completeness.

T. H. H.

NATURE STUDY AS A SCHOOL SUBJECT.

An Introduction to Nature Study. By E. Stenhouse. Pp. x + 422. (London: Macmillan and Co., Ltd., 1903.) Price 3*s.* 6*d.*

SINCE the attempt was made a year or two ago to introduce into our rural elementary schools the subject called "nature-study," really such a general introduction to the science of living things as will give the pupil a means of taking an interest in his environment, there has been a great lack of adequate books for the teacher. Several men, Dr. Armstrong, Prof. Miall, and Prof. Lloyd Morgan, for instance, have spoken about the spirit in which the work should be undertaken, nor are there wanting books which indicate the method to be followed, that of experiment and observation. But the ordinary teacher without any particular training in the subject has wanted more systematic guidance, his previous training has been in the wrong direction, and the many text-books that have been hurried on to the market have only tended to confirm his probable original error that nature-study consisted in reading about natural objects or anything bearing on country life.

At last, however, we have a text-book of the right kind, something that we can unreservedly recommend to the teacher, both as a guide to the method he should follow and as a storehouse of instructions concerning the details of experiments within his reach. The book is avowedly written to cover section i. of the Board of Education course in general biology; it is equally well suited to the more recent syllabuses in nature-study or the elementary stage in agriculture and rural economy issued by the same department.

The book opens with a study of the growth of the plant, first describing the elementary experiments illustrating the structure and development of the seedling, then the function of leaf, stem and flower.

A little more might have been done to show how many of the experiments can be rendered quantitative, so as to yield exercises in measurement and continuous record keeping; indications also might have been given of how the teaching could be brought home to the country child by illustrations from farm or garden practice. For example, it is easy to carry out experiments in the garden on the best depths at which seeds of various sizes should be sown, on the necessity of a good seed bed, or the harm wrought by plastering seeds into wet sticky soil, all of which give practical point to the lessons derived from the experiments in class. Again, the structure of the stem finds many appropriate illustrations in the various methods of propagation by cuttings or layers, buds or grafts, the healing of wounds on a tree, knots and other common features in timber.

The discussion of plant families and orders is refreshingly free from technicalities, though here again more might be made of systematic observations from month to month of the development of characteristic structures like tubers, bulbs, corms, &c.

The animal life section gives first of all some elementary instruction about physiology and structure, taking the rabbit as a text, and then discusses briefly the characteristics of our commoner mammals. The section on birds contains a good chapter on the development of the hen's egg during incubation, followed by an account, brief but suggestive, of a few familiar birds. A chapter on the frog and its development from the egg is followed by one on insects, dealing with the structure and life-history of one or two common forms.

The scope of the book is obviously considerable, and it is by no means desirable to use it wholesale, but in the hands of an intelligent teacher who will select the sections most suitable to his conditions, practise himself in the experiments, and then get his pupils to help him to carry out numerous repetitions, who finally will add local illustrations and practical applications, the book will be of the utmost service in systematising his instruction and guiding it along the fruitful lines of experiment and research.

A. D. H.

OUR BOOK SHELF.

Ergebnisse der Physiologie. Edited by L. Asher (Bern) and K. Spiro (Strassburg). Erster Jahrgang. 1 Abtheilung. Biochemie. Pp. xix+929. (Wiesbaden: J. F. Bergmann, 1902.) Price 17 marks.

THE German physiological school is engaged just now in producing a monumental work. Under the able editorship of Drs. Asher and Spiro, two of the most energetic of the younger physiologists of the Fatherland, the most eminent workers in different branches of the science have been persuaded to contribute of their best. We notice also that among the collaborators are several from other countries in addition. The editors do not aim at producing a text-book even for the advanced student, but a series of essays, each written by a master of his craft on some subject to which he has paid particular attention, and has himself made a subject of investigation. Giving, as each article does, not only the history of the subject with full biographical references, but also an account of the latest discoveries, and discussions of conflicting views on the many vexed questions treated, it will prove a veritable mine of facts to the investigator, and will, indeed, be indispensable to all who are attempting real and serious work in the future.

The volume before us treats of what it is now the fashion to call biochemistry, and we notice with pleasure that some of the articles deal with the comparative and also with the botanical aspects of this rapidly growing branch of physiology. We shall not attempt to give a *résumé* of the book, or even a list of the articles and their authors. This is a sort of book which must be read, and not merely talked about. Suffice it to say that among the authors are those of the standing of I. Munk, Hammarsten, F. Voit, Pawlow, Hugo Wiener, and Hofmeister.

In any work in which many participate, there is always a certain amount of inequality. In the present volume this is not so noticeable as in most books of a similar nature, for each author seems to have made a special effort to produce an article or articles of the highest possible standard.

We do not pretend that the book is light or attractive reading, and we imagine that the authors themselves would be the first to repudiate any suggestion that they intended it to be so. The German language, for one thing, does not lend itself to such a frivolous purpose. It is solid, hard reading, written with the German ideal of thoroughness for the student and the worker by those who are themselves workers and students.

Thermodynamik. By Prof. Dr. W. Voigt. Band i. (Sammlung Schubert, vol. xxxix.) Pp. xvi + 360; with 43 figures. (Leipzig: G. J. Göschen, 1903.) Price 10 marks.

THE subject of thermodynamics can be treated either as a deductive or as an experimental science. According to the former method, the second law affords a definition of absolute temperature, and a perfect gas is a hypothetical substance, defined by certain conditions, which is proved to possess the property of acting as a thermometer for the measurement of absolute temperature. In the present case the opposite treatment is followed. The book opens with an introduction dealing with thermometry and calorimetry, followed up by a section on the equivalence of work and heat in which the specific heat of water finds its old traditional title of mechanical equivalent of heat, and the methods of determining it are severally and separately discussed. The next chapter deals with the thermodynamics of perfect gases, and includes sections on Carnot's cycle as applied to such gases. It is not until the third chapter that the second law is applied generally to bodies defined by two variables, while in the fourth or last chapter the principles of thermodynamics are extended to systems defined by any number of variables. The book thus has its parallel, to a certain extent, in those treatises on applied mechanics which deal with the equilibrium of levers or motion of pulleys before introducing the parallelogram of forces or the laws of motion. At the present time many students working in physical laboratories acquire an experimental knowledge of principles which their lack of mathematical ability prevents them from approaching from the deductive side. No doubt this is a pity, but while such students continue to exist and to require teaching, it is difficult to see how a subject like thermodynamics could better be presented to them than is done in Prof. Voigt's treatise.

Arithmetic for Schools and Colleges. By John Alison, M.A., F.R.S.E., and John B. Clark, M.A., F.R.S.E. Pp. xliii+304. (Edinburgh: Oliver and Boyd, 1903.) Price 2*s.* 6*d.*

No better exposition of the nature of arithmetical operations and of proofs of the various rules of arithmetic than that which these two Scottish authors here present to us can be found. The first twelve chapters treat of the more theoretical branch of the subject, and explain with great exactness the laws of arithmetical processes and the manipulation of vulgar and decimal fractions. The authors never miss an opportunity of pointing out the means of shortening a calculation and, at the same time, of explaining and justifying the process. In these first twelve chapters we would specially signalise those on "laws of operations" and "decimal approximations" as interesting to the philosophically minded student; but, indeed, the whole of the work is marked by great thoroughness. In the chapter on evolution, Horner's method is explained and amply illustrated. There is a very good chapter on the metric system, including its employment in dynamics, heat, and electricity, illustrated by a large collection of examples. The nature of ratio and proportion is also very well explained and exemplified in three special chapters. The practical subjects (percentages, profit and loss, interest, &c.) are treated as mere examples of the theory of proportion.

Once only in the book do we meet with a vicious Saxon expression: "If the first term of a proportion be greater than the second, the third *shall be* [instead of *is*] greater than the fourth" (p. 202); but this is not repeated in subsequent similar propositions.

Except by the introduction of the diagrammatical relations between variable quantities, as exhibited by curves on squared paper, it is difficult to see how this very excellent treatise could be improved.

G. M. M.

Les Materiaux artificiels. By Marie-Auguste Morel. Pp. 178. (Paris: Gauthier-Villars and Masson et Cie.)

THIS volume belongs to the "Encyclopédie Scientifique des Aide-Mémoire," published under the general editorship of M. Léauté. It contains information of an interesting kind about numerous materials used in building and other constructive arts. The first chapter, on semi-artificial substances, includes a treatment of lime, cements, bricks, tiles, and other materials. This is followed by successive chapters giving accounts of those artificial materials dependent for their manufacture on technical chemistry; those used in association with metal armatures; those—such as mortar, artificial stone—formed when artificial materials are mixed with other non-metallic substances. The concluding sections include a miscellany of subjects, such as the preservation of wood, the use of soluble glass, and a description of Lincrusta-Walton.

LETTERS TO THE EDITOR.

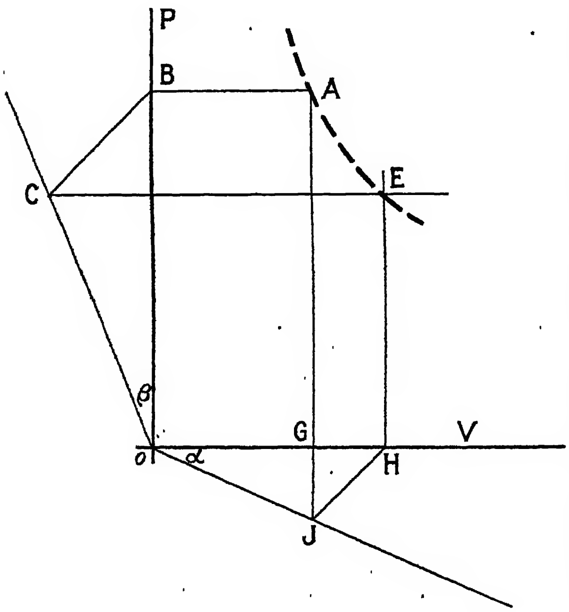
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Expansion Curves.

EVERY man who has studied steam or gas or oil engines knows that if there is one construction more important than another it is to draw a curve representing the law

$$pv^n = \text{constant}$$

through any given point. Here is an exceedingly simple, ingenious method of doing this which I have just found in a pamphlet by Mr. E. J. Stoddard, of Detroit. Let A be the given point so that AB represents a given volume,



and AG a given pressure. Set off any convenient angle, VOJ $= \alpha$ say. Compute an angle β such that

$$1 + \tan \beta = (1 + \tan \alpha)^n,$$

and set off BOC $= \beta$. Produce AG to J. Now make OBC $=$ JHO $= 45°$, and project from C and H to find E a point in the curve. The proof is obvious.

It is evident that OC may be drawn to the right of OB, and OJ above OV, to save paper if necessary.

J. PERRY.

Royal College of Science, S.W., September 23.

Botany in Boys' Schools.

PROF. W. W. WATTS said in his address to the Geology Section of the British Association, "there is no science in which materials for elementary teaching are so common, so cheap, and everywhere so accessible."

In the light of this statement I sought material for the teaching of another science—botany—in a north London playground last week.

The Angiosperms were represented by thirteen natural orders. With a single representative each of the algæ and fungi, thirty-eight species in all were found growing in or on a soil which is almost entirely ballast!

It seems a pity that botany should be so rarely taught in boys' schools when a single playground yields materials "so cheap and so accessible." H. J. GLOVER.

Stationers' School, Hornsey, N., September 23.

Radium and the Cosmical Time Scale.

CERTAIN letters have appeared in NATURE upon the bearing of the properties of radium upon the cosmical time scale. These letters are based on the assumption that radium, or some equally active body, exists in the sun and contributes materially to the output of solar energy. If this assumption were true, we ought, I think, to be able to detect the rays peculiar to radio-active bodies on the surface of the earth—they should bear some proportion to the great stream of light and heat waves which reaches us.

Now a solution of iodoform in chloroform is very sensitive to the β and γ rays. A purple coloration is produced by the rays from 5mg. of radium bromide even after filtering through 1cm. of lead. On the other hand, I find that direct sunlight (if heating be obviated) has no action when the thinnest opaque screen is interposed even after many days. Some of my solutions are now nearly two months old, and they have been exposed in light-tight cardboard boxes to such sunshine as has reached us during that period. They are quite unchanged.

It is, of course, possible that the stream of rays needs to be above a certain critical density in order to decompose the iodoform, but in any case my experiments prove that the β and γ rays reach us at most only in faint quantities from the sun. W. B. HARDY.

Gonville and Caius College, Cambridge.

Loss of Weight of Musk by Volatilisation.

I SHOULD like to direct the attention of your correspondent "S. W." (p. 496) to *N. Cimento* for May, 1902 (or abstract 1986, *Science Abstracts*, 1902), in which E. Salvioni says that he has shown the loss of weight of musk by volatilisation.

The measurements were made by a special form of balance. F. R. SEXTON.

Park Lodge, Kingston-on-Thames, September 5.

CONDENSATION NUCLEI.[1]

IN a previous paper under the not very appropriate title "Experiments with Ionised Air," Prof. Barus has described observations, made by means of his modified steam-jet methods, upon the nuclei found in air which has passed over phosphorus, together with measurements of the electrical leakage through air thus treated. The first chapter of the present volume is taken up with a continuation of the work by the methods there described.

There is no reason to expect the properties of air which has been exposed to phosphorus to be characteristic of ionised air generally; the recent experiments of Harms, and of Elster and Geitel, have, it is true, shown that ions are probably present, but the conditions are much more complicated than in cases of simple ionisation, such as that due to X-rays, owing to the presence of the products of the oxidation of the phosphorus. It is probably to the presence of the products of the oxidation of phosphorus vapour, as was pointed out in 1866 by Schmid, that the formation of the phosphorus cloud is due. The cloud nuclei are not free ions; in the "experiments with ionised air" it was found that the number of nuclei was undiminished by even a strong electric field; additional evidence is brought forward in the first chapter of the present paper, where experiments are described showing different temperatures for the maxima of nucleation and of ionisation. But such evidence was not required to show that these nuclei are not ordinary free ions, for in dust-free air ionised by X-rays or the rays from radio-active substances (in all cases, indeed, in which the ions have the normal velocity under

[1] "The Structure of the Nucleus, a continuation of 'Experiments with Ionised Air.'" By Carl Barus. (Smithsonian Contributions to Knowledge, Hodgkins Fund, 1903.)

a potential gradient of a volt per cm.) the same definite degree of supersaturation, approximately fourfold, is required to produce a cloud; the phosphorus cloud, on the other hand, does not require any sensible degree of supersaturation for its production.

There is evidence in these papers of strange misconceptions on the subject of ionisation. One is surprised in a paper dealing with "ionised air" to find such a statement as that on p. 53, "$n_0=3.6\times10^4$, agreeing very well with J. J. Thomson's 4×10^4 as the number of ions in air ionised to saturation by the X-rays."

In measurements of the leakage of electricity through air which has passed over phosphorus one would expect the apparatus to be designed in such a way that there should be no danger of the leakage observed being mainly due to the surface of the insulating supports becoming conducting by contact with the phosphorus fumes. The failure to take such precautions detracts greatly from the value of the electrical observation described in these papers.

Chapter ii. and the remaining chapters of the volume on the structure of the nucleus contain an account of experiments upon the clouds produced by rapid expansion. There can be no doubt that such experiments are easier of interpretation than those made by steam-jet methods. Prof. Barus begins with experiments on the colour phenomena attending the rapid expansion of moist air containing nuclei, generally phosphorus and "punk" nuclei. It is only when few nuclei are present, and the drops formed on expansion thus comparatively large, that *normal* coronas, as Barus calls them, are seen surrounding a luminous source viewed through the cloud. It is only to such coronas that the ordinary theory of the corona applies; the gorgeous colour phenomena observed when the drops are very small, numerous and uniform in size are much more difficult to interpret. If it were possible to deduce the size of the cloud particles from the colour phenomena observed with a given expansion, a most convenient method of determining the number of nuclei present would be available, for the quantity of water separating out as a consequence of a given expansion can be calculated, and hence the number of drops could be determined if the size of each were known. With this end in view Prof. Barus, in the absence of an exact theory of the colours, attempted to determine the size of the drops corresponding to a given arrangement of colours by an experimental method. On certain assumptions the relative numbers of the drops in a whole series of successive expansions, giving a corresponding series of colour phenomena, were known, the drops in the final expansions being large enough to give normal coronas, from which by comparison with lycopodium coronas the radii of the drops, and hence their number, could be determined; thence could be deduced the number and size of the drops in each of the previous expansions. It is very doubtful if the method can be made a trustworthy one.

Expansion experiments made with other vapours than that of water are next described, benzol, carbon bisulphide, ethyl and methyl alcohol and other vapours being used. Water vapour obviously differs from most other vapours in one very important respect, *i.e.* it is lighter than air. In the experiments made by Prof. Barus the air was contained in a large vessel with a pool of liquid at the bottom; when the liquid was water the moist air would rise to the top, and mixing would thus take place automatically by convection until the whole volume was saturated; in the case of liquids like benzol the heavy vapour-charged air would lie at the bottom, the vapour only gradually diffusing upwards. Uniform distribution of vapour, and hence the production of circular coronas on expansion, are to be expected with water, while with benzol, unless artificial stirring has been employed or a long interval has been allowed for diffusion, only the lowest strata will be saturated with vapour, and the amount of liquid available for each drop formed on expansion will, if the nuclei are uniformly distributed, diminish from below upwards; distorted coronas, or in extreme cases an arrangement of the colours in horizontal strata, are to be expected. The upper part of the vessel may remain free from cloud, the upper boundary of the cloud marking the level at which just enough vapour is present to give drops with the degree of expansion used. Even when uniform distribution of the vapour has been obtained, it will be destroyed by the first expansion made and the subsequent entrance of the dry air introduced to bring the pressure back to that of the atmosphere.

The phenomena observed by Prof. Barus are exactly what one would expect from these considerations, but he makes no reference to the above mentioned important difference in the conditions attending experiments with water vapour and with other vapours. His interpretation of the observed phenomena is, in fact, quite different. "When sulphur or other nuclei are put into the globe containing benzol vapour the result is peculiar. Instead of distributing themselves homogeneously throughout the receiver they usually collect in a heavy band near the bottom. This is invisible until revealed by the first exhaustion, when a heavy sluggish fog bank is seen, only a few centimetres high." Again, "The most curious feature in connection with benzol as well as the preceding liquids is the subsidence of the invisible nucleated air immediately after influx and without exhaustion." The "graded condensation" is interpreted as showing the nature of the distribution in the vessel, not of the vapour, but of the nuclei, and an elaborate series of experiments to determine the rates at which the nuclei travel in different vapours is described; that rate of diffusion of the vapour rather than of the nuclei is involved is by far the more natural interpretation. (In a short paragraph, inserted apparently subsequently to the writing of the paper, the possibility of this interpretation is admitted.)

The fifth chapter treats of the nuclei produced by shaking liquids, particularly aqueous solutions. The production of nuclei by shaking, bubbling and spraying has been noticed by several observers, and the effect of dissolved substances in the water upon the persistence of the nuclei has been studied by Mr. H. A. Wilson. Prof. Barus here gives an interesting series of observations on a large number of solutions of varying degrees of concentration. These nuclei are regarded as minute drops of the solution employed, which have evaporated until the concentration of the dissolved substance becomes great enough to counterbalance the effect of the curvature upon the vapour pressure. The conditions of equilibrium of small drops containing substances in solution are made clear by a diagram. There can be little doubt that the nuclei obtained by shaking solutions, and probably also those produced from phosphorus and from most of the other sources used by Prof. Barus, are of this nature. There is, indeed, nothing novel in the view that nuclei of this kind exist. Barus, however, seems to imply that all nuclei, including what other experimenters have taken to be the ions produced by X-rays and similar agents, are of this type.

An extraordinary interpretation is given (on p. 161) of the experiments by which it was sought to determine the difference in the action as condensation nuclei of the positive and negative ions. "If one introduces nuclei or makes nuclei by aid of the X-rays, in what is virtually the acid and alkaline side of a battery, even if the ionised moist air is the electrolyte,

one is conveying nuclei into or making nuclei out of different media." How it comes about that a perfectly definite degree of supersaturation is required to cause condensation on such nuclei, whether an electric field is applied or not, and whether they have been produced by strong or weak radiation or by other means, he does not attempt to explain. He brings forward in support of his view the further consideration that, "if a marked difference in efficiency of positive and negative ions is granted, then any ionised emanation neutral as a whole, like that of phosphorus, should produce two groups of nuclei. On condensation there should be two groups of coronal particles interpenetrating and subsiding through each other in the way I have frequently instanced in other experiments. No such effect has been observed." The answer to this is simply that the nuclei causing the phosphorus clouds are not free ions, like those produced by X-rays.

Prof. Barus concludes with a suggestion as to the origin of atmospheric electricity, according to which nuclei become negatively charged as the solution which they contain becomes diluted by absorption of water.

C. T. R. WILSON.

THE GEOLOGY OF AUSTRIA-HUNGARY.

TO know, even in a general fashion, the provinces of Austria-Hungary, with their immense range of scenic types and their picturesque variety of nationalities, goes far in itself towards a liberal education. The lover of landscape, as well as the geologist, will find much of interest in the new "Führer für die geologischen Exkursionen in Oesterreich," issued in connection with the ninth International Geological Congress in Vienna. This bulky work is divided, like that of the Russian congress, into numerous separate *brochures*, but forms, none the less, a permanent work of reference for our libraries. To obtain the guide and other publications before they become scarce, a subscription to the secretariat of the congress of twenty-seven shillings or so every three years seems not a heavy price to pay.

In the Austrian guide we have the work of some forty-five authors, describing in a compact and lucid form the districts that they have made their own. In this respect, though covering a far wider field, it resembles that handbook of English geology, the "Geological Excursions," issued by our Geologists' Association. The names of the writers imply in themselves the spirit of a scientific congress. We do not see the groups and cliques seated in the parliamentary Chamber in Vienna, and threatening one another with the literal outpouring of ink; but we find instead a body devoted in common to the reception of the stranger, and anxious that in each province he shall find something memorable and distinctive.

Dr. Jahn opens with the Older Palæozoic area of Bohemia, which includes the Moldau sections above Prag and the ravine at Karlstein, one of the noblest scenes of mediæval Europe. Prof. A. Hofmann describes the silver-mines of Přibram, and Prof. Slavík and others deal with the Cretaceous of northern Bohemia. In this latter paper it is pleasant to note the insertion of the euphonious Tchech names of villages after the German forms, a practice already to some extent imitated in Ireland. August Rosiwal conducts us through the more severely German district of Karlsbad and other health-resorts upon the frontier. Prof. Suess's important theory of the distinction between nascent and "vadose" waters appearing at the earth's surface is duly referred to. If this series of papers leads to a better appreciation of the rural districts of Bohemia, the writers will have done good service. Few visitors have seen what lies upon the plateau and outside the towns—the hamlets with bulbous church-towers, set of necessity beside the lakes, which gather in the hollows of the granite; the broad undulations of a purely agricultural landscape, broken here and there by some magnificent group of castle-towers; the crumpled rim of the country on the south-west, where one plunges down through the forest to Bavaria; or the sheer phonolite necks of the north, rising like islands above a haze formed by the smoke of Cainozoic coal. Here, however, we reach the holiday-region of the Elbe, known to dwellers in Dresden, and pleasantly described and illustrated by J. E. Hibsch in a *brochure* of seventy pages.

Another important series of papers deals with Galicia, the Miocene salt-beds of Wieliczka being, of course, included. Less visited are the petroleum-beds of Borysław, now one of the active fields of enterprise, where the folding of the Miocene strata assigns a maximum age to the uplift of the Karpathians. Oberbergrat Johann Holobek connects the various deposits of hydrocarbons with the extreme fissuring of the sandstones along the region of overfolding. Nearer the great chain, Oligocene menilite-shales are brought up over the Miocene on the south-west limb of the synclinal, and the oil, though flowing in fissures, appears generally accumulated in the bend.

What novelty lies before those who visit Drohobycz, Zaleszczyki, Kasperowce, and Worochta, following Drs. Grzybowski and Szajnocha, can only be known to those who have had glimpses of remote Galicia. Not the least interesting feature of Austrian Poland is the view of the drift-covered Russian plateau across the frontier, and the ever-present sensation of that mysterious and arbitrary *cordon*, along which the white-capped cavalry ride night and day and keep the verge of Europe.

From a geological point of view, the country of the famous limestone *Klippen* is of the first importance. Similar tectonic problems arise wherever beds of varying powers of resistance become crushed together. In a neat section V. Uhlig shows the relation of the northern "Klippenzone" to the overfolds and thrusts on the flank of the Tatra range. The fertile basin of Liptó is included on the south of the granite mass, and one can picture again the streams leaping into it from the forest-slopes of the Karpathians, and the grey crags towering up beyond, and the descent northward on the rain-swept levels of the Magura. This last region of little disturbed Eocene and Oligocene strata leads on to the highly faulted and upturned "Klippenzone." North of this the Older Cainozoic is strongly folded, whence Herr Uhlig concludes that the massive Klippen protected the corresponding beds on their south flank from the pre-Miocene earth-pressures. These same pressures had, however, considerable effect among the Klippen themselves, and have so far squeezed the masses of various ages together as to tend to obliterate unconformities. The author, however, urges that the band of Klippen represents a series of true islands of Jurassic strata in an Upper Cretaceous and Eocene sea, the deposits of which at one time practically overwhelmed them. They are thus not detached fault-blocks without roots, although the pre-Miocene movements have influenced their present prominence and position. Fig. 14 shows the bold character of the resulting scenery. The memoir then describes the structure of the Tatra chain, with a series of sections which will be welcomed by all who aspire to look further than the classic example of the Alps.

Perhaps one regretfully swings back to Salzburg and the Salzkammergut, though the detailed paper by E. Kittl on the stratigraphy of the latter area is accompanied by an admirable bibliography and a map

in colours. Yet why should one regret that a region of such preeminent scenery lies comparatively near us, and is at times unconformably overstepped by the non-geological tourist? The next series of papers carries us away to Styria and the valley of the Mur, where miles of torrent and ravine, of grey limestone crag above and sunny maize below, await the unconventional traveller, and lure him ever eastward, until he emerges on the plain of Hungary. Then follows a number of papers on the environs of Vienna, a city set so happily in a land of geological contrasts. Until we have seen and touched it, we scarcely realise that, a few miles south of Laxenburg, the dusty rise over a castle-crowned projection represents the passage of the Alps. South-west lies the true mountain-episode of the Semmering, fully expounded, with a fine map, by Franz Toula. Westward, we have the narrows of the Danube, and the variety of cliff and alluvial meadow so charmingly described by Prof. Penck. The river runs between Melk and Krems in a pre-Glacial valley, much of which was actually excavated before Oligocene times. The surface-features must originally have been very different, to allow of the formation of this deep cut across the southern projection of crystalline rocks, which almost connects Bohemia with the Alpine system.

The Dolomites, the Adige valley, and Predazzo still offer problems for many a friendly battle. The Carnic Alps present a newer field, and include the superb ravine of Pontebba, with a side-excursion to the limestone-fastness of the Predil. This comparatively low pass, with its fine angle on the south side, amid a veritable world of rocks, would in itself show how much awaits the tourist who will venture east of Venice.

Hungary will probably be dealt with in a special treatise for those who made the long excursion on the Danube. Bosnia and the Hercegovina are very briefly touched on, since the local government has prepared a separate "souvenir" for visitors. What this attention means will be appreciated by those who have experienced the hospitality of the "occupied provinces." From a congress down to the humble bicyclist, all receive a welcome in this old Slavonic highland, all visitors alike are considered of interest to the State. When one sits by the stream-side in some level *polje*, a lake-basin of Miocene times, and hears the muezzin call from the little wooden mosque among the trees, or when one chips the gabbros in the grim ravine of the Narenta, while sun-browned hill-men, like stage-bandits, stride gravely past upon the road, then one can realise, with a grateful heart, what Austria-Hungary means, not only to the geologist, but to Europe.

GRENVILLE A. J. COLE.

NOTES.

A COMMISSION has been appointed by the French Navy Board to inquire into the migrations of the sardine and the causes of the disappearance of this fish. The commission includes Prof. Vaillant, of the Paris Natural History Museum; M. Fabre Domergue, Inspector-General of Sea Fisheries; and M. Canu, director of the agricultural station at Boulogne-sur-Mer.

OWING to the appointment of Dr. Martin to the directorship of the Lister Institute, the chair of physiology is vacant at the University of Melbourne. Particulars as to duties, emoluments, &c., will be in the hands of the Agent-General for Victoria after October 8. The new professor will be required to commence his duties on March 1, 1904.

AN international exhibition of the manufacture and industrial applications of alcohol will be held in Vienna in April and May, 1904.

A PRESS despatch from Berlin states that the Imperial budget for 1904, now in preparation, allots 7500*l*. for combating typhus, which is specially virulent in Bavaria, Prussia and Alsace-Lorraine.

AN international congress on school hygiene is to be held at Nuremberg from April 4–9, 1904, under the presidency of Prof. Griesbach, of the University of Strassburg. The general secretary is Dr. Paul Schubert, to whom all communications relative to the congress should be addressed.

A REUTER telegram from Rio de Janeiro of October 1 states that the Brazilian Chamber has adopted the third reading of the Bill to establish an international steerable balloon competition to be held at Rio in 1904. The scheme has been submitted to the Senate.

MR. H. MAXWELL LEFROY, who has been appointed entomologist to the Government of India, is to be stationed at Surat, in the Bombay Presidency, pending the establishment of the permanent headquarters of the Imperial Agricultural Department now being organised under the orders of Lord Curzon.

THE necessary legal formalities in connection with the change of name of the Jenner Institute have now been completed, the Board of Trade having sanctioned the new name. The Institute will, therefore, now be known as the "Lister Institute of Preventive Medicine." The address, Chelsea Gardens, S.W., remains the same.

SIR THOMAS HANBURY has promised the Pharmaceutical Society of Great Britain securities of the annual value of 25*l*. for presentation with the Hanbury gold medal awarded biennially for research in the natural history of drugs. The medal, founded in memory of Daniel Hanbury, brother of Sir Thomas, was awarded this year to M. Eugène Collin, of Paris. As the result of Sir Thomas Hanbury's gift future recipients of the medal will also receive the sum of 50*l*.

A PROVISIONAL programme of the ordinary meetings of the Royal Geographical Society for the session 1903–4 has been published. Among the subjects to be dealt with in the meetings of this year we notice north polar exploration, 1898–1902, by Commander R. E. Peary, and the Patagonian Andes, by Colonel Sir T. H. Holdich. The arrangements made for meetings after Christmas include, among others, the Gulf Stream, by Mr. H. N. Dickson; the régime of the Nile, by Sir William E. Garstin, G.C.M.G.; the lakes of New Zealand, by Mr. Keith Lucas; and some adventures in Antarctic lands and seas, by Lieutenant E. H. Shackleton (Christmas lecture to young people).

A KITE-FLYING competition was held at the Alexandra Palace on Saturday last under the auspices of the Aëronautical Institute. The length of wire or string to be used was limited to one mile, and marks were awarded on the following points:—(*a*) The manner in which the kite leaves the ground; (*b*) the manner in which it ascends; (*c*) the steadiness of the kite; (*d*) the length of time required to let out the whole mile of wire or string; (*e*) the greatest average of the altitude as taken by a series of observations during the course of one hour; and (*f*) the rapidity and manner of descent. Only three competitors put their kites to the test, and the contest was easily won by Mr. S. F. Cody, whose kite quickly reached the limit distance and remained steady at that altitude in a strong wind. The kite used was one of a number which is being prepared for consignment to Portsmouth Dockyard.

AN influentially signed memorial on the subject of the improvement of agriculture was recently sent to the Government of Bombay, and is summarised in the *Pioneer Mail.* The memorialists propose that two botanic gardens should be established, one at Poona and one near Bombay, the former as the centre of investigation for the Deccan, and the latter for the Konkan and Gujarat. Each garden should be provided with a herbarium and with chemical and botanical laboratories, and to each should be attached a farm for agricultural and horticultural experiments. It is suggested that the scientific staff might be one chief botanist, one assistant botanist for Poona, one assistant botanist for Bombay, one chemist, one entomologist, and one mycologist. It is also suggested that the number of the experiment stations should be increased and the scope of the experiments extended; that local bodies should be encouraged by grants in aid to conduct experiments on lines prescribed by the department; that publicity should be given to the work of the department, and results of practical interest should be communicated through leaflets printed in the vernacular; that further measures for the improvement of agricultural stock should be taken by the State; and that the Forest Department should be invited to cooperate with the Agricultural Department in the work of experimenting with products likely to succeed in forest areas.

THE method of scientific investigation by observation and experiment was touched upon by Mr. Sidney Lee at the Working Men's College on Saturday last, in the course of a lecture on Bacon, who advocated and inaugurated the revival of experimental philosophy. Bacon's main anxiety, said Mr. Lee, was to see research in every branch of science adequately endowed and equipped, and in his "New Atlantis" he planned in somewhat fanciful language a great palace of invention, a great temple of science, where the pursuit of knowledge in all its phases was to be organised on principles of the highest efficiency. Whether a temple of science on the scale that Bacon imagined it would ever come into existence remained to be seen. At present the portents were not favourable for its emergence in this country. It seemed more likely to come first to birth in Germany or in America, where things of the mind received from the general public a consideration which was denied them here. The experience of a recent visit to America showed Mr. Lee that there was nothing here to compare with the widespread eagerness among the youth of the United States to enjoy academic scientific training. England's prestige owed very much to the triumphs won by men who were Bacon's disciples in methods of scientific research, many of whom stood indebted to ancient educational benefactors. Bacon was well alive to the means whereby a nation's intellectual prestige could best be sustained. He argued that for a nation to apply a substantial part of its material resources to the equipment of scientific work and exploration, a share of its resources which should grow greater with the growth of population and the increasing complexity of knowledge, was the surest guarantee of national glory and prosperity.

IN the report of observations made at the Bombay Government Observatory in the years 1900 and 1901, a feature which differentiates it from the reports of previous years is the prominence given to records obtained from seismographs. In the previous report a series of seismograms and a register of disturbances obtained from a Milne seismograph were given. These are now supplemented by similar information derived from a pair of heavy horizontal pendulums, which record with ink on a metal cylinder, and which have a sensibility for tilting three or four times that of the Milne apparatus. The chief differences in the records obtained from these two types of instruments are the ratios of the recorded amplitudes. These differ so widely that it may be inferred that "the dominant feature of the movements in the majority of disturbances does not indicate tilt." We are not told, however, whether the free periods of the three horizontal pendulums are identical or different.

M. E. ESTANAVE contributes to the *Journal de Physique* a list of the theses in mathematical and experimental physics presented for the doctorate of science in French universities during the nineteenth century.

MR. P. E. JOURDAIN contributes a note on Gauss's principle of least constraint to the *Mathematical Gazette*, and a general theorem on the transfinite cardinal numbers of aggregates of functions to the *Philosophical Magazine* for September.

A COMPARISON of Maxwell's theory with the older and newer theories of electromagnetism is given by Mr. Emil Cohn in the *Physikalische Zeitschrift* for September. It is pointed out among other conclusions that Maxwell's theory accounts in the simplest way for those phenomena which it is competent to explain.

IN a note contributed to the Lombardy *Rendiconti*, Prof. M. Cantone discusses the question whether the elastic constants of a substance are affected by the surrounding medium. The results obtained negative the idea of any such connection. In determining the torsional rigidity of platinum and caoutchouc filaments, the immersion of the filament in water produced no deviation in the torsion balance.

IN the *Proceedings* of the Physical Society, Dr. G. J. Parks describes some experiments on the thickness of the liquid film formed by condensation on the surface of the solid. In the case of cotton silicate, it was found by weighing the material before and after condensation that the thickness of the film came out to be about $13 \cdot 4 \times 10^{-6}$ of a centimetre, and when the film had reached this thickness no heating was produced on immersing the silicate in water.

THE *Journal* of the Western Society of Engineers contains a description of the latest experiments in aërial gliding by Mr. Wilbur Wright. A noticeable feature of these experiments is that the machine sustained as much as 165 lb. to the horse-power as contrasted with 28 in Mr. Maxim's machine and 31 in Prof. Langley's model of 1896. Furthermore, while Mr. Chanute's best experiments in 1896 gave angles of descent of 7½ to 11 degrees, Mr. Wright has succeeded in gliding at angles of 6 to 7 degrees, and even, in one case, at as low an angle as 5 degrees.

IN the *Rivista d'Italia*, Mr. Italo Giglioli, director of the agricultural station at Rome, deals with certain agricultural questions affecting the south of Italy. After reviewing the principal vegetable products now produced by Italy the author suggests, as possible outlets for fresh enterprise, the cultivation of (1) the camphor plant (*Laurus camphora*); (2) the insecticide *Pyrethrum cinerariaefolium*; and (3) the india-rubber plant (*Ficus elastica*). The author sees no reason why the production of india-rubber in Italy should not be a success.

PROF. ALESSANDRO VOLTA, in a note appended to a paper in the Lombardy *Rendiconti*, directs attention to an unpublished manuscript of Volta in which it is stated that negative electricity is dissipated with three times the facility of positive electricity. It thus appears that the difference

of the two electricities in their behaviour in electric discharges was known to Volta. Attention is also directed to remarks by Volta on flame discharges, in which it is asserted that such discharges are not affected by the smoke produced. Prof. A. Volta's own researches show that flames of oil, petroleum, gas, and alcohol have approximately the same resistance, but for alcohol flames containing copper chloride the resistance is lower.

THE August number of the *Journal* of the Royal Microscopical Society is mainly devoted to optical theories of the microscope. This subject is introduced by a paper on Helmholtz's theory by Mr. J. W. Gordon, in addition to which Lord Rayleigh's paper from the *Philosophical Magazine* of 1896 is reprinted, together with a further communication from the same writer, and remarks by Dr. Johnstone Stoney, Dr. Siedentopf and others are reported in the Society's *Proceedings*. Among important points under discussion is the property that there is no theoretical limit to the smallness of an isolated luminous object which can be visible through the microscope. The limitations imposed by the undulatory theory affect only the distance apart of two objects or the fineness of structures in order that they may be capable of resolution.

WE have received a circular issued under the auspices of the German Ornithological Society, and signed by Mr. J. Thienemann, of Rossitten, Keer, Nehrung, East Prussia, directing attention to an experiment about to be made with the view of increasing our knowledge of the seasonal wanderings of birds. During the present autumn and next spring it is proposed to capture at Rossitten some hundreds, or perhaps thousands, of rooks (or crows?), upon the foot of each of which is to be fastened a metal ring bearing a number and the date of capture, after which the birds are to be set at liberty. Whenever such marked birds are killed, it is requested that the leg bearing the ring may be cut off and forwarded to Rossitten, with a label recording the date and place of capture.

THE latest issue (vol. xxxi. parts ii. and iii.) of Gegenbaur's *Morphologisches Jahrbuch* appears in mourning on account of the death, in June last, of its learned founder, who superintended the journal nearly to the completion of the twenty-ninth volume. A full biography is promised in the next number. Among the contents of the present issue is an article on the comparative anatomy and development of the heart and aorta in vertebrates, by Mr. A. Greil, and a second, by Dr. K. Fürbringer, on the visceral skeleton of sharks and rays. In a third, Mr. K. Gehry demonstrates that the bunch of axillary muscles ("Achselbogen") in man really represents the panniculus carnosus of lower mammals.

THE first part of the "Aarbog" of the Bergen Museum is devoted entirely to descriptions of the invertebrate fauna of Norway and its seas. Miss E. Arnesen contributes the second instalment of her account of the sponges, dealing in this section with the halichondrine group of the Monaxonida. The nemertean worms are described at considerable length by Mr. R. C. Punnett, of Cambridge, who records a number of new species collected by himself and Dr. Nordgaard in the fjords round Bergen in the summers of 1901 and 1902. Another article, by Mr. E. T. Browne, of University College, London, deals with medusas from Norway and Spitsbergen, among which are several novelties.

WE have received vol. xxxiii. part ii. of *Travaux de la Société Impériale des Naturalistes de St. Pétersbourg*. Its contents include an article on biological method in "zoopsychology," by Mr. W. Wagner, a second, by Mr. H. Goebel, on the birds of Lapland and the Solovetski Islands, and a third, by Mr. K. St. Hilaire, on the change of substance in cells and connective tissue. The latter article is largely based on the acid-secreting glands of molluscs. As regards the birds of Lapland, the author finds that out of a total of 198 species, 133 are certainly known to breed in that country, while another 34 probably do so. Of the remainder, 17 are stragglers and 6 winter visitors, while 1 is a pelagic species, and the other 7 are found only in the Solovetski Islands.

THE September number of *Animal Life* contains an article by Mr. Lydekker on local variation in the giraffe, illustrated by one coloured plate and a number of photographic reproductions from paintings. After referring to the marked differences between the Somali giraffe (*Giraffa reticularis*) and the typical *G. camelopardalis*, the author points out that evidence is gradually accumulating as to the existence of a number of local races of the latter. The article is chiefly based upon specimens now, or recently, living in the Duke of Bedford's collection at Woburn and in the Zoological Society's Gardens, and on two mounted examples in the Natural History Museum. The Woburn and Regent's Park forms are definitely identified, but, owing to the unsatisfactory nature of the description of two subspecies founded by a German writer, the author has refrained from giving names to the British Museum specimens, which clearly indicate distinct races. A name is, however, assigned to the Congo giraffe.

AN official report has been issued in Simla on the mortality caused by wild beasts and snakes in India. In 1902 the total mortality caused by wild animals was 2836, of which 1046 are reported as being due to tigers, and deaths reported from snake-bite numbered 23,166. In addition 80,796 cattle were destroyed by wild animals, and 9019 by snakes. The number of wild animals for the destruction of which rewards were paid in 1902 was 14,983, of which 1331 were tigers; the number of snakes killed was 72,595. The amount paid in rewards for the destruction of wild animals was Rs. 1,00,987, and for the destruction of snakes Rs. 3529.

A NOTABLE contribution to the subject of proteid metabolism is made by Mr. E. Godlewski in a paper which appears in the *Bulletin international de l'Académie des Sciences de Cracovie*. The general conclusions arrived at are that flowering plants, *i.e.* germinating seedlings as well as fungi, can, in the dark and in an atmosphere devoid of CO_2, absorb and work up nitrogen from nitrates even to the extent of building up proteid substances; but for the continued formation of proteids to any considerable extent a supply of plastic carbohydrate must be present in order to furnish the energy required, such, for instance, as the sugar or starch present in germinating tubers or bulbs. Also, according to the author, light has a direct as well as an indirect action in increasing the amount of proteid substances formed.

A SMALL brochure on "Propagating Plants," written by Mr. D. S. Fish, of the Royal Botanic Garden, Edinburgh, will be found useful by amateur gardeners who wish to obtain practical information on the methods of raising seedlings, striking cuttings, and similar matters. It is published by Messrs. Dawbarn and Ward, London.

THE "Guide to the Sydney Botanic Gardens," which has been prepared by the director, Mr. J. H. Maiden, with assistance from other members of the staff, bears witness to the wealth of vegetation which has been planted round

Farm Cove, a bay in the famous harbour of Port Jackson. The collections of cycads and conifers, including nearly a dozen species of both Macrozamia and Podocarpus, are particularly noteworthy. The plan adopted in the "Guide" is to give a list of the important plants to be found in each bed, with brief notes on native and the more interesting foreign species.

Two handy little publications have been issued by Messrs. James Woolley, Sons, and Co., Ltd., of Manchester. One, known as the "Science Teacher's Pocket Book and Diary, 1903–4," costs a shilling, and the other, the "Science Student's Note Book, 1903–4," costs 6*d*. Both books contain about forty pages of useful constants in physical and chemical science, together with other numbers in constant use in the laboratory.

MESSRS. ASTON AND MANDER are now manufacturing for the use of technical and other schools drawing instruments provided with several useful improvements. The adjusting screws cannot be detached from the instruments, and so be lost, the inking-in pens are easily cleaned, and a patent hook-and-nut method of holding the needles effectually prevents breakages when clamping, and renders it easy to change the needles.

SEVERAL volumes of the first annual issue of the "International Catalogue of Scientific Literature" have recently been received. The volume on chemistry (part ii.) contains 671 pages, referring to papers published since the end of 1900. The literature published in 1901, together with a portion of that published in 1902, is catalogued in the volumes on palæontology, general biology, human anatomy, physical anthropology, and physiology (part ii.); the last volume includes papers on experimental psychology, pharmacology, and experimental pathology, and occupies 664 pages.

COPIES have been received of the last two half-yearly volumes—xxxii. and xxxiii.—of the *Journal* of the Anthropological Institute of Great Britain and Ireland. Among numerous other important contributions, the earlier volume contains the Huxley lecture for 1902, on right-handedness and left-brainedness, by Prof. D. J. Cunningham, F.R.S. The more recent volume includes the address by the president, Dr. A. C. Haddon, F.R.S., delivered at the annual general meeting of the Institute in January last. The volumes are profusely illustrated with beautifully reproduced plates, and serve to show the excellent work the Institute is doing. Similar researches are, in the United States and elsewhere, liberally subsidised by the State, but the Anthropological Institute, working without such support, is enriching the Empire by collecting and publishing a mass of well-arranged information of which any scientific department might legitimately be proud.

THE additions to the Zoological Society's Gardens during the past week include a Chimpanzee (*Anthropopithecus troglodytes*) from the Albert Nyanza, a Patas Monkey (*Cercopithecus patas*) from Gondokoro, presented by Colonel Bruce; two Geoffroy's Cats (*Felis geoffroii*) from Chaco, Argentina, presented by Mr. A. C. Crewe; a Puma (*Felis concolor*), two Vicunas (*Lama vicugna*), a Condor (*Sarcorhamphus gryphus*) from Puna de Jujuy, presented by Baron Ott; a Rosy-faced Love-bird (*Agapornis roseicollis*) from South Africa, presented by Mrs. Healey; a Mandarin Duck (*Æx galericulata*) from China, presented by Mrs. Balston; two Wagler's Pit Vipers (*Lachesis wagleri*) from Singapore, presented by Mr. A. Herbert; a Back-marked Snake (*Coluber scalaris*), European, presented by Mr. W. A. Harding; four Horned Lizards (*Phrynosoma cornutum*) from Colorado, presented by Mr. Edwin Webb; two Carinated Lizards (*Liocephalus carinatus*) from the West Indies, five Hispid Lizards (*Agama hispida*) from South Africa, five Round-spotted Lizards (*Stenodactylus guttatus*) from North Africa, five Black-spotted Lizards (*Algiroides nigropunctatus*) from the Borders of the Adriatic, two Wall Lizards (*Lacerta muralis*, var. *genéi*), two Wall Lizards (*Lacerta muralis*, var. *badriagoe*) from Corsica, two Alaska Geese (*Bernicla minima*) from the Pacific Coast, deposited.

OUR ASTRONOMICAL COLUMN.

THE ROTATION OF SATURN.—Writing to the October number of the *Observatory*, Herr Leo Brenner states that the rotation period of Barnard's large white spot on Saturn, as deduced from his observations, is *exactly* 10h. 38m., and that this value is rigidly confirmed by the observations of other German observers.

This period exactly agrees with that obtained by Mr. Denning as a mean of all the published observations, and, as that observer points out in a communication to the above-named journal, it indicates that the various belts and zones on Saturn have different rotation periods in a manner similar to those of Jupiter.

The recent disturbances on Saturn have now practically subsided, and can only be seen with the larger instruments.

THE BROADENING OF SPECTRAL LINES.—In a paper communicated to No. 34 vol. vi. of the *Philosophical Magazine* Mr. G. W. Walker discusses the causes which lead to the asymmetrical widening of spectral lines.

Taking it for granted that near to a luminous source, whether the luminosity be produced by electricity or by flame at high temperature, there must be a number of free negatively charged particles, he proceeds to show how these particles may modify the light which they receive, and again scatter it in a manner quite different to that obtaining in the "Doppler" or in any "damping" effect. These charged particles, under the influence of the plane waves, will then vibrate with a period different from that of the incident waves; thus, instead of homogeneous light, there will be a portion of the light scattered by the charged particles, and this portion will have a longer wave-length than the original light, its intensity varying in proportion to the number of freely charged particles present. This, however, does not account for those rare cases where the broadening takes place on the violet side of the normal line. To explain these cases Mr. Walker suggests that the continuous streams of charged particles will set up a magnetic field which may produce the Zeeman effect, in which Zeeman has frequently noted asymmetrical broadening towards the violet. Where this latter effect is greater than the former, then the broadening takes place on the violet edge of the original line.

THE SPECTRUM OF HYDROGEN.—With the purpose of elucidating the connection between the "four-line" spectrum and the "many-line" spectrum of hydrogen, Mr. Louis A. Parsons, of the Johns Hopkins University, has made a series of experiments dealing with the spectrum of hydrogen obtained under many various conditions, and has embodied his results in a paper communicated to No. 2 vol. xviii. of the *Astrophysical Journal*.

After discussing the various theories which have previously been put forward in explanation of the phenomena, and dealing especially with that of Prof. Trowbridge, who supposes that the line spectrum is due to water vapour, and not to hydrogen pure and simple, Mr. Parsons describes the various pieces of apparatus he used and the experiments he performed, and then summarises his results in the following conclusions:—(1) The compound spectrum never occurs without the line spectrum, although the latter may occur alone at high pressures; (2) the line spectrum is characteristic of an abruptly oscillatory discharge, whilst the compound spectrum is produced by the continuous discharge; (3) the line spectrum may be produced by high temperatures occurring *locally* at points where the disruptive dis-

charge occurs, but it is not due to the high temperature of the gas considered as a whole.

In regard to the fourth point, viz. the action of water vapour in producing the line spectrum, the experiments showed that the presence of moisture is an important factor in the production of this type of spectrum, but they do not lead to Prof. Trowbridge's conclusion that it is the spectrum of water vapour. Mr. Parsons is inclined to believe that the ionisation of the atoms, as they enter or leave the water molecule, may set up a distinct local oscillatory discharge, which he previously shows to be necessary for the production of the line spectrum.

THE ORBIT OF ξ BOÖTIS.—In a previous computation of the orbit of ξ Boötis, by Prof. W. Doberck, the elements obtained represented the observed angles up to the year 1888, but did not faithfully represent the observed distances for some time prior to that (*Astronomische Nachrichten*, No. 2129). It now appears that the angles might be represented by orbits having widely differing periods, so the same observer has recomputed the elements, mainly using the measured distances as is done in the case of η Cassiopeia. Using Thiele's method, which he recommends especially in the case of very eccentric orbits, he obtained the following elements, referred to the equinox of 1900·0, from normal places for 1836·5, 1876·5, and 1896·5 (*Astr. Nach.*, No. 3900):—

$\Omega = 183^\circ\ 8'$	$P = 140{\cdot}84$ years.
$\lambda = 314\ 6$	$T = 1907{\cdot}10$
$\gamma = 46\ 8$	$a = 5''{\cdot}115$
$e = 0{\cdot}6163$	Retrograde.

IN the *Memorie* of the Italian Spectroscopists' Society Mr. G. Boccardi gives a list of errata in various star catalogues and trigonometric tables which he discovered in the course of compiling the catalogue of stars of reference in the zone 46° to 55°, published by the Observatory of Catania. In addition, the same writer gives corrections for the ephemerides of the asteroid 292 Ludovica. An Italian translation, by Mr. A. Mascari, of Dr. W. J. S. Lockyer's paper on a probable relation between the solar protuberances and the corona is also published in the *Memorie* of the Society.

OPENING OF THE MEDICAL SCHOOLS.

AS usual at this time of the year, introductory addresses have been delivered during the past week at the opening of the various medical schools in different parts of the country. Some of these addresses are summarised below.

At the opening of the medical session at University College, London, on Monday, Prof. E. H. Starling, F.R.S., pleaded for the establishment of a post-graduate school of medicine. He remarked that the crying need at the present time was clinical research, which must be carried out in hospitals by men trained in scientific methods and willing to spend laborious days in their application to the problems of disease. The absence of workers who might utilise to the full the great mass of material presented by our hospitals was due to two factors, namely, the absence of academic ideals in London, and the lack of any adequate provision which might enable our best men to devote their early years to the advance of their profession by conscientious study and research. Prof. Starling advocated the foundation, in the University of London, of a school specially devoted to the advancement of medicine. Such post-graduate school must be in connection with a hospital, and might be founded by a modification of one of the existing medical schools, or be created *de novo* in connection with some general hospital. Forming part of the school should be laboratories for experimental physiology and pathology, for bacteriology, for medical chemistry, and for normal and morbid histology. In addition to the experimental department, there should be, preferably in the hospital building itself, a series of observational laboratories, where the conditions of the patients could be investigated with a scientific precision. Such a school could detract in no way from the present advantages of our medical schools, but would rather add to their efficiency.

Sir Victor Horsley delivered an address on the subject of university education at the University of Birmingham on Monday. In the course of his remarks he urged the necessity for a multiplication of universities, and deprecated Sir W. Anson's dictum that what was wanted before universities was "an intelligent population." Under the present Government the whole direction of the Education Department had been placed in the hands of those whose ideas were regulated by the sterile training in dead languages and somewhat moribund systems of philosophy, unfortunately characteristic of an old university like Oxford. It did not seem to have occurred to the Parliamentary Secretary to the Board of Education that to the ordinary person the more obvious way of obtaining an intelligent population was to provide them with the highest and best means of educating themselves, and to increase and multiply those means in the midst of each populous district. It seemed to him shocking that the leading expert of the Education Department should hostilely attack not merely the present evolution of universities, but also the very earnest and carefully thought out propositions which the president of the British Association recently put forward with fresh force and interest. It had been reserved for Sir William Anson to raise the barren and worn-out strife between classical and scientific education. How could the physical science laboratories of our universities be considered to be too favoured by public opinion, as Sir William asserted, when their equipment and buildings left so much to be desired, and their endowments were so meagre that some 24 millions, it was estimated, must be expended to bring them into line with the universities of America? It was most unfortunate for the nation that the educational policy of the present Government was directed by officials holding such reactionary views. Let them hope that when the greatest statesman of our generation was placed by the country in his proper position as Prime Minister and leader of the nation a change would come over the spirit of the Education Department. The nation was under the delusion that universities flourished, first, on private endowments and benevolence; and, secondly, on the fees of students. Legislation to provide State aid for the universities was a duty which pressed heavily on a Government which did nothing to protect the people from the injury of drink and the waste of money which the drinking habit entailed. He suggested that the universities should cooperate in pressing a definite programme of State aid.

The first autumn term of the faculty of medicine at the University of Liverpool was inaugurated by Sir Dyce Duckworth, who, during an address on reverence and hopefulness in medicine, told the students that to equip themselves fittingly for the profession of medicine would demand some knowledge of the several sciences on which the science and art of medicine are based. Those who have had experience as examiners know well the difference, said Sir Dyce Duckworth, between candidates who have had the benefit of a liberal education before they entered upon medical study, and those who, although showing aptitude, have not had that advantage. It is the difference between efficiency and expertness, between width and narrowness.

Dr. J. W. Swan, F.R.S., gave the introductory address to the school of pharmacy of the Pharmaceutical Society. The events of the last sixty years, he said, showed conclusively that our want of thoroughness in education and the consequent want of imagination and capacity to appreciate the value of scientific research had caused us immense national loss. Dr. Elizabeth M. Pace, in addressing the students of the London School of Medicine for Women in connection with the Royal Free Hospital, gave an interesting historical sketch of the growth of facilities for the medical education of women during the last sixty years. At the Middlesex Hospital Mr. Justice Wills presided at the opening of the session, and Mr. William Hern, in welcoming the new students, pointed out that one of the great differences between the medical methods of past and present times was the substitution for the old empiricism, of treatment based upon an inquiry into the causes of disease. Mr. J. A. Bloxam, in the inaugural address at the Royal Veterinary College, told the students that if veterinary education was to march with the times, and if this country was to bear its part in the advancement of veterinary knowledge in the future, the State must follow the example set by other countries and contribute handsomely to the equipment and upkeep of the veterinary schools.

THE BRITISH ASSOCIATION.

SECTION K.

BOTANY.

OPENING ADDRESS BY A. C. SEWARD, F.R.S., FELLOW AND TUTOR OF EMMANUEL COLLEGE, LATE FELLOW OF ST. JOHN'S COLLEGE, CAMBRIDGE; LECTURER ON BOTANY IN THE UNIVERSITY, PRESIDENT OF THE SECTION.

IN 1883, the date of the last meeting held by the British Association at Southport, the late Prof. Williamson, of Manchester, delivered a Presidential Address before the Geological Section, in which he reviewed recent progress in palæobotanical research, with special reference to the vegetation of the Coal period. It would have been an interesting task to traverse the same ground to-day, in order to show what a vast superstructure has been built on the foundations which Williamson laid. In alluding to the controversies in which he bore so vigorous a part, Williamson spoke of the conflict as virtually over, though still reflected, "in the ground-swell of a stormy past." Now that twenty years have elapsed we are able to recognise with no little satisfaction that his views are firmly established, and that the debt which we owe to his able interpretation of the relics of Palæozoic plant-life is universally acknowledged. Williamson's labours demonstrated the possibilities of microscopical methods in the investigation of Carboniferous plants; but at the time of publication his results did not receive that attention which their importance merited, and it is only in recent years that botanists have been induced to admit the necessity of extending their observations to the buried treasures of bygone ages. We have been slow to realise the truth of the following statement, which I quote from an able article on Darwinism in the *Edinburgh Review* for October of last year: "The recognition of the fact that in every detail the present is built on the past has invested the latter with a new title to respect, and given a fresh impulse to the study of its history." The anatomical investigation of extinct types of vegetation has done more than any other branch of botanical science in guiding us along the paths of plant-evolution during the earlier periods of the earth's history.

I cannot conclude this brief reference to Williamson's work without an expression of gratitude for the help and encouragement with which he initiated me into the methods of palæobotanical research.

FLORAS OF THE PAST: THEIR COMPOSITION AND DISTRIBUTION.

Introduction.

It is by no means easy to make choice of a subject for a presidential address. There is the possibility—theoretical rather than actual—of a retrospective survey of modern developments in the botanical world, and the opportunity is a favourable one for passing in review recent progress in that department of the science which appeals more especially to oneself. In place of adopting either of these alternatives, I decided to deal in some detail with a subject which, it must be frankly admitted, is too extensive to be presented adequately in a single address. My aim is to put before you one aspect of palæobotany which has not received its due share of attention: I mean the geographical distribution of the floras of the past. In grappling with this subject one lays oneself open to the charge of attempting the impossible—a not unusual characteristic of British Association addresses. I recognise the futility of expecting conclusions of fundamental importance from such an incomplete examination of the available evidence as I have been able to undertake; but a hasty sketch may serve to indicate the impressions likely to be conveyed by a more elaborate picture.

One difficulty that meets us at the outset in approaching the study of plant distribution is that of synonymy. "The naturalist," as Sir Joseph Hooker wrote in his "Introductory Essay to the Flora of New Zealand," "has to seek truth amid errors of observation and judgment and the resulting chaos of synonymy which has been accumulated by thoughtless aspirants to the questionable honour of being the first to name a species." Endless confusion is caused by the use of different generic and specific names for plants that are in all probability identical, or at least very closely allied. Worthless fossils are frequently designated by a generic and specific title: an author lightly selects a new name for a miserable fragment of a fossil fern-frond without pausing to consider whether his record is worthy of acceptance at the hands of the botanical palæographer.

An enthusiastic specialist is apt to exaggerate the value of his material, and to forget that lists of plants should be based on evidence that can be used with confidence in investigations involving a comparative treatment of the floras of the world. As Darwin said in the "Origin of Species": "It is notorious on what excessively slight differences many palæontologists have founded their species; and they do this the more readily if the specimens come from different sub-stages of the same formation." It would occupy too much time to refer to the various dangers that beset the path of the trustful student, who makes use of published lists of local floras in generalising on questions of geographical distribution during the different eras of the past. Such practices as the naming of undeterminable fragments of leaves or twigs, the frequent use of recent generic names for fossil specimens that afford no trustworthy clue as to affinity, belong to the class of offences that might be easily guarded against; there are, however, other obstacles that we cannot expect to remove, but which we can take pains to avoid. An author in naming a fossil plant may select one of several generic names, any of which might be used with equal propriety; individual preferences assert themselves above considerations as to the importance of a uniform nomenclature. The personal element often plays too prominent a part. To quote a sentence from a non-scientific writer: "The child looks straight upon Nature as she is, while a man sees her reflected in a mirror, and his own figure can hardly help coming into the foreground."

In endeavouring to take a comprehensive survey of the records of plant-life, we should aim at a wider view of the limits of species and look for evidence of close relationship rather than for slight differences, which might justify the adoption of a distinctive name. Our object, in short, is not only to reduce to a common language the diverse designations founded on personal idiosyncrasies, but to group closely allied forms under one central type. We must boldly class together plants that we believe to be nearly allied, and resist the undue influence of considerations based on supposed specific distinctions.

The imperfection of the Geological record was spoken of by one of England's greatest geologists, in a criticism of the "Origin of Species," as "the inflated cushion on which you try to bolster up the defects of your hypothesis." On the other hand, Darwin wrote, in 1861: "I find, to my astonishment and joy, that such good men as Ramsay, Jukes, Geikie, and one older worker, Lyell, do not think that I have in the least exaggerated the imperfection of the record." No one in the least familiar with the conditions under which relics of vegetation are likely to have been preserved can for a moment doubt the truth of Darwin's words: "The crust of the earth, with its embedded remains, must not be looked at as a well-filled museum, but as a poor collection made at hazard and at rare intervals."

As a preliminary consideration, we must decide upon the most convenient means of expressing the facts of geographical distribution in a concise form. The recognised botanical regions of the world do not serve our purpose; we are not concerned with the present position of mountain-chains or wide-stretching plains that constitute natural boundaries between one existing flora and another, but simply with the relative geographical position of localities from which records of ancient floras have been obtained. In the accompanying map I have divided the surface of the earth into six belts, from west to east. The most northerly or *Arctic Belt* includes the existing land-areas as far south as latitude 60°, comprising—1, Northern Canada; 2, Greenland and Iceland; 3, Northern Europe; 4, Bear Island and Spitzbergen; 5, Franz Josef's Land; 6, Northern Asia. The *North Temperate Belt*, extending from latitude 60° to 40°, includes—7, South Canada and the northern United States; 8, Central and Southern Europe; 9, Central Asia. The *North Subtropical Belt* comprises the land between latitude 40° and the Tropic of Cancer, including—10, the Southern States of North America; 11, Northern Africa, part of Arabia and Persia; 12, Thibet and part of China; 13, Japan. The *Tropical Belt*, embracing the land-areas between the Tropics of Cancer and Capricorn, includes—14, Central America and the northern part of South America; 15, Central Africa and

Madagascar; 16, India, the Malay Archipelago, and Northern Australia. The *South Subtropical Belt*, extending from the Tropic of Capricorn to latitude 40° south, includes —17, Central South America; 18, South Africa; 19, Central and Southern Australia. The *South Temperate Belt* includes—20, the extreme south of South America; 21, Tasmania; 22, New Zealand.

Pre-Devonian Floras.

The scanty records from pre-Devonian rocks afford but little information as to the nature of the vegetation that existed during the period in which were deposited the Cambrian, Ordovician, and Silurian strata that now form the greater portion of the Welsh and Cumberland hills. We must wait for further discoveries before attempting to give more than the barest outline of the plant-life of these remote epochs. Our knowledge of the plant-world which existed during the Silurian period is far too meagre to justify any statement as to geographical distribution. Of the few records of supposed Silurian plants, several have been shown to be unsatisfactory, and the nature of others is too uncertain to admit of accurate identification. The Lepidodendron-like fossil from the Clinton limestone of Silurian age in Ohio, described by Claypole in 1878 as Glyptodendron, has been referred by a later writer to a Cephalopod. Stur's Bohemian plants, described in 1881, are too imperfect to afford any information of botanical value; while the ferns and lepidodendroid plants recently recorded by Potonié from the Hartz Mountains are more likely to be of Devonian than Silurian age.

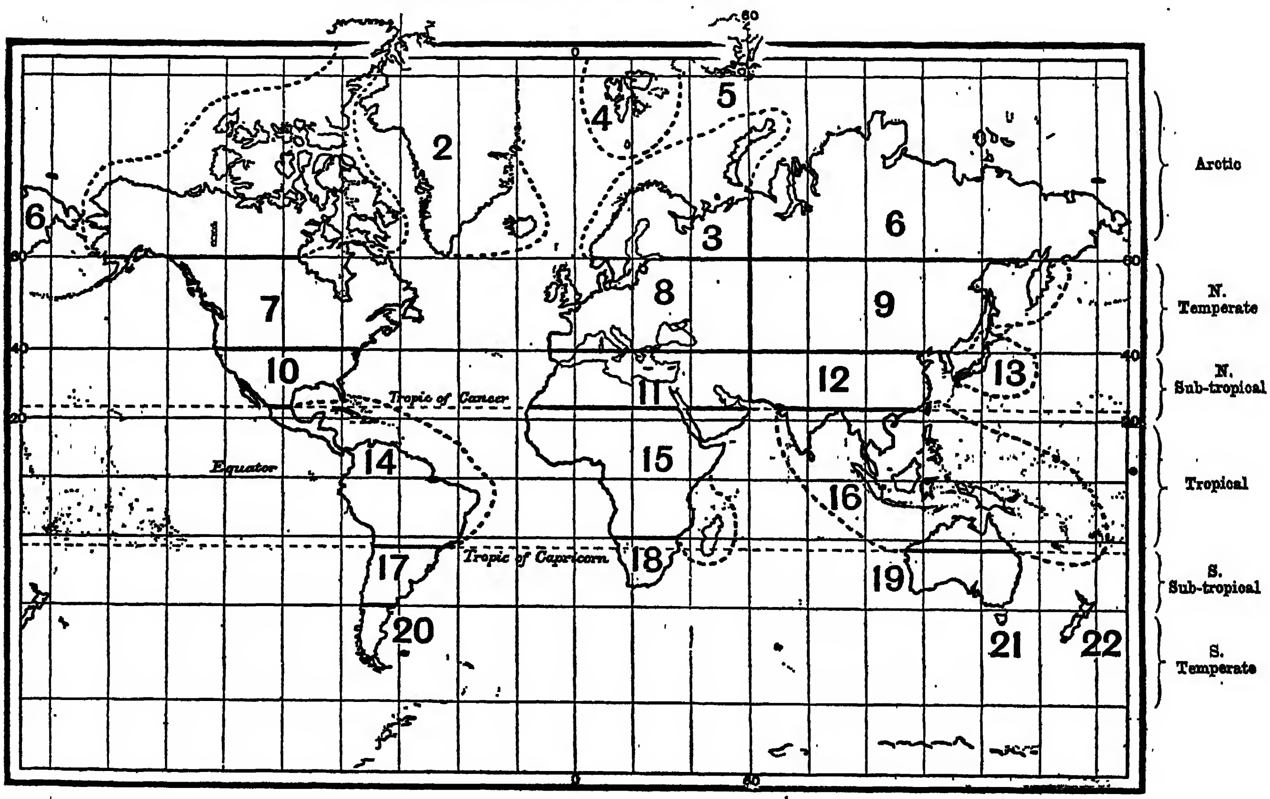
The genus Nematophycus, originally described by Dawson as Prototaxites, and afterwards referred by Carruthers to the Algæ, constitutes the most satisfactory example of a Silurian plant. This genus, which has fortunately been preserved in such a manner as to admit of minute microscopical examination, represents a widely spread algal type in Silurian and Devonian seas. It has been found in Silurian strata in Wales, Shropshire, and New Brunswick; also in Devonian rocks of Eastern Canada, New York, Ohio, and North-West Germany. The tubular elements composing the stems of some species of Nematophycus —which reached a diameter of 2 or 3 feet—exhibit a regular variation in width, giving the appearance of concentric rings of growth, as in the stems of the tree-like Lessonia, an existing genus of Antarctic seaweeds. This structural feature presents an impressive image in stone of a plant's rhythmical response to some periodically recurring conditions of growth in the waters of Palæozoic seas.

Devonian and Lower Carboniferous Floras.

The earliest plants that have been found in sufficient number, and in a state of preservation which renders their identification possible, are those from Devonian rocks. From Bear Island, a small remnant of land situated within the Arctic circle, the late Prof. Heer described several Devonian plants; and more recently Prof. Nathorst, of Stockholm, has given a full account of this interesting and comparatively rich flora. The relics of plant-life preserved in this Arctic island carry us back through countless ages to a time when a luxuriant vegetation flourished in a region now occupied by ice-bound land and polar seas. As Edward Fitzgerald said, in speaking of his enjoyment of some geological book: "This vision of time is in itself more wonderful than all the conceptions of Dante and Milton." Devonian plants have been described by Feistmantel, Etheridge, and others from Australia; and the well-known Kiltorkan grits of Ireland have supplied a few well-preserved impressions of the oldest land-plants disinterred from British rocks.

As my aim is to sketch in broad outline the general facies of the vegetation which flourished at different stages in the earth's history, rather than to undertake a critical examination of the evidence as to the precise geological age of the plant-bearing beds, I propose to treat of Devonian and Lower Carboniferous floras as constituting one phase in the evolu-

MAP I.—The Earth's Surface divided into Areas (1–22) for convenience in recording the Geographical Distribution of Fossil Plants.



tion of the plant-world. In speaking of the plants of the Devonian and Lower Carboniferous or Culm phase, it is not assumed that the specimens entombed in the snow-covered cliffs of Bear Island were actually contemporaneous with those found in rocks of the same geological period in the Southern hemisphere. The Bear Island rocks are, in the language which Huxley taught us to use, homotaxial with certain Devonian plant-bearing strata in other parts of the world; they occupy the same relative position in the geological series.

Homotaxy by no means implies contemporaneity; indeed, the late Edward Forbes maintained that similarity of organic contents of distant formations should be accepted as *prima facie* evidence of a difference in age.

What do we know as to the composition of the floras that flourished in the later stages of the Devonian and in the latter part of the Carboniferous era? The following list, which is by no means exhaustive, represents some of the more important generic types which may be very briefly described:—

1. EQUISETALES.
   Archaeocalamites.

2. SPHENOPHYLLALES.
   Sphenophyllum.
   Cheirostrobus.
   [*Pseudobornia?*]

3. LYCOPODIALES.
   Lepidodendron.
   Bothrodendron.

4. FILICALES.
   Archaeopteris.
   Adiantites.
   Rhodea.
   Cardiopteris.
   Todeopsis.
   Cephalotheca.
   Rhacopteris.

5. CYCADOFILICES.
   Calamopitys.
   Heterangium.
   Lyginodendron.

6. GYMNOSPERMÆ.
   (CORDAITALES).
   Cordaites.
   Pitys.

In Archæocalamites we have the oldest example of an undoubted Equisetaceous genus. The structure of its comparatively thick and woody stem is practically identical with that of our common British type of Calamites, one of the most abundant of the Coal period genera, while the strobilus differed in no essential feature from that of a modern Horsetail. The genus Cheirostrobus, founded in 1897 by Dr. D. H. Scott on a single specimen of a petrified cone discovered in the rich volcanic beds of Lower Carboniferous age at Pettycur on the shores of the Firth of Forth, affords a striking illustration of a Palæozoic plant exhibiting a structure far more complex than that of any known type among existing Vascular Cryptogams. As Scott clearly shows in his admirable memoir, Cheirostrobus is a synthetic or compound genus, one of the numerous extinct types brought to light by the anatomical investigation of fossil plants, from which we have learnt more about the inter-relations of existing classes than we could ever hope to discover from the examination of recent species.

In this Scotch cone, about 3·5 cm. in diameter, we recognise Equisetaceous and Lycopodinous characters combined with morphological features typical of the extinct genus Sphenophyllum. Some specimens of vegetative stems described by Nathorst from Bear Island under the name Pseudobornia—characterised by their whorled leaves with fimbriate blades borne on nodal regions separated by long internodes—may, as Scott has suggested, represent the branches of the tree of which Cheirostrobus was the cone. Both Devonian and Culm rocks have furnished many examples of Lycopodinous plants. The genus Bothrodendron, closely allied in habit to Lepidodendron, has been recorded from Bear Island, Ireland, and Australia, and the cuticles of a Lower Carboniferous species form the greater portion of the so-called paper-coal of Tula in Russia. Lepidodendron itself had already attained to the size of a forest tree, with anatomical features precisely similar to those of the succeeding Coal period species.

Our knowledge of the ferns is not very extensive. The genus Archæopteris from Ireland, Belgium, Bear Island, and North America has always been regarded as a fern, but we must admit the impossibility of accurately determining its systematic position until we possess a fuller knowledge of the reproductive organs and of its anatomical structure. Similarly the genera Rhacopteris, Adiantites, and Rhodea, with other characteristic members of the Lower Carboniferous vegetation, may be provisionally retained among the oldest known ferns. The genus Cardiopteris—a plant with large oblong or orbicular pinnules borne in two rows on a stout rachis—is known only in a sterile condition, and it is quite as likely that its reproductive organs may have been of the Gymnospermous as of the Filicinean type.

Renault has described under the name Todeopsis some petrified sporangia which appear to be practically identical with those of existing Osmundaceæ, and a new Devonian genus Cephalotheca has been instituted by Nathorst for fertile specimens of a strange type of plant which he refers to the Marattiaceæ. Of much greater importance than the sterile fern-like fronds, which cannot be assigned with confidence to a definite position, are the petrified remains of stems and leaves of such plants as Heterangium, Lyginodendron, Calamopitys, and others which demonstrate the existence of a class of synthetic genera combining Filicinean and Cycadean characters. These plants are of exceptional interest as showing beyond doubt that Ferns and Cycads trace their descent from a common ancestry. Some of the supposed ferns from Lower Carboniferous rocks are known to have been fronds borne on stems with the structure of cycads, and we have good reason for believing that some at least of the gymnospermous seeds of Palæozoic age are those of plants of which the outward form was more fern-like than cycadean. The announcement made a few months ago by Prof. Oliver and Dr. Scott that they had obtained good evidence as to the connection of the gymnospermous seed known as Lagenostoma with the genus Lyginodendron is one of the most important contributions to botany published in recent years; if, as I firmly believe, the evidence adduced is convincing, it gives satisfactory confirmation to suspicions that previous discoveries led us to entertain. The fact demonstrated is this: the genus Lyginodendron, a plant known to have existed during the greater part of the Carboniferous epoch, possessed a stem of which the primary structure was almost identical with that which characterises some recent species of Osmundaceæ, while the secondary wood produced by the activity of a cambium is hardly distinguishable from the corresponding tissue in the stem of a recent cycad. The fronds were those of a fern, both in the anatomy of their vascular tissue and in their external form; so far, therefore, as the vegetative characters are concerned, we have a combination of ferns and cycads. We still lack complete knowledge of the nature of the reproductive organs, but it seems clear that Lyginodendron bore seeds constructed on the Gymnospermous plan, but characterised by an architectural complexity far beyond that represented in the seeds of any modern Conifer or Cycad.

In such genera of Gymnosperms as Cordaites, Pitys, and others, we have examples of forest trees possessing wood almost identical with that of existing species of Araucaria, but distinguished by certain peculiarities which point to a relationship with members of the Cycadofilices, and suggest that Conifers as well as Cycads may have sprung from a filicinean stock.

These waifs and strays from the vegetation of an era incredibly remote, when strange amphibians were lords of the animal world, afford, as Newberry expresses it, "fascinating glimpses of the head of the column of terrestrial vegetation that has marched across the earth's stage during the different geological ages."

Two facts stand out prominently as the result of a general survey of what are practically the oldest records of plant-life. One is the abundance of types which cannot be accommodated in our existing classification founded solely on living plants.

The Devonian and Lower Carboniferous plants lead us away from the present along converging lines of evolution to a remote stage in the history of life; they bring us face to face with proofs of common origins, which enable us to recognise community of descent in existing groups between which a direct alliance is either dimly suggested or absolutely unsuspected if we confine our investigations to modern forms. We recognise, moreover, in such a plant as Archæocalamites an ancestor from which we may derive in a direct line the existing members of the Equisetales. In other types, by far the greater number, we see striking examples of Nature's many failures, which, after reaching an extraordinary com-

plexity of organisation, gave place to other products of evolution and left no direct descendants.

Another fact that seems to stand out clearly is the almost world-wide distribution of several characteristic Lower Carboniferous plants. The accompanying table (Table I.), based on the artificial divisions marked out on the map, to which reference has already been made, shows how widely some of the plants had migrated from an unknown centre far back in a still more remote age. We are, as yet, unable to follow these Devonian plants to an earlier stage in their evolution. We are left in amazement at their specialised structure and extended geographical distribution, without the means of perusing the opening chapters of their history.

Upper Carboniferous (Coal-measures) and Permian Floras.

From the Lower Carboniferous formation we pass on to the wealth of material afforded by the Upper Carboniferous and Permian rocks. From the point of view of both botanists and geologists, the fossil plants obtained from the beds associated with the coal are of greater interest and importance than those of any other geological period. By a fortunate accident our investigations are not restricted to the examination of carbonaceous impressions and sandstone casts left by the stems and leaves of the Coal-period plants. By means of thin sections cut from the calcareous nodules of the coal-seams of Yorkshire and Lancashire, and from the silicified pebbles of France and Saxony, it is possible to make anatomical investigations of the coal-forest trees with as much accuracy as that with which we can examine sections of recent plants. The differences between the vegetation that witnessed the close of the Carboniferous era and that which flourished during the opening stages of the succeeding Permian epoch are comparatively slight. It has been demonstrated by Grand'Eury, Kidston, Zeiller, Potonié, and others, that it is possible both to separate the floras of the Coal-measures from those of Lower Permian age, and to use the plant species as trustworthy guides to the smaller subdivisions of the Coal-measures; but apart from these minor differences, the general facies of the vegetation remained fairly constant during the Upper Carboniferous and Lower Permian periods.

The vast forests of the Coal age occupied an extensive area of land on the site of the present United States of North America, stretching across Europe into Eastern Asia; under the shade of their trees lived "the stupid, salamander-like Labyrinthodonts, which pottered with much belly and little leg, like Falstaff in his old age." The plants of these Palæozoic forests seem to be revivified, as we subject their petrified fragments to microscopical examination. Robert Louis Stevenson has referred to a venerable oak, which has been growing since the Reformation and is yet a living thing liable to sickness and death, as a speaking lesson in history. How much more impressive is the conception of age suggested by the contemplation of a group of Palæozoic tree-stumps exposed in a Carboniferous quarry and rooted where they grew! An examination of their minute anatomy carries us beyond the mere knowledge of the internal architecture of their stems, leaves, and seeds; it brings us into contact with the actual working of their complex machinery. As we look at the stomata on the lamina of a leaf of one of those strange trees, and recognise a type of structure in the mesophyll-tissues which has been rendered familiar by its occurrence in modern leaves, it requires but little imagination to see the green blade spreading its surface to the light to obtain a supply of solar energy with which to extract carbon from the air. We can almost hear the murmur of plant-life and the sighing of the branches in the wind as the sap courses through the wood, and the leaves build up material from the products of earth and air; products that are to be sealed up by subsequent geological changes, until after the lapse of countless ages the store of energy accumulated in coal is dissipated through the agency of man.

The minute structure of the wood of the Calamites, Lycopods, and other trees, agrees so closely with that of existing types that we are forced to conclude that these Palæozoic plants had already solved the problem of raising a column of water more than 100 feet in height. The arrangement of the strengthening or mechanical tissues in the long flat leaves of Cordaites is an exact counterpart of that which we find in modern leaves of similar form. The method of disposition of supporting strands in such manner as to secure the maximum effect with the least expenditure of material was as much an axiom in plant

architecture in the days of the coal-forests as it is now one of the recognised rules in the engineer's craft.

We need not pause to discuss the various opinions that have been expressed as to the conditions under which the forests grew; we may adopt Neumayr's view, and recognise a modern parallel in the moors of the sub-arctic zone, or find a close resemblance in the dismal swamp of North America. There is also the view expressed many years ago by Binney and warmly advocated by Darwin, that some at least of the Coal-period trees grew in salt-marshes, an opinion which receives support from several structural features suggestive of xerophytic characters recognised in the tissues of Palæozoic plants.

Time does not admit of more than the most cursory glance at the leading types of the Permo-Carboniferous floras. The general character of the preceding vegetation is retained with numerous additions. Archæocalamites is replaced by a host of representatives of the genus Calamites, an Equisetaceous type with stout woody stems and several forms of cones of greater complexity than those of modern Horsetails. Side by side with the Calamites there appear to have existed plants which, from their still closer agreement with Equisetum, have been described by Zeiller, Kidston, and others as species of Equisetites. The genus Sphenophyllum, a solitary type of an extinct family, was represented by several forms which, like the Galium of our hedgerows, may have supported their slender branches against the stems of stronger plants. Lycopods, with trunks as thick and tall as forest trees, were among the most vigorous members of the later Palæozoic forests. Although recent research has shown that several of the supposed ferns must be assigned to the Cycad-fern alliance, there can be no doubt that true ferns had reached an advanced state of evolution during the Permo-Carboniferous epoch. The abundance of petrified stems of the genus Psaronius, of which the nearest living representatives are probably to be found among the tropical Marattiaceæ, demonstrates the existence of true ferns. Others had more slender stems which clambered over the trunks of stouter trees, while some grew in the shade of Lepidodendron and Cordaites. The most striking fact as regards the Permo-Carboniferous ferns is the abundance of fertile fronds bearing sporangia which exhibit a more or less close agreement with those of the few surviving genera of Marattiaceæ. The more familiar type of sporangium met with in our existing fern-vegetation is also represented, and we have recently become familiar with several genera bearing sporangia exhibiting a close resemblance to those of modern Gleicheniaceæ, Schizæaceæ, and Osmundaceæ. The sporangial characteristics of the different families of living ferns are many of them to be found among Palæozoic types, but there is a frequent commingling of structural features showing that the ferns had not as yet become differentiated into so many or such distinct families as have since been evolved.

Prominent among the Gymnosperms of the Palæozoic forests must have been the genus Cordaites: tall handsome trees, with long strap-shaped leaves, recalling on a large scale those of the kauri pine of New Zealand. This genus, which has been made the type of a distinct group of Gymnosperms, combined the anatomy of an Araucaria with reproductive organs more nearly allied to the flowers of Cycads, and exhibiting points of resemblance with those of the Maidenhair-tree. It is not until the later stages of the Permo-Carboniferous epoch that more definite coniferous types make their appearance. The genus Walchia, in habit almost identical with *Araucaria excelsa*, the Norfolk Island pine, with Ulmannia and Voltzia, are characteristic members of the vegetation belonging to the later phase of the Permo-Carboniferous era. The Maidenhair-tree of the far East, one of the most venerable survivors in our modern vegetation, is foreshadowed in certain features exhibited by Cordaites and, as regards the form of its leaves, by Psygmophyllum, Wittleseya, and other genera. Psygmophyllum is known to have existed in Spitzbergen in the preceding Culm epoch, and Wittleseya occurs in Canadian strata correlated with our Millstone Grit. Leaves have been found in Permian rocks of Russia, Siberia, Western and Central Europe, referred to the genus Baiera, a typical Mesozoic type closely allied to Ginkgo. In the upper Coal-measures and lower Permian rocks a few pinnate fronds have been discovered, such as Sphenozamites, from the Permian of France, Pterophyllum from France and Russia, and Plagiozamites from the Permian of Alsace, which bear a striking likeness to modern Cycadean leaves. Throughout the Permo-Carboniferous era the Cycadofilices formed a dominant group; Lyginodendron, Medullosa, Poroxylon, and many other genera flourished in abundance as vigorous members of an ancient class which belongs exclusively to the past.

One distinctive characteristic of the vegetation of later Permo-Carboniferous days is the occurrence of the Cycad-like fronds already referred to; also the appearance of Voltzia and other conifers with species of Equisetites, pioneer genera of a succeeding era that constitute connecting links between the Palæozoic and Mesozoic floras.

What we may call the typical vegetation of the Coal-measures, which continued, with comparatively minor changes, into the succeeding era, flourished over a wide area in the northern hemisphere, suggesting, as White points out, an almost incredible uniformity of climate. The same type of vegetation extended as far south as the Zambesi in Africa, and to the vast coal-fields of China; it possibly existed also in high northern latitudes, but, since Heer's record of Cordaites in Novaya Zemlya in 1878, no further traces of arctic Permo-Carboniferous plants have been found. Calamites, Lepidodendron (with its near relative Sigillaria), Ferns, Cycadofilices, Cordaites, and other Gymnosperms, constitute the most familiar types. We have already noticed the existence in the southern hemisphere of Lower Carboniferous and Devonian genera identical with plants found in rocks of corresponding age within the Arctic circle. This agreement between the northern and southern floras was, however, not maintained in the later stages of the Palæozoic epoch. Australian plant-bearing strata homotaxial with Permo-Carboniferous rocks of Europe, have so far afforded no examples of Sigillaria, Lepidodendron, or of several other characteristic northern forms; in place of these genera we find an enormous abundance of a fern known as Glossopteris, a type which must have monopolised wide areas, suggesting a comparison with the green carpet of bracken that stretches as a continuous sheet over an English moor. With Glossopteris was associated a fern bearing similar leaves, known as Gangamopteris, and with these grew Schizoneura and Phyllotheca, members of the Equisetales. In addition to these genera there are others which bear a close resemblance to northern hemisphere types, such as Noeggerathiopsis, a member of the Cordaitales, and several species of Sphenopteris. Similarly, in many parts of India, Glossopteris has been found in extraordinary abundance in the same company with which it occurs in Australia. In South Africa an identical flora is met with which extends to the Argentine and to other regions of South America. A few members of this southern flora have been recorded from Borneo, and the genus Glossopteris is said to occur in New Zealand, but the latter statement has been called in question and requires confirmation. It is clear that from South America, through South Africa and India to Australia, there existed a vegetation of uniform character which flourished over a vast southern continent at approximately the same period as that which, in the northern hemisphere and in China, witnessed the growth of the forests the trees of which formed the source of our coal-supply.

Since attention was drawn by Dr. Blanford and other writers to the facts of plant-distribution revealed by a study of the later Palæozoic floras, it has been generally admitted that during the Permo-Carboniferous era there existed two fairly well-marked botanical provinces. The more familiar and far richer flora occupied a province stretching from the western States of North America across Europe into China and reaching as far as the Zambesi; the other province was occupied by a less varied assemblage of plants, characterised by the abundance of Glossopteris, Gangamopteris, Neuropteridium, Noeggerathiopsis, Schizoneura, and other genera, stretching from South America through India to Australia.

Two questions at once suggest themselves: first, were these two botanical provinces defined by well-marked boundaries, or did they dovetail into one another at certain points? Secondly, is there any probable explanation of this

difference between northern and southern floras, a feature not shown either by the preceding Devonian and Lower Carboniferous or by the succeeding Lower Mesozoic floras?

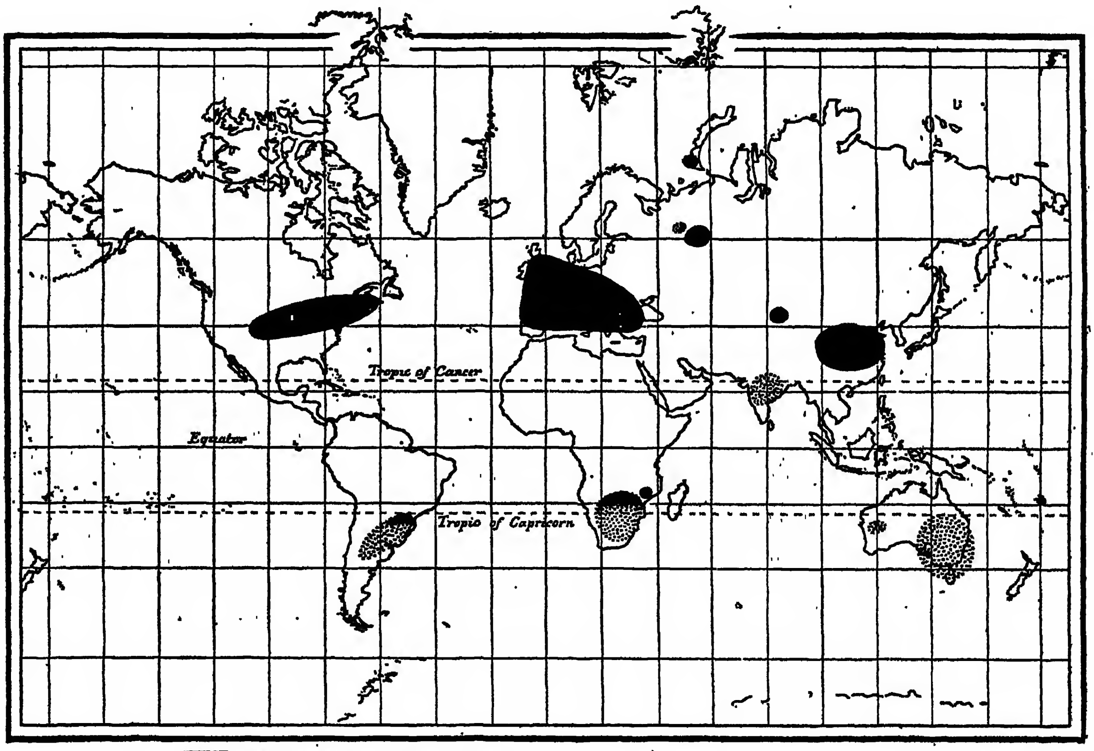
In Brazil, Prof. Zeiller has recorded the occurrence of a flora including Lepidophloios, a well-known European member of the Lycopods, associated with such characteristic southern types as Gangamopteris and Noeggerathiopsis. Similarly from the Transvaal a European species of Sigillaria, with a Lepidodendroid plant, and another northern genus, Psygmophyllum, have been found in beds containing Glossopteris, Gangamopteris, Noeggerathiopsis, Neuropteridium, and other members of the so-called Glossopteris flora. In India, the Glossopteris flora exhibits an entire absence of Lepidodendron, Calamites, Sigillaria, and other common northern genera, while Sphenophyllum is represented by a single species. The Australian Permo-Carboniferous flora is also characterised by the absence of the great majority of the northern types. Until a few years ago the genus Glossopteris had not been discovered in Europe, but in 1897 Prof. Amalitzky recorded the occurrence of this genus in association with Gangamopteris in Permian strata in northern Russia.

We see, then, that in Brazil and South Africa the Glossopteris flora and the northern flora overlapped, but the former was the dominant partner. On the other hand, in rocks belonging to a somewhat higher horizon in Russia, we meet with a northern extension of the Glossopteris flora. Map II. serves better than a detailed description to illustrate the geographical distribution of these two types of vegetation in the Permo-Carboniferous era.

There is little doubt that the differences between the flora of the southern continent, that existed towards the close of the Carboniferous and during the succeeding Permian period, and that which flourished farther north have in some respects been exaggerated; geographical separation has played too conspicuous a part in influencing botanical nomenclature. Granting the existence of identical genera or representative types, there remains a striking difference between the two provinces into which the Permo-Carboniferous vegetation was divided. As regards an explanation of this fact, we can only hazard a guess; as Dr. Blanford and others have pointed out, there is a probable solution to hand. Briefly stated, the Upper Palæozoic plant-bearing strata of India, South America, Australia, and South Africa are in close association with boulder-beds of considerable extent. In some places, as for example in India and Australia, the boulder-beds rest on rocks bearing unmistakable signs of the grinding action of ice. There can be no reasonable doubt that the huge continental area of which India, South Africa, parts of South America, and Australia remain as comparatively insignificant remnants, was exposed to climatal conditions favourable to the accumulation of snow and to the formation of glaciers. One possible explanation, therefore, of the existence of a distinct vegetation in the southern area is that the climate was such as to render impossible the existence of those coal-forest plants that exhibited so vigorous a development in northern latitudes. There is, moreover, another consideration, and that is the effect on the vegetation of an enormous continental mass; in North America and Europe it is probable that the forests grew on low-lying land penetrated by lagoons and in part submerged under shallow brackish water, a disposition of land and sea very different from that in the so-called Gondwana Land of the South. Possibly the apparently uniform vegetation of the Devonian and Lower Carboniferous period was unable, through stress of climatal conditions, to prolong its existence in the southern area, while in the north it continued to flourish, and as the evolution of new types proceeded in rapid succession it was not slow to colonise new areas stretching in South America and South Africa to the confines of the Glossopteris flora.

There seems good reason for assuming that the Glossopteris flora originated in the South and before the close of the Permian period, as well as in the succeeding Triassic era, pushed northward over a portion of the area previously occupied by the northern flora. This northward extension

MAP II.—Permo-Carboniferous Floras.



= *Glossopteris* (Southern Flora).
= Northern Flora.

is shown by the existence of Glossopteris in Upper Permian rocks of Russia, by the occurrence of several southern types in plant-bearing beds of the Altai mountains, and by the existence in Western Europe during the early stages of the Triassic era of such southern genera as Neuropteridium and Schizoneura.

Triassic, Jurassic, and Wealden Floras.

It is unfortunate that the records of plant-life towards the close of the Palæozoic and during the succeeding Triassic period are very fragmentary; the documents are few in number, and instead of the fairly continuous chapters in which the records of the Coal age have been preserved, we have to be content with a few blurred pages. During the Triassic period the vegetation of the world gradually changed its character; the balance of power was shifted from the Vascular Cryptogams, the dominant group of the Palæozoic era, to the Gymnosperms. It is not until we pass up the geologic series as far as the Rhætic formation, that we come to palæobotanical records at all comparable in their completeness with those of the Permo-Carboniferous era; but before considering the Rhætic vegetation we must glance at such scattered relics as remain of the vegetation belonging to the period of transition between the Palæozoic and Mesozoic facies. It is regrettable that this transitional period is unusually poor in documentary evidence that might throw light on the gradual change in the facies of Palæozoic vegetation. The new order, when once established, persisted for many succeeding ages without undergoing any essential alteration.

One of the few floras of early Triassic age of which satisfactory relics have been preserved is that described in 1844 by Schimper and Mougeot from the Bunter Sandstones of the Vosges. The genus Neuropteridium, a plant which may be a true fern, or possibly a surviving member of the Cycadofilices, is represented by a species which can hardly be distinguished from that which flourished in South America, South Africa, and India in the Permo-Carboniferous period. This genus and another southern type, Schizoneura, both of which are met with in the Triassic rocks of the Vosges, would seem to point to a northern migration of certain members of the Glossopteris flora, which took place at the close of the Palæozoic era. In the Lower Triassic flora Conifers are relatively more abundant than in the earlier periods; such genera as Albertia (resembling in its vegetative features some recent species of Araucaria), Voltzia (with cones that cannot be closely matched with those of any existing members of the Coniferæ), and other representatives of this class are common fossils. Lepidodendra have apparently ceased to exist; Sigillaria may be said to survive in one somewhat doubtful form, *Sigillaria oculina*. The genus Pleuromeia, which makes its appearance in Triassic rocks, is known only in the form of casts exhibiting a strong likeness to some Palæozoic Lycopods, and is perhaps more akin to Isoetes than to any other existing plant. The Calamites are now replaced by large Equisetaceous plants, which are best described as Horsetails with much thicker stems than those of their modern descendants.

From Recoaro in Northern Italy some of the Vosges genera have been recorded, and a few other European localities have furnished similar relics of a Triassic vegetation. Passing to the peninsula of India, we find the genus Glossopteris abundantly represented in strata which there is good reason for regarding as homotaxial with the European Trias, and the occurrence in the same beds of some other genera of Permo-Carboniferous age shows that the change in the character of the southern vegetation at the close of the Palæozoic era was much more gradual than in the north.

The comparative abundance of plant remains in the northern hemisphere in rocks belonging to the Rhætic formation, a series of sediments so named from their development in the Rhætian Alps, is in welcome contrast to the paucity of the records from the underlying Triassic strata. From Virginia and adjacent districts in the United States a rich flora has been described, which by some authors is assigned to the Keuper or Upper Triassic series, while others class it as Rhætic. A similar assemblage of plants is known also from the Lettenkohle beds of Austria which, as Stur has shown, clearly belong to the same period of vegetation as the American flora. We need not, however, concern ourselves with discussions as to the precise stratigraphical position of these American and European plant-beds, but may conveniently group together floras of Upper Triassic and Rhætic age since they exhibit but minor differences from one another. Plants of Upper Triassic or Rhætic age are known from Scania and Franconia in Europe, Virginia and elsewhere in North America, Honduras, Tonkin, Australia, South Africa, Chili, and other parts of the world.

The geographical distribution of plants of approximately Rhætic age is shown in the following table, No. II., on p. 563, which demonstrates an almost world-wide range of a vegetation of uniform character. The character of the plant-world is entirely different from that which we have described in speaking of the Palæozoic floras. Gymnosperms have ousted Vascular Cryptogams from their position of superiority; ferns, indeed, are still very abundant, but they have undergone many and striking changes, notably in the much smaller representation of the Marattiaceæ. The Palæozoic Lycopods and Calamites have gone, and in their place we have a wealth of Cycadean and Coniferous types. As we ascend to the Jurassic plant-beds the change in the vegetation is comparatively slight, and the same persistence of a well-marked type of vegetation extends into the Wealden period. It is a remarkable fact that after the Palæozoic floras had been replaced by those of the Mesozoic era, the vegetation maintained a striking uniformity of character, from the close of the Triassic up to the dawn of the Cretaceous era. This statement is open to misconception; I do not wish to convey the idea that a palæobotanist would be unable to discriminate between floras from Rhætic and Wealden rocks; but I wish to emphasise the fact that in spite of specific, and to a less extent of generic, peculiarities, which enable us to determine, within narrow limits, the age of a Mesozoic flora, the main features of the vegetation remained the same through a long succession of ages. The accompanying tables (Nos. III. and IV.) illustrate the geographical distribution of some of the leading types of Mesozoic plants during the Jurassic and Wealden periods, and demonstrate not only the striking differences between the Mesozoic and Palæozoic floras, but also the much greater uniformity in the vegetation of the world during the Secondary era than in the preceding Permo-Carboniferous epoch.

Mesozoic Floras.

It may be of interest to glance at some of the leading types of Mesozoic floras with the view of comparing them with their modern representatives. We are so familiar with the present position of the flowering plants in the vegetation of the world, that it is difficult for us to form a conception of a state of things in the history of the plant-kingdom in which Angiosperms had no part.

a. Conifers.

How may we describe the characteristic features of Rhætic and Jurassic floras? Gymnosperms, so far as we know, marked the highest level of plant-evolution. Conifers were abundant, but the majority were not members of that group to which the best known and most widely distributed modern forms belong.

A comparison of fossil and recent conifers is rendered difficult by the lack of satisfactory evidence as to the systematic position of many of the commoner types met with in Mesozoic rocks. There are, however, certain broad generalisations which we are justified in making; such genera as the Pines, Firs, Larches, and other members of the Abietineæ appear to have occupied a subordinate position during the Triassic and Jurassic eras; it is among the relics of Wealden and Lower Cretaceous floras that cones and vegetative shoots like those of recent Pines occur for the first time in a position of importance. There are several Mesozoic Conifers to which such artificial designations as Pagiophyllum, Brachyphyllum, and others have been assigned, which cannot be referred with certainty to a particular section of the Coniferæ; these forms, however, exhibit distinct indications of a close relationship with the Araucarieæ, represented in modern floras by Araucaria and Agathis. The abundance of cones in Jurassic strata showing the characteristic features of those of recent species of Araucaria affords trustworthy evidence as to the antiquity of the Araucarieæ and demonstrates their wide geographical distribution during the Mesozoic era. At the present day the Araucarieæ comprise the two genera Araucaria and

Agathis, the former including ten species occurring in South America and Australia, and the latter comprising four species which flourish in the Malay Archipelago, New Zealand, the Philippines, North-East Australia, and elsewhere. Sir William Thiselton-Dyer pointed out, in a lecture on plant-distribution, delivered in 1878, that the genus Araucaria appears to have been extinct in a wild state north of the Equator since the Jurassic epoch. Additional confirmation of the important status of this section of the Coniferæ is afforded by the abundance of petrified wood exhibiting Araucarian features, in both Jurassic and Wealden rocks. There is good reason to believe that the well-known Whitby jet was formed by the alteration of blocks of Araucarian wood drifted from forest-clad slopes overlooking a Jurassic estuary that occupied the site of the moors and headlands of North-East Yorkshire. Among familiar Jurassic genera, mention must be made of the genus Brachyphyllum, including species referred by some authors to Athrotaxites, represented by fragments of leafy twigs and branches bearing a striking resemblance to those of the isolated Tasmanian genus Athrotaxis. Omitting further reference to the various indications afforded by a study of Mesozoic Conifers as to the former extension of many of the more isolated recent types, we may present in a tabular form an epitome of the past and present range of the Araucarieæ:—

b. *Cycads.*

One of the most striking features of the Mesozoic vegetation is the abundance and wide distribution of Cycadean plants. To-day the Cycads or Sago-Palms are represented by ten genera and about eighty species; they are plants which occupy a subordinate position in modern floras, and occur for the most part as solitary types in tropical latitudes, never growing together in sufficiently large numbers to constitute a dominant feature in the vegetation. Cycads have long attracted attention as exhibiting morphological features of considerable interest. During the last few years the work of Ikeno, Webber, and Lang has shown us that the pollen of Cycas, Zamia, Stangeria, and probably of the other recent genera, produce spirally ciliated motile spermatozoids, the type of male cell previously regarded as constituting one of the well-defined distinctions between the Vascular Cryptogams and the Seed-bearing plants. The study of Palæozoic plants has done even more to break down the artificial barrier between Cycads and Vascular Cryptogams, by demonstrating beyond all reasonable doubt that our modern Cycads represent a small group of survivals descended from ancestors common to themselves and the ferns. Cycadean plants must have been among the commonest members of Mesozoic floras. Before the end of the Palæozoic era there existed plants bearing pinnate fronds similar to those of recent species of Cycadaceæ, and

Geographical Distribution of Past and Present ARAUCARIEÆ.

Agathis 4 species																×			×			×

in succeeding ages the group rapidly increased in number and variety until, in the Jurassic and the early Cretaceous periods, the Cycads asserted their superiority as the leading type of vegetation. The majority of Mesozoic Cycadean fronds are assigned to artificial or form-genera as an indication of our ignorance of their reproductive organs, or of the anatomical structure of their stems. As Prof. Nathorst has recently suggested, it is convenient to speak of these Cycadean remains as belonging to the group Cycadophyta. On the other hand, we find numerous petrified stems bearing well-preserved reproductive organs which enable us to compare the extinct with the existing species. We are in possession of enough facts to justify the statement that the majority of Mesozoic Cycads bore reproductive organs which differed in important morphological characters from those of existing forms. The researches of Williamson, Carruthers, Solms-Laubach, Lignier, and others, have revealed the existence of a large group of Cycadean plants—known as the Bennettiteæ—almost identical in habit with modern sago-palms, but distinguished by the complexity of their reproductive shoots. The Bennettiteæ, originally founded on a petrified stem discovered more than fifty years ago in the Isle of Wight, and represented by another fossil which Carruthers made the type of a new genus, Williamsonia, in 1870, possessed a thick stem, clothed with an armour of persistent leaf-bases and bearing a crown of pinnate fronds, as in most modern Cycads; but their flowers, which were borne on lateral shoots, were more highly specialised than those of the true Cycads. While most of the Mesozoic Cycads were no doubt members of the Bennettiteæ, others appear to have possessed reproductive organs like those of recent species. The Bennettiteæ belong to that vast army of plants that succumbed in the struggle for existence æons before the dawn of the Recent period. The other section of the Cycadophyta, the Cycadaceæ, still lingers on as one of the select band the present insignificance of which constitutes a badge of ancient lineage, and a faint reflection of past supremacy.

The wealth of Cycadean vegetation during the latter part of the Jurassic and the earlier stages of the Cretaceous periods is admirably illustrated by the discovery in the Black Hills of North America, and in other districts of the United States of hundreds of silicified trunks of Cycadean plants. The first discovery of petrified Cycadean stems in America was made by Tyson in 1859, who found two specimens in the Potomac beds of Maryland; since then more than 700 trunks, remnants of a vast Cycadean forest, have been obtained from the Black Hills alone. The investigations of Mr. Wieland, of Yale, who has been engaged for some time on the examination of this rich material, have already revealed the fact that in some of the Bennettiteæ the male and female organs were borne in a single flower, the female portion having a structure identical with that previously described from European stems, while the male flowers bear a close resemblance to the fertile fronds of a Marattiaceous fern. We have watched the progress of Mr. Wieland's researches with keen interest and look forward to further important developments. With some of us, indeed, the feelings of the ideal student of science are in danger of being overshadowed by a sensation akin to envy and a desire to invade American territory.

c. *Ginkgoales.*

Before leaving the Gymnosperms a word must be said about another section—the Ginkgoales—represented by the Maidenhair-tree of China and Japan. *Ginkgo* (or *Salisburia*) *biloba* has almost, if not quite, ceased to exist in an absolutely wild state, but as a cultivated tree it has now become familiar both in America and Europe. The living Maidenhair-tree is in truth an anachronism, a solitary remnant that brings us into touch with a vanished world and appears as an alien among its modern associates. The abundance of fossil leaves, like those of *Ginkgo biloba*, and of other slightly different forms referred to the genus Baiera, associated not infrequently with remains of male and female flowers, demonstrates the ubiquitous character of the Ginkgoales during the Rhætic, Jurassic, and Wealden periods. In the Jurassic shales of the Yorkshire Coast, Ginkgo and Baiera leaves occur in plenty, some of them practically identical with those of the existing species. The abundance of fossil Ginkgoales in other parts of the world—in Australia, South Africa, South America, China, Japan, North America, Greenland, Franz Josef's Land, Siberia, and throughout Europe—demonstrates the former vigour of this class of plants of which but one member survives. This type of Gymnosperm is distinctly foreshadowed in the Palæozoic vegetation, and as recently as the Eocene period a species of Ginkgo, indistinguishable in the form of its leaves from the living Maidenhair-tree, flourished in Western Scotland.

The accompanying table of distribution shows how extensive was the range of the Ginkgoales in the Mesozoic era—both geographically and stratigraphically.

d. *Ferns.*

Although many of the Mesozoic ferns are preserved only in the form of sterile fronds and are of little botanical interest, several examples of fertile leaves are known which it is possible to compare with modern types. The Polypodiaceæ, representing the dominant family of recent ferns, are met with in nearly all parts of the world and possess the attributes of a group of plants at the zenith of its prosperity. We may confidently state that so far as the somewhat meagre evidence allows us to form an opinion, this family occupied a subordinate position in the composition of Mesozoic floras. Polypodiaceous sporangia have been met with in Palæozoic rocks, and their existence during the Mesozoic period is not merely a justifiable assumption, but is demonstrated by the occurrence of undoubted species of Polypodiaceæ. It seems clear, however, that this family did not attain to a position of importance until the Mesozoic vegetation gave place to that which characterises the present period. The Osmundaceæ are now represented by five species of Todea and four of Osmunda; *Todea barbara* occurs in South Africa, Australia, Tasmania, and New Zealand, the other species are all filmy ferns and occur in New Zealand, New South Wales, New Caledonia, Samoa, and in a few other southern regions. The genus Osmunda has a wider range, occurring in Europe, Asia, North America, India, Japan, Southern China, Java, South Africa, and other parts of the world. During the Rhætic and Jurassic periods the Osmundaceæ flourished over the greater part of Europe; their remains have been recorded from England, Germany, Scandinavia, Russia, Poland, Siberia, and Greenland, also from North America, Persia, and China.

Similarly the Schizæaceæ, a family now represented by a few genera in India, North America, South America, Africa, Australia, Japan, China, and elsewhere, were among the more abundant ferns in the Jurassic vegetation. The Cyatheaceæ, a family that is now for the most part confined to the tropics, constituted another vigorous and widely

spread section in the Jurassic period; we find them in Jurassic rocks of Victoria, as well as in several regions in Europe, North America, and the Arctic regions.

The fertile fronds of many of the fossil Cyatheaceæ bear a striking resemblance to that isolated survivor of the family in Juan Fernandez—*Thyrsopteris elegans*. It is true that a considerable number of ferns of Jurassic and Wealden age have been described by the generic name Thyrsopteris without any adequate reason; but, neglecting all doubtful forms, there remain several types represented in the Jurassic flora of Siberia, England, and other parts of the world, which enable us to refer them with confidence to the Cyatheaceæ and to compare them more particularly with the sole existing species of Thyrsopteris. The Gleicheniaceæ, at present characteristic of tropical and southern countries, were undoubtedly abundant in the northern hemisphere in early Cretaceous days; abundant traces of this family are recorded from Greenland as well as from more southern European latitudes.

One of the most striking facts afforded by a study of the Mesozoic fern vegetation is the former extension and vigorous development of two families, the Dipteridinæ and Matonineæ, which are now confined to a few tropical regions and represented by six species. The tall graceful fronds of *Matonia pectinata*, forming miniature forests on the slopes of Mount Ophir and other districts in the Malay Peninsula in association with *Dipteris conjugata* and *Dipteris Lobbiana*, represent a phase of Mesozoic life which survives—

"Like a dim picture of the drowned past."

The fertile fragment of a frond of Matonidium exposed by a stroke of the hammer in a piece of iron-stained limestone picked up on the beach at Haiburn Wyke (a few miles north of Scarborough), is hardly distinguishable from a pinna of the Malayan *Matonia pectinata*. Rhætic and Jurassic ferns referred to the genus Laccopteris afford other examples of the abundance of the Matonineæ in the northern hemisphere during the earlier part of the Mesozoic era.

The modern genus Dipteris, with its four species occurring in India, the Malayan region, Formosa, Fiji, and New Caledonia, stands apart from the great majority of Polypodiaceous ferns, and is now placed in a separate family—the Dipteridinæ. Like Matonia it is essentially an ancient and moribund type with hosts of ancestors included in such Rhætic and Jurassic genera as Dictyophyllum, Camptopteris, and others which must have been among the most conspicuous and vigorous members of the Mesozoic vegetation. The appended table illustrates in a concise form the former extension of the Matonineæ and Dipteridinæ:—

geological history written in the rocks that constitute the Wealden series of Britain exposed in the Sussex cliffs and in the Weald district of south-east England. According to the geologist's reckoning, the Cretaceous period is of comparatively modern date; it occupies a position near the summit of a long succession of ages representing an amount of time beyond the power of imagination to conceive. On the other hand, to quote from Huxley's lecture on a piece of chalk, "not one of the present great physical features of the globe was in existence. . . .Our great mountain-ranges, Pyrenees, Alps, Himalayas, Andes, have all been upheaved since the chalk was deposited, and the Cretaceous sea flowed over the sites of Sinai and Ararat." This Cretaceous epoch, so recent geologically if measured by the standard of the antiquity of the everlasting hills, has a remoteness beyond our power to appreciate.

One interesting fact as regards the composition of the Jurassic Flora is the absence of any plants that can reasonably be identified as Angiosperms. In the Wealden flora of England no vestige of an Angiosperm has been found; this statement holds good also as regards Wealden floras in most other regions of the world. On the other hand, as soon as we ascend to strata of slightly more recent age we are confronted with a new element in the vegetation, which with amazing rapidity assumes the leading *rôle*. It is impossible to say with confidence at what precise period of geological history the Angiosperms appeared. When the rocks that now form the undulating country of the Weald were being accumulated as river-borne sediments on the floor of an estuary, this crowning act in the drama of plant evolution was probably being enacted.

"Nothing," wrote Darwin to Sir Joseph Hooker in 1881, "is more extraordinary in the history of the vegetable kingdom, as it seems to me, than the apparently very sudden or abrupt development of the higher plants. I have sometimes speculated whether there did not exist somewhere during long ages an extremely isolated continent, perhaps near the South Pole." We date the appearance of a new product of evolution from the age of the strata in which it first occurs; but this may well be a misleading criterion: all that we can say is that at a particular period certain new types of organisms are brought within our ken.

To quote Darwin again: "We continually forget how large the world is, compared with the area over which our geological formations have been carefully examined; we forget that groups of species may somewhere have long existed, and have slowly multiplied, before they invaded the ancient archipelagoes of Europe and the United States. We do not make due allowance for the intervals of time

Geographical Distribution of the Matonineae and Dipteridinae.

Matonineæ and Dipteridinæ	Arctic						N. Temperate			N. Sub-tropical				Tropical			S. Sub-tropical			S. Temperate

Dipteris 4 species																×						

Could we but question these survivors from the past, we should hear a tragic story of hopeless struggle against stronger competitors, and learn the history of their gradual migration from an ancient northern home to regions at the other end of the world.

e. *Flowering Plants.*

Our retrospect of the march of plant-life has so far extended to the dawn of the Cretaceous period, a chapter in

which have elapsed between our consecutive formations, longer, perhaps, in many cases than the time required for the accumulation of each formation."

On another occasion Darwin wrote to his friend Hooker: "The rapid development, as far as we can judge, of all the higher plants within recent geological times is an abominable mystery." Such evidence as we possess, meagre as it admittedly is, shows that "this overshadowing type of plant-life" no sooner appeared than it asserted itself

with extraordinary vigour and created a revolution in the plant-world. Let us glance for a moment at the facts to be gleaned from an examination of the records of this critical period in the history of vegetation.

I have already pointed out that we have as yet recognised no Angiosperms in the Wealden floras of England, Spitzbergen, Germany, France, Austria, Belgium, Russia, and Japan; but from plant-bearing rocks of Portugal, regarded as homotaxial with those which British geologists speak of as Wealden, the late Marquis of Saporta named a fragment of a leaf *Alismacites primaevus*, a determination that, while possibly correct, cannot be accepted as conclusive testimony. In Virginia and Maryland there occurs a thick series of strata known as the Potomac formation from which a rich harvest of plant-remains has been obtained. Prof. Lester Ward has recently shown that under this title are included several floras, some of which are undoubtedly homotaxial with the Wealden of Europe, while others represent the vegetation of a later phase of the Cretaceous era. From the older Potomac beds a few leaves have been assigned to Dicotyledons and referred to such genera as Ficophyllum, Myrica, Proteæphyllum, and others. Some of these may well be small fronds of ferns with venation characters like those of the Elk's Horn fern (Platycerium), while others, though presenting a close resemblance to Dicotyledonous leaves, afford insufficient data for accurate generic identification. In dealing with fossil leaves of the dicotyledonous type, we must not forget that the recent genus Gnetum—a gymnosperm of the section Gnetales—possesses leaves that may be said to be indistinguishable in form and venation from those of certain Dicotyledons. Before the close of the Potomac period these few fragmentary relics of possible Dicotyledons are replaced by a comparative abundance of specimens which must be accepted as undoubted Angiosperms. Previous to the discovery of the supposed Angiosperms in Wealden strata of Portugal and North America, the earliest record of an Angiosperm was represented by Heer's *Populus primaeva* from Northern Greenland. This name was applied to a fragmentary specimen which may be a true dicotyledonous leaf. In 1897 Dr. White, of the Geological Survey of the United States, stated that additional examples of dicotyledonous leaves had been obtained during the visit of the Peary Arctic expedition to the well-known locality in Greenland where Heer's *Populus primaeva* was discovered in the so-called Kome series. From strata known as the Atane beds, which rest on the Kome series, unmistakable Angiosperms have been collected in abundance.

Another indication of the sudden increase in the number of dicotyledons is furnished by the Dakota flora of the United States—in age somewhat more recent than the older Potomac beds. In these plant-beds it is stated that Angiosperms constitute two-thirds of the vegetation.

We may sum up the whole matter in a few words. There is some evidence of the existence of Angiosperms before the close of the Wealden period. It may be added that the Stonesfield Slate of England (a formation of approximately the same age as the Inferior Oolite plant-beds of Yorkshire) has afforded a single specimen of a leaf which in form and venation has as much claim to be referred to the dicotyledons as many of the leaves from Wealden rocks. These earliest records are, however, unsatisfactory, and the names assigned to them are often misleading. As soon as we ascend a stage higher in the geological series, not only do the Angiosperms at once become abundant, but the whole facies of the vegetation undergoes a striking change. The Gymnosperms, especially the Cycads, are ousted from a supremacy maintained through countless ages, and the vegetation becomes essentially modern. Many of the earlier angiospermous plants may be referred to existing genera and present no features of special interest from a phylogenetic standpoint.

One of our most pressing needs is a thoroughly critical revision of the late Cretaceous and earlier Tertiary floras, with the object both of determining the systematic position of the older Angiosperms and of mapping out with greater accuracy the geographical distribution of the floras of the world in post-Wealden periods. This is a task which is sometimes said to be impossible or hardly worth the attempt; the available evidence is indeed meagre, and much of it has been treated with more respect than it deserves, but it is at least a praiseworthy aim, not to say a duty, to take stock of our material and to compile lists of plants that may bear the scrutiny of experienced systematists. We are profoundly ignorant of the means by which Nature produced this new creation; we can only emphasise the fact that in the early days of the Cretaceous era a new type was evolved which no sooner appeared than it swept all before it and by its overmastering superiority converted the past into the present.

Conclusion.

In conclusion, I would urge the importance of taking stock of our accumulated facts, and of so recording our observations that they may be safely laid under contribution as aids to broad generalisations. Detailed descriptions and the enumeration of small collections are a necessity, but there is danger of the student neglecting the application of his results to problems of far-reaching import. We may borrow a saying of a great artist in regard to attention to detail—"I see it, but I prefer to construct the synthesis."

There is no more fascinating task than to follow the onward march of the plant-world from one stage to another and to watch the fortunes of the advancing army. We see from time to time war-worn veterans dropping from the ranks and note the constant addition of recruits, some of whom march but a short distance and fall by the way; while others, better equipped, rise to a position of importance.

At long intervals the formation is altered and the constitution of the advancing and increasing host is suddenly changed; familiar leaders are superseded by new-comers who mark their advent by drastic reorganisation. To change the metaphor, we may compare the stages of plant-evolution to the records of changing architectural styles represented in Gothic buildings. The simple Norman arch and massive pier are replaced, with apparent suddenness, by the pointed arch and detached shafts of the thirteenth century; the latter style, which marked an architectural phase characterised by local variations subordinated to a uniformity in essential features, was replaced by one in which simplicity was superseded by elaboration, and new elements were added leading to greater complexity and a modification of plan. Similarly the Palæozoic facies of vegetation passes with almost startling suddenness into that which monopolised the world in the Mesozoic era, and was in turn superseded by the more highly elaborated and less homogeneous vegetation of the Cretaceous and Tertiary periods. In taking a superficial view of architectural styles we are apt to lose sight of the signs of gradual transition by which one period passes into the next; so, too, in our retrospect of the changing scenes which mark the progress of plant-evolution, we easily overlook the introduction of new types and the gradual substitution of new for old. The invention of a new principle in the construction of buildings is soon followed by its wide adoption; new conceptions become stereotyped, and in a comparatively few years the whole style is altered. As a new and successful type of plant-architecture is produced it rapidly comes into prominence and acts as the most potent factor in changing the facies of a flora. Making due allowances for the imperfection of the Geological record, we cannot escape from the conclusion, which is by no means opposed to our ideas of the operation of the laws governing evolutionary forces, that the state of equilibrium in the vegetable kingdom was rudely shaken during two revolutionary periods. The earlier transitional period occurred when Conifers and Cycads became firmly established, while for the second revolution the introduction of the Angiospermous type was mainly responsible. As in the half-effaced documents accessible to the student of architecture "the pedigrees of English Gothic can still be recovered," so also we are able to trace in the registers imprinted on the rocks the genealogies of existing botanical types.

In the course of this address I have given but scant attention to the lessons we have learnt and are still to learn as to the family-history of plants. As Prof. Coulter says: "The most difficult as well as the most fascinating problem in connection with any group is its phylogeny. The data upon which we base opinions concerning phylogeny are never sufficient, but such opinions usually stimulate research and are necessary to progress."

We who attempt to read the records of the rocks may be tempted to magnify the importance of the work, but I do not hesitate to add that botanists as a whole have but half realised the fact that the study of living plants alone supplies but a portion of the evidence bearing on problems of plant-evolution. To ignore the facts that may be gleaned from the investigation of extinct types is like attempting to draw up a genealogy by merely questioning an individual without consulting the documentary evidence of registers and other chronicles.

Each successive stage through which the organic world has passed contains some relics of a preceding age; in comparing the chalk with the calcareous ooze now accumulating on the bed of the Atlantic, Carpenter expressed the partial agreement between the two deposits by saying that we are still living in the Cretaceous period. Dr. Moore's recent researches, demonstrating a striking resemblance between many of the molluscs of Lake Tanganyika and fossils preserved in the sediments of Jurassic seas, led him to describe some constituents of the fauna of this inland lake as so many "lingering shadows of the past," while Tanganyika itself is a dwindled remnant of a Mesozoic sea. Similarly our modern vegetation differs enormously from that of the Mesozoic era, yet in the sago-palms of the Tropics and in species of Malayan ferns we recognise proofs of the continuity of plant-types through successive ages. One stage is superseded by another, but some characteristic elements of each period persist into the next, carrying on the traditions of the past and demonstrating the futility of our system of classification, a system in which we express the limitations of our knowledge, as we suit our convenience, by dividing into periods the history of geological and organic evolution.

"It is only our ignorance that fixes a limit, as the mist gathered round the mountain's brow makes us fancy we are treading the edge of the universe."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

In connection with the Technical Education Board of the London County Council, a course of ten free lectures to teachers on "Animal Life in a Freshwater Aquarium" will be given by Dr. A. C. Haddon, F.R.S., at the Horniman Museum on Saturday mornings, at 11.30, from October 10 to December 12. Tickets of admission may be obtained from the Clerk of the London County Council, County Hall, Spring Gardens, S.W.

A course of eight lectures on "The Relation of the Composition of the Plant to the Soil in which it Grows" will be given at the Chelsea Physic Garden by Mr. A. D. Hall (director of the Rothamsted Experimental Station) on Tuesdays from October 13 to December 8, in connection with the University of London. The lectures are addressed to advanced students. Two courses of lectures on advanced physiology will be given at the university during the present session. Commencing on October 16, Dr. F. W. Mott, F.R.S., will lecture on "The Structure and Function of the Cerebral Cortex," and on October 20 Dr. Buckmaster will lecture on "The Blood." On October 13 Dr. A. D. Waller will lecture on "The Anæsthetic Action of Chloroform and Ether." Admission to the lectures is by ticket, to be obtained from the Academic Registrar.

The Act of Parliament under which the University College of Liverpool, hitherto associated with Owens College, Manchester, and Yorkshire College, Leeds, in Victoria University, begins its independent existence as the University of Liverpool, came into operation on October 1. This charter, which was obtained last July, provides that all the courses shall be open to women. Lord Derby is the first Chancellor and Principal Dale the Vice-Chancellor, and the university possesses a strong staff. Chairs have recently been endowed in tropical medicine, bio-chemistry, and electrotechnics, besides additions to other teaching resources. It is anticipated that the existence of the new university will greatly stimulate the work in the secondary a well as other schools.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 28.—M. Albert Gaudry in the chair.—The myelocytes of the olfactory bulb, by M. Johannes **Chatin**.—Remarks by M. Alfred **Picard** on the "Rapport général administratif et technique sur l'Exposition universelle internationale de 1900."—On a combination of aluminium sulphate with sulphuric acid, by M. E. **Baud**. By the action of sulphuric acid upon bauxite, aluminium hydrate, or aluminium sulphate, a compound possessing the composition $Al_2O_3.4SO_3.4H_2O$ is formed, which dissolves very slowly in cold water. It is analogous to the ferrisulphuric acid of M. Recoura.—On the nitrosite of pulegone, by M. P. **Genvresse**. Pulegone, dissolved in petroleum ether, and saturated with either nitrogen peroxide or nitrous fumes from starch and nitric acid, gives a nitrosite, $C_{10}H_{16}.N_2O_3$, the properties of which are described.—On the production of sulphuretted hydrogen by extracts of organs and albumenoid materials in general, by M. Emm. **Pozzi-Escot**. Yeast extract, treated with sulphur, gives rise to a considerable quantity of sulphuretted hydrogen; if the extract is boiled for a short time before adding sulphur, no sulphuretted hydrogen is evolved. From this it is concluded that the reaction is of a diastatic nature. —On the phagocytic resorption of unutilised genital products in *Echinocardium cordatum*, by MM. Maurice **Caullery** and Michel **Siedlecki**.—On the formation of the egg and the multiplication of an antipode in Juncus and Luzula, by M. Marcellin **Laurent**.—The morphological variation in the leaves of the vine following grafting, by M. A. **Jurie**. The experiments described show the great variability of certain morphological characters in the leaf of the vine under the influence of grafting.—On the relations between the structure of the French and Swiss Alps, by M. **Kilian**.

EGYPTIAN GEOLOGY.

Topography and Geology of the Eastern Desert of Egypt (Central Portion). By T. Barron, A.R.C.S., F.G.S., and W. F. Hume, D.Sc., A.R.S.M., F.G.S. Geological Survey Report. Pp. viii + 331. (Cairo: National Printing Department, 1902.)

THE work before us is the largest instalment yet published of the results of the explorations which have been carried on with such success by the Egyptian Geological Survey, under the able and energetic direction of Captain Lyons. The district now described was actually surveyed in the years 1897 and 1898, but there appear to have been many delays in arranging for the publication—the time of the authors being taken up by fresh work undertaken in widely distant regions. At the geological congress held in Paris in 1900, however, the two authors of the memoir were permitted to lay some of the chief results obtained from the study of this region before the geologists who had assembled there, and abstracts of their papers have appeared in the *Geological Magazine* for 1901; but the publication of this large and well-illustrated memoir has long been eagerly anticipated, and its appearance will be everywhere welcomed as a most valuable addition to the scientific literature of the district.

The authors must be congratulated upon the excellent use they have made of the vast mass of literature dealing with the geology of the area. In an appendix they have given an admirable abstract of the results obtained by De Rosière, Wilkinson, Schweinfurth, Klunzinger, Walther, and many other travellers, who have by their writings added to our knowledge of this very interesting region. The work of the geological surveyors—a very important one—has been that of correlating and correcting these various sources of information and of supplying, by actual observations in the field, the links necessary to combine the whole into a connected monograph dealing both with the topography and geology of the district.

Like the work carried on in the western territories of North America by the United States Geological Survey, the work in the Egyptian deserts has to be a combination of a geological and a topographical survey. Each working party had to consist of a geologist and a topographer, with a small caravan consisting of eleven Arabs and fifteen camels. The topographical work was done by using a measuring wheel for determining a base line, and working from this with plane-table and theodolite, frequent observations for latitude being made to correct the results; the heights were determined by the aneroid in most instances, but in important cases hypsometer and theodolite determinations were made also. The chief difficulties experienced in the topographical work—apart from those arising from traversing waterless districts—were caused by the mirage and by the frequent presence of great masses of magnetic rock.

While the topographers were engaged in making the map as complete as possible, the geologists were busy examining and recording the interesting features exhibited by the various rock-masses encountered in the different traverses. The district described includes the famous porphyry quarries of Djebel Dokhan, and the ancient upraised coral reefs and their modern representatives on the shores of the Red Sea—some of these reefs being of especial interest, owing to the partial dolomitisation which they have undergone.

The first 115 pages of the volume (which extends to 331 pages) are occupied by an account of the topography of the Red-Sea Hills, and in this part of the work there is much matter of archæological interest in the account of the numerous remains of Roman buildings, and of ancient quarrying and mining works. A very excellent account is also given of the meteorology and of the botany and zoology of the district.

The description of the geology which occupies the second and larger half of the volume deals with the Pleistocene gravels, old beaches, and raised coral reefs, the Pliocene gravels, conglomerates and limestones, the Miocene and Eocene limestones, marls, &c., the Cretaceous limestones, and the "Nubian Sandstone," which in this particular district appears to be in no part older than the Cretaceous. The sedimentary rocks of the district are about 2000 feet in thickness, and cover unconformably the metamorphic and associated igneous rocks. The latter consist of quartz-diorites or grey granites which are younger than and invade the metamorphic rocks, and are themselves intruded into by masses of red granite, with, probably associated, dykes of quartz-felsite and dolerite. These rocks with veins of diabase which intersect them have all been planed down by denudation before the deposition of the sedimentaries. The only later igneous rocks are the andesites which have been intruded into the Eocene limestones, and have produced contact metamorphism in them, and certain igneous gravels and conglomerates which unconformably overlie the sandy limestones of Pliocene age.

The volume is admirably illustrated. Besides the general topographical map of the district and the same geologically coloured, there are five geological maps of areas of special interest. There are also four plates containing coloured panoramas, which give an excellent idea of the relations of the various igneous and other rock masses in this region; and the geological structure of the district is further illustrated by eleven plates of longitudinal sections. The general aspects of this, it must be confessed, rather uninviting region are shown by nine beautiful photogravures by Dr. E. Albert and Co., of Munich, from photographs taken by the authors, while three plates and six photographs are devoted to objects of archæological and general interest.

The important palæontological researches of Beadnell and Andrews have attracted the attention of all geologists to the important work which is being accomplished by the Geological Survey of the Egyptian Government, and the present work will serve to show that every branch of geological science is receiving

due attention from the officers of that survey. It is well known that important explorations have been carried on in other portions of the vast territories now under the rule of the Khedive, and it may be hoped, in the interests of science, that these results may be published with less delay than those we have now been noticing. J. W. J.

EXPERIMENTS ON HUMAN MONSTERS.

Essai sur la Psycho-physiologie des Monstres Humains. By N. Vaschide and Cl. Vurpas. Pp. 294. (Paris: F. R. de Rudeval, n.d.) Price 5 francs.

THE substance of two-thirds of this book has already appeared in various scientific and medical journals. The last ninety-four pages are devoted to the researches of other workers in the same field. The first of the two monsters examined by the authors was an anencephalous male child, which was continuously under observation during the thirty-nine hours of its extra-uterine life. An examination *post mortem* revealed the complete absence of cerebral hemispheres, cerebellum, pons, restiform body, inferior and accessory olives, and pyramidal tract. The monster's apparent lack of taste and smell is devoid of theoretical interest, as the authors omit to mention whether the trigeminal and olfactory nerves were developed. Certainly they failed to find traces of the third and fourth cranial nerves, coincident with the lack of which the infant presented exophthalmos, external squint, dilatation of the pupil, absence of the pupil-reflex, and ptosis. The cerebral hemispheres were replaced by a protruding cystic tumour; throughout the brain and cord the ependyma, neuroglia and ventricles were much hypertrophied, and atrophied degenerated nerve-cells were met with, especially in the cranial region, together with much vascular engorgement and diapedesis. In order to explain the yet healthy state of the retinæ and optic nerves, the authors conclude that the cerebral hemispheres at first developed normally, and were only later affected by "an inflammatory process of an infectious nature," which produced the anencephaly and other abnormalities. But the authors' interpretation of their histological investigations is far from convincing. It is hardly a matter for surprise to find hæmorrhages and wandering leucocytes in the profoundly disturbed nervous system of a cold, moribund, cyanotic creature that breathed only about eight times a minute, and then with a well-marked Cheyne-Stokes rhythm. Moreover, some secondary degeneration may have followed from the complete absence of the pyramidal tract. The authors allude to an insufficiency of myelinisation and to the abnormal proportions between white and grey matter. But these statements, and the rather indifferent plates and illustrations upon which they are founded, would have carried greater conviction, were it certain that the authors (of whom one is an experimental psychologist and the other a hospital resident physician) are perfectly familiar with the corresponding appearances in a healthy newly-born babe.

On pp. 47 and 48 we read:—

> "It seems that a class of psychic phenomena, which hitherto have been attributed exclusively to the cerebral hemispheres, such as the special sensibility to touch, pain, and warmth . . . existed in our anencephalous subject independently of the action of the brain."

In point of fact, the reflex movements experimentally obtained by tactual, painful, and thermal stimuli, likewise the abortive attempts of the subject to swallow, its cries and convulsive seizures, one and all are just what might have been expected from a "decerebrate" vertebrate; they are quite void of "psychic" significance in the ordinary meaning of the term, and throw no fresh light on the subject whatever. Surely the presence of these reflex actions, and the integrity of the nerve-trunks, might have led the authors to suspect that nerve-cell degeneration had been neither as extensive nor as intense as they had imagined. But, on the contrary, they incline (p. 76) "to the opinion of certain authors who see in the cell a centre having a function purely trophic and in no way motor," and further urge (p. 75) the impossible view that the infant's (very doubtful) manifestations of spontaneous activity "seem to show that the pyramidal tract has a *rôle* essentially inhibitory instead of dynamogenic." The authors might to their advantage have kept in mind the words of their own preface (p. 16):—

> "Nous avons laissé à dessein de côté dans nos travaux et recherches les hypothèses, . . . en nous imposant de ne pas sortir du cadre de l'expérience et des données précises."

The subject of the second far more satisfactory study was a "xiphopage," as the authors call it, in other words, an example of Siamese twins. It was composed of two perfectly formed Chinese boys, fifteen years old, of whom the right was called Liao Toun Chen and the left Liao Sienne Chen. They were united in the region of the xiphoid part of the sternum by a somewhat extensible bridge of tissue which contained cartilage, blood vessels, and very probably a remnant of hepatic substance. This bridge revealed a narrow median anæsthetic zone, surrounded on either side by a hypoæsthetic zone, cutaneous stimulation of which affected only that individual to whom the stimulated area was nearest, but never both individuals. It is, however, difficult to reconcile this interesting observation with another, viz. that if the points of Weber's compasses were separated by 15mm., and the compasses placed astride the median anæsthetic zone, so that one point rested on an area felt by one subject, and the other on an area felt by the other subject, then each child perceived that he was touched in two points. The characteristics of the two children were very different. Liao Toun Chen was mentally and physically more vigorous than his brother. He was more curious and roguish, while Liao Sienne Chen was more attentive and serious. The latter, as we should expect, gave shorter and more trustworthy reaction-times. His sensibility to stimuli was also keener. His body-temperature and his arterial pressure were higher than those of his stronger brother, who in turn breathed with greater rapidity, and had a more frequent pulse. Save in

violent emotion, the respirations of the two brothers were never isochronous, but in opposite phases. Owing to congenital association, these differences of character were found to be harmonised, as might be anticipated, in action. Quarrels were rare; Liao Sienne Chen meekly followed his better half. They had from their birth eaten and performed other functions simultaneously. In waking, however, one recovered consciousness before the other, and roused him. It was found possible for one of the brothers to sleep while the other kept awake. But does this in reality, as the authors affirm (p. 175), "speak singularly against a chemical theory of sleep which makes it appear under the influence of toxic products"?

C. S. MYERS.

OUR BOOK SHELF.

Electrolytic Preparations. By Dr. Karl Elbs, translated by R. S. Hutton, M.Sc. Pp. xi + 100. (London: Edward Arnold, 1903.) Price 4s. 6d. net.

ELECTROCHEMICAL methods are now becoming of such importance, and are being so largely employed both in the laboratory and in technical processes, that the translation of Dr. Elbs's little work on electrolytic preparations—"Exercises for use in the laboratory by chemists and electrochemists"—will be sure to be welcomed by English-speaking students.

The book is divided into two parts. Part i., which is general, deals with sources of current and connections, resistances, apparatus for electrolysis, &c. Dr. Elbs considers that accumulators can alone be looked upon as a source of current for laboratory purposes, and he gives some useful hints as to coupling up and how to use the cells.

Several pages are devoted to apparatus for electrolysis. As kathode material almost any metal may be employed, unless the electrolyte is very strongly acid. But for anodes, nearly all metals, with the exception of platinum, are attacked. Lead may often be used owing to its becoming coated with a superficial layer of peroxide which prevents further action taking place.

Part ii. is devoted to the experimental portion of the work. The examples from inorganic chemistry which come first are divided into two parts. The first deals with experiments with unattackable anodes, the second portion with soluble anodes. Under the first heading are given the methods of preparation of such substances as chlorates, bromates and iodates, and persulphates, under the second heading the preparation of white lead, cuprous and cupric oxide.

On p. 47 the student is introduced to the electrolysis of organic acids. This part is well arranged, and the theoretical principles are carefully and clearly gone into. A detailed explanation is given of the various reactions which may occur in the electrolysis of organic acids. Here there seems to be a field for further research, because although many of the explanations given probably approximately explain what actually does occur, others seem hardly conclusive, so that at any rate further light upon the subject would be welcome.

No less than eighteen examples of electrolytic reduction are given, while there are only two on electrolytic oxidation. This is mainly due to the fact that reduction work, generally speaking, is much easier to carry out than work on oxidation. This applies both to pure chemistry and to electrochemistry. Further, electrochemical methods of oxidation have not been tried by chemists to anything like the same extent as have reduction methods.

The book is very well printed and got up, and Mr. Hutton has done his part—the translation of the work—very satisfactorily.

F. M. P.

A Concise Handbook of Garden Flowers. By H. M. Batson. Pp. vii + 256. (London: Methuen and Co., 1903.) Price 3s. 6d.

THIS is an alphabetical list of a large number of ordinary garden plants, together with brief indications of height, colour of flowers, native country, natural order, season of flowering, mode of propagation, and purpose for which they may be used in the garden. Within its rather restricted limitations the book seems carefully compiled, and the proofs have evidently been read with attention, for abundant as are the opportunities for falling into error, misprints are hardly to be found. The word "family" is, however, used in many cases where "genus" should be employed; thus the Galegas are styled a hardy family. Of course, Galega is a genus of the family Leguminosæ. An even more misleading statement is that in which *Narcissus Barrii* is spoken of as "a family of star-narcissus," whatever that may be.

The cultural details, though very concise, are apparently trustworthy, but there is ample room for difference of opinion about these matters. Thus the author says of *Gentiana acaulis* that "it is easy of culture." It may be so in places, but after a long experience with it under varying conditions, but in one particular garden, we have never been successful in getting it to flower, whilst in another we have experienced no difficulty. The author has succeeded in finding English names for most, if not all, of the plants he mentions. If such names are to be given, they should be employed with as much precision as the technical appellations. To call *Narcissus poeticus* the "poet's daffodil," or *Narcissus Tazetta* "the polyanthus flowered daffodil," is surely to introduce confusion where none need be experienced. A full index is added, which adds greatly to the convenience of the reader. We should like to suggest to the author that, in a future edition, he should enumerate the names of the genera in alphabetical order under the heading of the natural order to which they belong. Search for the name of a plant would by such means be much facilitated, as most lovers of plants are familiar at least with the principal natural orders.

Lavori marittimi ed Impianti portuali. By Flavio Bastiani. Pp. xxiv+424. (Milan: Ulrico Hoepli, 1903.) Price 6.50 lire.

THIS is one of the "Manueli Hoepli," a series of pocket books in which the Italian "man in the street" can, at a small cost, obtain information on such diverse subjects as elliptic functions, Volapük, botany, oils and olives, Greek mythology, and English weights and measures. The present volume deals with the construction and working of docks, harbours, wharves, canals, lighthouses, in short all fixed structures connected with navigation. It is illustrated by 209 woodcuts, and the last part contains a summary of Italian laws relating to harbours, harbour dues, and such matters.

Il Moto degli Ioni nelle Scariche elettriche. By Augusto Righi. Pp. 66; with 3 plates and several woodcuts. (Bologna: Nicola Zanichelli, 1903.)

THIS book contains, with some amplifications, an almost verbatim report of a lecture delivered by Prof. Righi to a branch of the Italian Electrotechnical Society at Bologna. It deals with the theory of electrons, considered with special reference to kathodic rays, ionisation of gases, Lorentz's theory, and the production of electric shadows.

LETTERS TO THE EDITOR.

Radium and the Sun's Heat.

IN your last week's issue Mr. Hardy directs attention to the fact that no Becquerel rays can be detected from the sun, and regards this as an objection to the view that the solar heat may be accounted for by the presence of radium.

Let us attempt to calculate the effect to be expected if the sun's heat were due to this cause.

In doing this, we may assume that the sun contains 3·6 grams of radium per cubic metre. This was the amount which Mr. W. E. Wilson gave in NATURE of July 9 as required to emit the observed amount of heat. Experiment shows that when the Becquerel radiation has to pass through lead screens of thickness 1 cm. or more, the radiation transmitted is practically all of the γ variety. This is cut down to half its value by 8 cm. of aluminium, and in the case of other substances by strata of equal mass per unit area. Now the earth's atmosphere constitutes a stratum far more absorbent than 1 cm. of lead. We need, therefore, only consider the γ rays, for if these cannot be detected, it is certain that the α and β rays cannot.

For the sake of simplicity of calculation, we shall treat the sun as a cube, with its side equal to the diameter of the real sun; and so placed that the normal to one face, which passes through the centre, shall also pass through the earth. This will be for all practical purposes near enough to the truth.

Let a be the side of the cube, q the quantity of radium per c.c., and λ the coefficient of absorption of the radiation. Then, from an elementary slice, thickness dx, and distance x from the face, the intensity of radiation at a distant point will be

$$a^2qe^{-\lambda x}dx$$

if the radiation due to 1 gram of pure radium at the same (great) distance be taken as unity.

The radiation due to the entire mass will be

$$a^2q\int_0^a e^{-\lambda x}\,dx=a^2q\left[\frac{-e^{-\lambda x}}{\lambda}\right]_0^a=\frac{a^2q}{\lambda}\left(1-e^{-\lambda a}\right)$$

Now $a=1\cdot4\times10^{11}$ cm.; q, from Mr. Wilson's estimate $=3\cdot6\times10^{-6}$.

Assuming that the coefficient of absorption is proportional to the density, and taking the sun's density as 1/7, and the value of λ for aluminium as 0·086, the value of λ for the sun comes out 0·0046. Substituting these values, we find that the effect of the sun is equivalent to that of $1\cdot53\times10^{19}$ grs. of radium at the same distance, assuming this radium to be spread out into a thin layer, so that all the radiation can escape without undergoing absorption in the mass.

Now I have found that the γ radiation from 10 milligrams of radium bromide can barely be detected by the electrical method, where 10 cm. of lead intervene between it and the testing vessel. To decide whether the solar rays would be detectable, we must compare their expected effect after enfeeblement by distance, and by the absorption of the atmosphere, with this.

The distance of the sun is 1.5×10^{12} times greater than the distance of the radium from the testing apparatus, so that, apart from the atmospheric absorption, the effect of the sun would be equivalent to that of $\frac{1.5\times10^{19}}{(1\cdot5)^2\times10^{24}}$, or $6\cdot7\times10^{-6}$ grams of radium, 10 cm. from the apparatus. This is less than one-thousandth part of the radium used in the experiment cited, and the solar radiation, instead of passing through only 10 cm. of lead, would have to pass through the atmosphere, equal in mass to 32 feet of water, or about 89 cm. of lead. This would, of course, reduce it many million times further. So that, even if all the sun's heat were due to radium, there does not appear to be the smallest possibility that the Becquerel radiation from it could ever be detected at the earth's surface.

R. J. STRUTT.

REFERRING to Mr. Hardy's experiment described in his letter in NATURE, October 8, it is easy to show that whatever the intensity of radio-activity might be at the surface of the sun, by mere surface ratios and assuming no absorption its activity per unit area at the distance of the earth must fall to about one forty-thousandth part. Now, if the sun were composed of solid radium bromide, the radiation reaching Mr. Hardy's indicator from the sun will be only about one-thousandth part of that derived from a sphere of radium bromide three millimetres in diameter and twenty millimetres distant from the indicator: the probable conditions of Mr. Hardy's experiment.

In the experiment one centimetre thickness of lead is interposed. The earth's atmosphere is equivalent in mass to 76 cm. of mercury. This supposes no absorption from, possibly, some thousands of miles of solar atmosphere. Moreover, we assume in the comparison a sun of solid radium bromide. It would appear, however, that a very small percentage of this body in the materials of the sun would suffice to account for many millions of years of solar heat.

The absence of β and γ radiations at the earth's surface is, therefore, not a weighty argument against the presence of radium in the sun.

The arguments in favour of supposing that this element exists in the sun are:—(1) The presence of radium on the earth; (2) the high atomic weight of radium; (3) the presence of helium in the sun; (4) Arrhenius's theory of the Aurora Borealis; (5) the fact that the estimate of the duration of solar heat from the dynamical source appears to run counter to geological data.

J. JOLY.

Trinity College, Dublin, October 10.

Cambridge in the Old World and in the New.

ONE of the most striking features of the universities of the United States is the wealth of their endowment. During the writer's visit to Cambridge, Massachusetts, for example, Harvard University was successfully collecting large sums towards a new building for philosophy in memory of Emerson, and within the last few months has been promised two million dollars by two millionaires towards her new medical school.

Reasons for such well-known munificence of Americans towards their universities are not hard to find. Pauperism is an almost negligible quantity in America, so that the money, which drains away on this side in charity, finds an outlet there in the advancement of education and research. Primogeniture, again, is contrary to American ideals. While the newly-made English millionaire thinks it his duty to sink a considerable part of his fortune in buying and maintaining a family estate for his son and heir, the American more often divides his property equally between his children, and feels at greater liberty to dispose of much of it in his lifetime as he pleases, for he is willing that the uphill life he has lived himself shall be lived again by his descendants. The absence of inherited titles in America tends, of course, towards the same end. Many of the younger universities, too, are in districts where huge fortunes have been rapidly made and civic pride runs high, producing numerous benefactions in the cause of local institutions. But although all these are reasons, none of them is sufficient to explain the situation satisfactorily. To find the true cause, we must enter into the differences in life and education between the older English and American universities.

The average English youth, passing from public school to Oxford or Cambridge, intends to make his living by some profession, perhaps as minister, teacher, barrister, or physician; relatively seldom has he sufficient to live upon without further exertion. He spends his three or four years in one of the seventeen or more colleges from which he has to choose, and his college becomes the centre of his social life. Probably there he makes his greatest friendships; certainly the number of men he knows outside his own college is comparatively small. In eights, elevens, or fifteens, the various colleges are pitted against one another. Nor, indeed, is inter-collegiate competition confined to athletics. Each college is continually struggling against the rest to secure the most promising boys from the public schools, and to acquire the greatest number of university distinctions. Each has to maintain a more or less separate

staff, partly to supplement university lectures, but partly also to give more individual instruction to the duller or idler students. One of the results of this system can be easily seen—the average graduate quits his university with the greatest affection for his college, but with little or nothing of that broader *esprit de corps* towards his university as a whole.

In America, on the other hand, each university has only one college preparing him for the B.A. degree. Consequently, a single American college, *e.g.* Harvard College, Cambridge, contains several thousand students.[1] The centre of social life can no longer be in the college; it is transferred to the class, the class consisting of all students who are in the same year. Each class elects its own president and other officers, has its various rowing, football, and baseball teams, and holds meetings for the discussion of matters of common interest. A class in Cambridge, Massachusetts, knits the students together in somewhat the same way as does a college in Cambridge, England, although, of course, far less closely.

In the second place, there is a comparatively large number of students in American universities, who intend to lead, or finally do lead, a business life after they leave college. It is true that just now the question is being raised whether a college training is the right one for an American business man, but the only probable outcome of this discussion will be an improved adjustment of the college curriculum in the interests of those who intend to embark on a business career. Already at Harvard there is a proposal on the part of the president to make it possible for such students to complete their training in a shorter time than the usual four years.

In the end these two American features, the formation of class ties and the presence of students who are intended for a business career, combine to place a number of wealthy *alumni* at the beck and call of the universities. It is a common occurrence for the class of a certain year to defray, wholly or in part, the cost of a building of which their *alma mater* stands in need; at Cornell alone twenty-two class-gifts of this or similar kind are on record. Moreover, the *alumni* of the various universities form themselves into societies, both local and general. Every important city in America contains various associations of *alumni*, each association representing one of the more important universities. The *alumni* of various classes, dispersed throughout the States, are periodically invited to revisit their university. In some universities they directly elect a certain number of their body to serve on the board of trustees or corporation of the university. Such is the hold exercised by many American universities on their former students.

But it is not only from wealthy *alumni*, but also from citizens who have never been to college, that the universities of the United States derive their greatest benefactions. Now this would be impossible unless the American people were in full sympathy with American university work. Indeed, the university holds as warm a place in the heart of the American as the hospital holds in that of the Englishman. He feels that it is a living organisation, not an inert out-of-date machine, which is doing necessary work in the advancement of the civilisation of his country. Further, we come to understand the reason of this feeling when we contrast the undergraduate courses at the two Cambridges. At Harvard, the examination for admission consists of papers in English, history, algebra, geometry, and natural science, Latin *or* Greek, and French *or* German. After passing this, the student has to choose four courses of lectures per year in *more than one* of the following subjects:—English, German, French, Italian, Spanish, history, government, economics, philosophy, fine arts, music, mathematics, engineering, or some natural science. Apart from certain reasonable restrictions, which prevent him from acquiring a too superficial knowledge in too many subjects, the student is at liberty to select just those courses which will best suit him in after life; and, of course, he can readily obtain advice in any difficulties that may beset him when making his choice. In his second and later years he may specialise more deeply in these and other subjects. He is examined twice a year, and shows thereby whether he is capable of proceeding to more advanced courses advantageously. He obtains his degree on the result of these bi-annual examinations. For an honours degree a thesis or special examination is required.

[1] The words college and university have thus acquired a significance in America which is unfamiliar to us. No college is regarded as a university unless, besides teaching, it encourages post-graduate research.

The undergraduate of our English Cambridge, on the other hand, having mastered at school the modicum of compulsory Greek required for the previous examination, has the choice of two distinct paths. He can straightway read for an honours degree in any *one* of the triposes which suits his requirements, the classical, mathematical, theological, natural sciences, mental and moral sciences, mechanical sciences, mediæval and modern languages, oriental languages, historical or other tripos—in which case he takes his degree almost always upon the results of a single examination in a single tripos at the end of his three years[1]; or he may be content to take an ordinary degree, for which he must devote at least the whole of his first year to Greek, Latin, English, algebra, statics, hydrostatics and heat, and spend his later years preparing for examination in any *one* subject (*inter alia*) of the following:—theology, economics, law, history, logic, mathematics, classics, music, chemistry, physics, botany, physiology, zoology, or agriculture. This examination, qualifying him for the ordinary B.A. degree, is completed at the end of his third year.

Few graduates who have been educated on the basis of a Cambridge tripos would welcome changes in so admirably conceived a system of education. At one time it was believed that the student who devoted his three or four years in this manner to a single subject must suffer in general culture, whereas it is nearer the truth to believe that there is scarcely any branch of learning which cannot impart a very high degree of culture, provided only that it be taught from a sufficiently wide and liberal point of view. On the other hand, there are probably few who would not desire considerable changes in the regulations for the ordinary degree. The examination is hardly more than an advanced Little-go, ending in a feeble effort at specialisation. Instead of having to spend a year or more at Greek, hydrostatics, heat, &c., why should it not be possible for the undergraduate who is bent on an army career to qualify in modern or oriental languages, geography, surveying, and ethnology, or for him who intends to enter into finance to study mercantile law, economics, and modern languages, or for the future country squire to read straightway in history, literature, law, and agriculture? Is a university to confine herself solely to the encouragement of research and to the preparation of ministers, teachers, physicians, engineers, and musicians? Or is it impossible to prepare men for other walks of life without the sacrifice of culture in the interest of practical needs? Surely America gives us a useful lesson as to the unwisdom of driving away such embryo financiers and others elsewhere owing to the lack of attractive and useful courses of study which they could pursue after leaving school. The expenses of administration in our universities increase so enormously from year to year that, unless they are to receive State aid or to decay from sheer stagnation, they must be continually appealing to the public for support. And public interest can only be maintained when the universities are prepared to equip men appropriately for many more different walks in life than they are at present. Such changes, which involve merely the framing of new regulations, cannot fail to be followed by an increase in benefactions, whereby training in languages, archæology, history, and economics may be improved, and the teaching and laboratories be alike brought to the requisite condition of efficiency for establishing a successful school of post-graduate research.

C. S. MYERS.

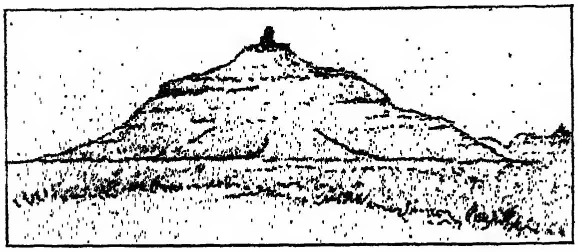
Gonville and Caius College, Cambridge.

[1] No mention is here made of the still more specialised second part of the triposes which corresponds in many respects to the training given in the post-graduate schools of the better American universities.

An Ancient Lava Plug like that of Mont Pelée.

THE photograph of what is described as "a gigantic plug of solidified lava" in the centre of the new cone of Mont Pelée, which appears in NATURE of October 1 (p. 530),

reminds me of similar columns of ancient lava not uncommon among the trap rocks of the Deccan, and I enclose a copy of a sketch I made of one of these in 1839, the re-



markable similarity of which to the column on Mont Pelée seems to be worthy of notice. A second similar column is seen in the distance on the right. RICHARD STRACHEY.

69 Lancaster Gate, W.

"Lessons on Country Life."

IN your issue of September 24 you published a review of "Lessons on Country Life," by Messrs. Buchanan and Gregory, but may I ask, with all deference, if your reviewer has not omitted to read an important part of this useful little book? He refers to Mr. Buchanan's earlier works, "Country Readers," Nos. 1 and 2, as "most excellent books for children," but had he read the *preface* to the "Lessons" he would have found that these were intended, not for children, but for teachers. Your reviewer truly says:—"Country life is a vast subject, so vast that no child can learn during his school life even a fraction of the information it may be desirable he should possess," and the same remark may be equally well applied to teachers. This book travels over much the same ground as "Reader" No. 1, but the matter is differently treated. In one case simplicity of language is aimed at, in the other the information is condensed, with a view, as it appears to me, of leaving it to the discretion of individual teachers to use such lessons, or portions of each lesson, as are most suitable to their own districts.

I do not wish wrongly to attribute ideas to the joint authors, but I fancy their intention is to put before rural teachers (many of whom have had little or no country training) as complete a summary as possible, taking it for granted that they would be able to pick out and study the essential parts.

This series of agricultural Readers and Lessons will, I think, do much to create a love of country life, may even help to counteract the attractions of town life. Rural depopulation is one of the most serious problems of the day, and if these books will assist, in only a small way, to arrest this migration, I feel sure you will not detract from their value by a few words which were probably due to a pardonable oversight.

A. H. H. MATTHEWS, Secretary.

Central Chamber of Agriculture, Broad Sanctuary Chambers, 20 Tothill Street, Westminster, S.W., September 30.

MR. MATTHEWS has hardly grasped the point of our notice—that Messrs. Buchanan and Gregory's book approaches the subject in the wrong spirit. The teacher is provided with a mass of indifferently selected information about farming matters, which he will pass on to his class instead of trying to lead it to observe and reason on its own account. The latter process is more difficult, but it happens to be education. We have of late had only too many occasions to deplore the "rural teachers with little or no country training," who hand out "condensed information" from little books about the country. It is this kind of instruction which offends both farmers and educationists, and if Mr. Matthews imagines it is going to counteract the attractions of town life and arrest rural depopulation, we can only hope that on this occasion he does not represent the opinion of the Central Chamber of Agriculture. THE REVIEWER.

CRATER LAKE IN OREGON.[1]

TWENTY years ago, as Mr. Diller informs us, this picturesque record of a strange episode in volcanic history was unknown to any but the Indians. It is still not very accessible, for it lies in an unfrequented region, deep set in the summit of the Cascade Range, some sixty-five miles north of the California line, but the United States Government, "recognising its worth as an educational feature," has already wisely secured it from the speculator and spoiler by making it a national park. An area of two hundred and fifty square miles is thus protected, of which we find a description in the present memoir. The first part, by Mr. Diller, deals with the geology and physical history of the great volcano, named after a local society Mount Mazama, which was shattered to form Crater Lake, and the second, by Mr. Patton, discusses the petrography of its rocks. It was virtually discovered by Captain Dutton, by whom and by Mr. Diller it has already been noticed; the U.S. Geological Survey has also published a special map, but the story is now completed in this excellently illustrated memoir.

The Cascade Range is largely, if not wholly, built up of volcanic material. In Cretaceous times it had no existence, "there flowed the sea"; this retreated during the Eocene, when vents opened in the Coast Range region, possibly also, though that is not yet quite certain, on the site of the Cascade. Here, however, volcanoes were in full activity during the Miocene, and built up a large part of the Range, where eruptions have continued almost to the present time. Post-Glacial outbursts occurred in some places, but seem to have ceased before history began, though hot springs and fumaroles show that the subterranean hearths are not yet cold. Some of the peaks rise above 10,000 feet, Mount Rainier even attaining 14,525 feet, and the surface of Crater Lake is rather more than 6200 feet above sea-level. It is an oval basin between twenty and twenty-one square miles in area, surrounded by cliffs which range from more than 500 to nearly 2000 feet in height, the ground falling more gradually from their rim to the present upland level. This great sheet of blue water, in places almost 2000 feet deep, is interrupted near its western margin by a pyramidal rocky mass, called Wizard Island, itself evidently a volcanic vent, and a study of the enclosing walls of the great caldera proves them to be built up in the usual way by ash-beds and lava-flows, dipping outwards from its axis, and riven by occasional dykes. The exterior slopes are dotted by parasitic cones, and exhibit occasionally moraines and Glacial striæ; they are also furrowed by valleys, which in some cases run up to and actually notch the edge of the cone, so that they evidently cannot have been formed on Mount Mazama as it now exists. They, like it, have been truncated, and the bowl occupied by Crater Lake has been formed by the destruction of a volcanic cone which must once have risen some six thousand feet above its present rim. Of this there can be no doubt; it is substantiated by numerous facts cited in this memoir, and we have only to study the geological map which it contains to see that the present lava streams are merely remnants of those discharged from sources at a greater elevation and nearer the central axis of the cone.

But the precise mode in which the upper part of the original Mount Mazama was destroyed, and Crater Lake formed among its ruins, is not quite so certain. Two explanations are possible. All the upper part of the mountain may have been hurled in shattered fragments through the air by a series

[1] "The Geology and Petrography of Crater Lake National Park." By Joseph Silas Diller and Horace Bushnell Patton (U.S. Geological Survey). Pp. 168. Plates i–xix. (Washington, 1902.)

of tremendous explosions, like those which truncated Papandayang in Java and shattered Rakata in Krakatoa, or the cone may have collapsed and been engulfed; mother earth, like the fabled Saturn, devouring her own offspring—which has happened on a smaller scale at Kilauea. Mr. Diller, after a discussion of the rival hypotheses, follows Captain Dutton in preferring the latter. Space does not allow of a full discussion of the reasons, but it may be enough to say that the explosive destruction of a great central cone might be expected to have piled up the fragments more or less symmetrically around the margin of the void; but, though much fragmental volcanic material has been scattered over not a few square miles of the surrounding region, this does not exhibit any such arrangement, and its presence may be explained by eruptions posterior to the formation of the caldera, such as that which built up Wizard Island. It must, however, be admitted that such a vast engulfment seems to demand the withdrawal of a corresponding quantity of lava from beneath the cone, and its discharge—as in the Kilauea eruption of 1840—from some distant vent, of which at present no evidence has been found. It is thus possible that each hypothesis is in part correct, for engulfment and explosion may have cooperated in the work of destruction, vast blocks of the ruined cone tumbling inwards to be blown out in shattered fragments and distributed over many miles of country—so that the volcano practically became an automatic muzzle-loader. But that Mount Mazama was not destroyed merely by an explosion like that of a colossal powder magazine, seems to be evident.

FIG. 1.—Western Border of Crater Lake with Wizard Island.

In the second part of the memoir Mr. Patton gives us a careful petrographical study of the materials of Mount Mazama. They are mostly, as is so usual with the volcanoes of the great mountain chains of the two Americas, andesites, among which the hypersthene-bearing varieties are common, though on the one hand dacites, and on the other basalts, are to be found. Full descriptions of these and their included minerals are given, as well as of certain portions of a rather different mineral character, which Mr. Patton regards as secretions. It is difficult to form an opinion without an actual study of the rock specimens and slices, but we venture to suggest that they may rather be inclusions—that is, to say, material which, though it may have been originally separated by some kind of differential action, and might so far be called a secretion, owes its present position to being caught up and carried away by the general mass of molten material. This, however, is a very small criticism. The memoir is a most valuable one, and its printing and illustrations maintain the usual high standard of the publications of the United States Geological Survey.

T. G. BONNEY.

THE BRUSSELS AND TERVUEREN MUSEUMS.

FOR many years past the Royal Brussels Museum of Natural History has presented attractions for the vertebrate palæontologist which can be rivalled by few and excelled by none of the institutions of a similar nature in Europe. But those who have not had an opportunity of seeing the collections recently will scarcely fail to be surprised at the vast increase which has been made in the exhibited series, and at the excellent manner in which the specimens are displayed even in the limited space at present available. A still greater degree of astonishment, and, we may add, of admiration, will be expressed by the visitor when he is shown the new buildings, now nearing completion, designed for the housing of the entire recent and fossil fauna of the country.

When the present writer (some twelve or fifteen years ago) last saw the collection, only a single skeleton of the far-famed Bernissart iguanodons was mounted in the exhibition galleries. Now there are no less than five such skeletons set up in their natural posture, while a sixth is shown lying on a mass of Wealden rock as it was exhumed from the quarry. A more magnificent display than the one presented by the skeletons of these mighty dinosaurs can scarcely be imagined.

Next in importance to the unrivalled iguanodons and associated reptiles from the Bernissart Wealden may probably be ranked the magnificent series of mosasaurian remains which have been obtained in working the phosphatic beds of the Upper Cretaceous strata of the Maastricht district and other parts of the country. In addition to several more or less imperfect skulls and other parts of the skeleton of the typical Mosasaurus, the collection includes remains of several other generic types, some of which, such as Hainosaurus, are peculiar to Belgian territory. Unlike so many European fossil vertebrates of large size, most or all of these generic types are represented by skeletons so nearly perfect as to admit of their being set up like those of recent animals. One of the treasures of the museum is the skeleton of the fore-paddle of a representative of these gigantic marine lizards, this specimen being believed to be the only known example of this part of the mosasaurian skeleton hitherto discovered in Europe. Another noteworthy specimen in this group is the skull of Prognathosaurus, remarkable for the exquisite state of preservation of the bones of the elongated muzzle. The turtles of the Upper Cretaceous, as represented by the well-known *Chelone hoffmanni*, and a still more gigantic unnamed species characterised by the extreme flatness of the carapace, likewise form a large and interesting exhibit.

Much more might be written about the Mesozoic vertebrates, but, from exigencies of space, it must

suffice to refer to an imperfect skeleton of *Plesiosaurus homalospondylus*, and another of *Ichthyosaurus platyodon* from the Lias of Luxembourg. The special interest attaching to these specimens is that, unlike the majority of "halosaurians" from the English Lias, the bones are separate, so as to admit of the skeletons being mounted after the fashion of the Oxfordian plesiosaurs in the British Museum.

Turning to Tertiary fossils, the magnificent series of cetacean remains from the Pliocene of Antwerp is too well known to need more than passing reference. Special attention may, however, be directed to the beautifully preserved skulls of long-nosed dolphins (Eurhinodelphis) from the Miocene deposits of the same locality, which have been recently described by Dr. Abel, and are some of the most interesting of all cetacean fossils. Neither is the collection lacking in valuable remains of sirenians, one case containing no less than five more or less imperfect skeletons of a representative of the widely spread Oligocene genus Halitherium, while in a second is displayed the skeleton of the body of an allied Miocene type, for which Monsieur Dollo has proposed the name of Miosiren. Evidently a large and specialised form descended from Halitherium, this genus is characterised by the enormous stoutness and solid structure of the ribs, which are so close together as to simulate a massive carapace in the region of the thorax. The specimens of the rhynchocephalian Champsosaurus, from the Lower Eocene, are likewise unique treasures of the collection.

The collection of remains from the cavern and other Pleistocene deposits forms another striking feature of the museum. Among the mounted specimens are three skeletons of the cave-bear, one of the cave-lion, and three of the woolly rhinoceros. The mammoth skeleton from a superficial deposit is one of the finest in existence out of Russia; while of especial interest is the imperfect skull of a very young individual of the same species, with the earlier milk-molars in position. A skeleton of the much rarer *Elephas antiquus* is likewise noteworthy, first, because the tusks are strongly curved, and, secondly, on account of the peculiar manner in which their tips are worn. This curvature of the tusks suggests that the title of straight-tusked elephant, which has been proposed for this species, is not so diagnostic as it might be. As regards the tips of the tusks, each has been ground into a blunt wedge—a mode of wear never observable in those of either the Indian or African species, and the cause of which is at present inexplicable.

Owing to lack of space, the fossil collections are now mingled with the series of skins and skeletons of recent animals in a manner calculated to confuse the non-scientific visitor, while at the same time the proportions of many of the specimens are not so well displayed as is desirable. All this, however, will soon be remedied, for the magnificent new wing, destined to contain the entire collection of indigenous Belgian animals, is, as already mentioned, fast nearing completion, the whole of the building itself being finished. A notable feature is the entire absence of any architectural decoration in the interior, a feature which might advantageously have been adopted in our own museums. The main hall of this magnificent building is no less than 100 metres in length by 30 in width. The floor is on four different levels, rising in terraces one above the other from the entrance. On the entrance level will be arranged the recent and Quaternary vertebrates (other than fishes); on the first terrace the Tertiary vertebrates, on the second the Upper Cretaceous vertebrate fauna, and on the third and highest the iguanodons and other reptiles of the Wealden. The visitor will thus obtain a *coup-d'oeil* of the whole effect immediately on entering. The iguanodons will be represented by no less than thirteen skeletons, of which nine are to be mounted and erect, while the remainder are to occupy a large tank-like excavation in the floor, in which they are to lie as in their native quarry. In the gallery running round this hall are to be arranged the recent and fossil fish-fauna of Belgium, while the invertebrates are to be housed on the floor above. By an ingenious arrangement of details, space has been found for a numerous series of large and well-lighted work-rooms. Some idea of the lavish scale on which the new building is planned may be gathered from the fact that the space available for the display of the Belgian fauna alone is four times as great as that allotted in the Paris Museum to the fossil vertebrate fauna of the whole world.

Eventually, I am told, it is hoped that a similar wing may be built on the opposite side of the museum for the exhibition of the fauna and products of the Congo Free State. At present the large collection from that territory (which is the private property of King Leopold) is housed at Tervueren, reached by a tram-ride of about fifty minutes from Brussels. In addition to many interesting anthropological and ethnological objects, the collection contains a fine mounted pair of okapis, as well as numerous antelopes and other representatives of the mammalian fauna of the Congo State, not to mention specimens of the birds, reptiles, fishes, and lower forms of life.

R. L.

TECHNICAL EDUCATION AND INDUSTRY.

THE national importance of a close and strong relationship between science and industry is shown by Sir William Ramsay in a letter in Monday's *Times*. Two points upon which emphasis is laid are that numerous scholarships awarded by county councils represent an expenditure of public funds which can do little to promote industrial progress, and that our manufacturers offer few openings for men who have received a sound and scientific education. Technical education, as it is understood in this country, and as most of our technical schools are compelled to understand it if they wish to obtain students, consists of lectures on the rudiments of science, illustrated by practical work of a very elementary kind. It is scarcely necessary to say that the training thus received is of little value to the students or to the community in comparison with the work carried on in the technical high schools of Germany. Sir William Ramsay recently had an opportunity of conversing with the manager of a large chemical works in Germany, which manufactures no product of which it sells less than 100 tons a year, and he directs the attention of our manufacturers to the following facts as to the connection between science and industry in Germany.

The company has seventy chemists, of whom twenty are employed in analysing the raw materials and intermediate and finished products; twenty-five are engaged in superintending the processes of manufacture; and the remaining twenty-five are exclusively employed in scientific work—*i.e.* in endeavouring to improve the present processes of manufacture, and in trying new suggestions, either their own, or those brought to the notice of the firm by patentees. Almost all these chemists have been trained in universities, but a few come from technical high schools or Polytechnika. It is common for the best of such men to receive a "call" to a chair in a university or a Polytechnikum, and it is also usual for a company to offer a lucrative post to one who already holds a chair, even though he may have had no technical experience, and in this way a close bond has been

established between science and industry to the enormous advantage of both.

A large part of the duties of the director consists in attending congresses and in every way keeping abreast of the most recent discovery, with the object, of course, of gaining information which may be turned to practical utility.

While in Germany there is thus a fairly lucrative career for a young chemist, in England, although there will soon be many well-trained men, the openings are few. Such as there are are filled by men whose minds are occupied with too many things. The chemist is often analyst, works-manager, and investigator all at once; and it is no wonder that he is not a success, and that manufacturers doubt his utility in their business. Moreover, it is very desirable that a closer touch between universities or university colleges and manufactures should be brought about, if possible, for it cannot fail to be to the advantage of both industry and science—to industry, in order that technical problems may receive scientific treatment, and to science, because some of the most interesting problems are often suggested by the technologist.

Now, we are producing trained engineers and chemists quite as inventive and capable as our German competitors. But the prospect of a reasonably remunerative career is generally wanting. It would obviously be to the advantage of manufacturers to engage such young men, not expecting them, of course, to be able at first to introduce improvements which will effect a saving; but by looking out for young men with some originality, by giving them time to learn their business, and by offering an ultimate inducement in the shape of a share of profits, our manufacturers will undoubtedly reap the benefits which have given our German competitors their lead in industries in which chemistry plays a part.

NOTES.

AT the Institution of Civil Engineers on Tuesday, November 3, an inaugural address will be given by the president, Sir William H. White, K.C.B., F.R.S.; the medals and other awards made by the council will be presented, and there will be a reception in the library of the Institution.

MR. MARCONI arrived at Liverpool on board the *Lucania* last Saturday. The results of his experiments are said to have been very satisfactory; whilst in mid-Atlantic he was able to receive simultaneously communications from England and America. It is also stated that he hopes within six or eight months to re-establish commercial communication across the Atlantic.

THE trials of the high-speed electric cars on the Berlin-Zossen military line have been continued with much success. A maximum speed of 125½ miles an hour was attained by the Siemens-Halske car last week; the average speed over the whole run of 14 miles, including the time of starting and stopping, was 109½ miles an hour. The trials of the rival car, which the Allgemeine Elektricitäts Gesellschaft is building, have yet to be made. The track has been relaid since the experimental runs last year, and it is stated that it is now thoroughly satisfactory. The result of the trials is looked upon as demonstrating the practicability of high speed working over long distances, and it is estimated that it will be possible to reduce the time taken over the journey from Berlin to Cologne from nine to three and a quarter hours.

THE secretary of the Institution of Electrical Engineers informs us that the bronze shield subscribed for by the students of the Institution at the beginning of the present year has now been placed upon the tomb of Volta at Camnago, near Como. The ceremony of fixing it in place was performed on Sunday, October 4, with many expressions of international good feeling, in the presence of Prof. Count Alessandro Volta, Cav. Franchi, the Sindaco of Camnago, with several members of the Volta family and a number of other guests. The shield is mounted on a slab of green marble supported on granite in front of the tomb. The electrotype reproduction, which was officially deposited on the tomb on the occasion of the visit of the Institution in April last, has been transferred to the Civic Museum in Como, where it is placed in the collection of Volta relics.

DR. W. A. NOYES, of the Rose Polytechnic Institute, has accepted the position of chemist in the United States National Bureau of Standards.

DR. B. A. WHITELEGGE, C.B., His Majesty's Chief Inspector of Factories, has been appointed president of the Epidemiological Society in succession to the late Dr. W. H. Corfield.

AN International Fine Art and Horticultural Exhibition is to be opened at Düsseldorf on May 1, 1904. A hope is expressed that England will contribute largely to this exhibition.

REUTER reports that Prof. Langley's aërodrome, for which the U.S. Government granted a subvention of 15,000*l*., was launched on October 7 from the railway over the flat boat on Whitewater, a section of the Potomac River. The machine balanced perfectly when it started, but soon struck the water, with the result that it was wrecked. Previous experiments have been made with models only, and this trial was the first made with the full-sized airship, which is constructed to carry a passenger.

THE Home Counties Nature-Study Exhibition, which is being organised by the Middlesex Field Club and Nature-Study Society, and delegates from the Selborne Society, will be held from October 30 to November 3 at the offices of the Civil Service Commission, Burlington Gardens, London, W. Intending exhibitors should communicate with the honorary secretary, Mr. Wilfred Mark Webb, 20 Hanover Square, London, W., who will be pleased to supply full information.

WE learn from *Science* that the American Grape Acid Association, 318 Front Street, San Francisco, Cal., offers a premium of 5000*l*. for any person who devises a process or formula for the utilisation of California grapes containing more than 20 per cent. of saccharin, worth 2*l*. a ton, to produce tartaric acid at a price that would permit of exportation without loss. The decision in awarding the amount is to rest with a jury of five, of which Prof. E. W. Hilgard, of the University of California, is one. The offer closes on December 1, 1904.

THE first meeting of the Manchester Astronomical Society—a new local association of persons interested in astronomy and observational work—was held on Wednesday, October 7, when an address on solar parallax was given by the president, Prof. T. Gore. The Society has its centre and home in the Municipal School of Technology, Manchester, and members have the privilege of using the telescopes and other instruments in the new Godlee Observatory.

THE death is announced of Mr. Henry M. Brunel, the second son of I. K. Brunel, the engineer. Mr. Henry Brunel entered into partnership with Sir John Wolfe Barry in the 'seventies of last century, and took active interest in the scientific researches bearing upon naval architecture carried on by the late Mr. William Froude, F.R.S. He was largely associated in the work of Barry Dock, the railway bridge over the Thames at Blackfriars, the bridge erected at Connel Ferry, and with the Tower Bridge. He was a member of the Institution of Civil Engineers and of the Institute of Naval Architects.

AN excessive downpour of rain is reported from New York on October 8–9, amounting to more than ten inches in thirty hours. This is said to be the greatest fall at that place since the Weather Bureau was established there, in 1867, and has caused great damage to property. The streets resembled rivers, and in some parts the water rose waist-deep. The train service between New York and Philadelphia was temporarily suspended; the Delaware River rose to the highest level ever known, and several bridges have collapsed. Since 1889, the U.S. Weather Bureau has published tables of excessive rainfall from self-recording gauges. We have referred to these, and find that, although such excessive falls do occur from time to time, they are of rare occurrence. During the years 1889–1896, for instance, the highest record was 9·86 inches in twenty-four hours, at Jacksonville (Florida), in September, 1894.

WE have received the report of the director of the Philippine Weather Bureau, 1902, part iii., containing very clearly printed hourly observations of atmospheric phenomena at the Manila Central Observatory, with hourly and monthly means. The extreme daily values of each of the elements are brought together in a separate table. This is one of the few observatories at which observations of ozone are taken. Parts iv. and v. still remain to be published, and will contain magnetic observations and the results for the secondary stations of the Archipelago. The complete series will form a valuable contribution to the climatology of the Far East.

WE have received the report of the Hong Kong Observatory for the year 1902, containing hourly readings of the different meteorological elements, together with some magnetic and astronomical observations. The weather forecasts issued during the year have been very satisfactory; 56 per cent. were completely successful, and 35 per cent. partially successful. According to the practice usually followed in dealing with the results, 91 per cent. of the forecasts may be therefore considered as more or less successful. The collection of observations at sea for the construction of trustworthy monthly pilot charts has been vigorously continued; the number of days' observations obtained during the year was 9073, while the total number of sets now collected amounts to nearly 261,000. The area dealt with lies between 9° S. and 45° N. latitude, and between the longitude of Singapore and 180° east.

M. K. OLSZEWSKI describes in the Cracow *Bulletin* a new apparatus for the liquefaction of hydrogen, differing from his previous models in having both regenerators and the intermediate cooler for receiving liquid air all placed in a common vacuum chamber. The apparatus is said to work faultlessly.

THE formation of "Liesegang's rings" by the precipitation of silver chromate in gelatin forms the subject of a paper by Messrs. H. W. Morse and G. W. Pierce in the *Proceedings* of the American Academy. The formation of the precipitate in rings is clearly a case of supersaturation, and the authors now obtain a definite constant value for the product of the concentrations of the silver and chromate ions in order that supersaturation may take place.

SEVERAL papers on the so-called N rays discovered by M. Blondlot are printed in the *Journal de Physique* for August. M. Blondlot shows that these rays are of common occurrence, being emitted by an Auer lamp and an incandescent silver lamina, and being present in sunlight. M. G. Sagnac describes determinations of the wave-length of these rays by means of their diffraction. It appears that the rays in question are about two octaves below the Rubens infra-red rays, and intermediate between these and the Hertzian radiations of Lampa. Their wave-length is about 0·2 of a millimetre.

SEVERAL writers have raised difficulties in connection with Boltzmann's minimum theorem in the kinetic theory of gases on the ground of the reversibility of the motions of the individual gas-molecules. Some remarks on this point are contributed by Dr. A. Pannekoek to the *Proceedings* of the Amsterdam Academy. For the case considered the author finds that when in a purely mechanical reversible process, which is repeated a number of times, a small variation in the initial data causes a large variation in the final state, the total process assumes the properties of an irreversible process.

SOME observations made in the Arosa Valley on atmospheric electricity at high altitudes are described by Mr. W. Saake in the *Physikalische Zeitschrift*, 23. The most noteworthy results were the observation of a negative fall of potential on certain clear and cloudless winter days, the facts that the coefficient of electric dispersion of electricity was increased by the Föhn and that under normal conditions the coefficient of negative dispersion attained a maximum at about 8 a.m. and between 4 and 5 p.m., and the large capacity of the atmosphere for radio-active emanation, which was about three times as great as in Wolfenbüttel.

THE Hopkins-Stanford Expedition to the Galapagos Islands in 1898–99 turns out to have been remarkably successful in the matter of new species of marine fishes from that area. According to a paper by Messrs. Heller and Snodgrass, published in the *Proceedings* of the Washington Academy (vol. v. pp. 189–229), the number of novelties is twenty-three, of which no less than five are regarded as indicating new generic types. Most of the species are figured in the plates accompanying the memoir, and we may particularly direct attention to the excellent effect produced by the sepia-like printing of plates 8 and 9.

IN the October issue of *Bird Notes and News*, attention is directed to the power now possessed by county councils of extending protection during winter to birds of any kind, and the value of this to many resident species. The introduction last July into Parliament of a Bill to abolish the pole-trap is likewise the subject of a commendatory note. A letter from Colonel Irby, which appeared in the *Saturday Review* of July 18, on the subject of taking rare birds and their eggs for so-called scientific purposes is reproduced. In this communication the writer directs attention to the shooting of a pair of pratincoles last spring near Romney, and likewise to the taking of a nest of the blue-headed wagtail near Winchelsea.

THE *Century Magazine* for October contains an account by Mr. L. O. Howard of the recent investigations which have served to connect the propagation of yellow fever with a certain species of mosquito (*Culex aeniatus*). A map (after Mr. Theobald) is given of the distribution of this mosquito, which coincides exactly with that of yellow fever. To protect oneself from the malaria mosquito, it is only necessary to use gauze curtains at night; the yellow fever mosquito, on the other hand, is a diurnal species, so that escape from its stab is a matter of much greater difficulty. In a well-illustrated article in the same journal entitled "The Wild Bird by a New Approach," Mr. F. H. Herrick comments on the revival of interest in nature generally, and natural history in particular, which has taken place of late years in the United States. Birds have been specially

favoured in this respect, and the author directs attention to the amount of information with regard to their habits obtainable by the new method of photography at short distances, to which allusion has been previously made in these columns.

WE have received a copy of the eighth report on the periodic variations of glaciers, by Dr. S. Finsterwalder and E. Muret (*Arch. des Sc. phys. et nat., Genève*).

WE have received from the Queensland Department of Mines, Geological Survey Reports, Nos. 181 and 183, by Mr. Walter E. Cameron. The author deals with recent mining developments on the Ravenswood Gold Field, where rather more than 2 oz. 7 dwt. of gold per ton has been raised during the past three years. He also gives further particulars relating to coal, and gold, silver, and copper ores in the Mackay and Bowen districts.

PROF. W. M. DAVIS has sent us copies of two recent essays on earth sculpture (*Bull.* Mus. Comp. Zool., Harvard Coll., vol. xlii.). One deals with the plateau province of Utah and Arizona. Evidence is given to show that the greater part of the faulting had been accomplished before the uplift of the region by which the erosion of the Colorado canyon was initiated, but some modern faulting of large amount has taken place. The other essay is on the mountain ranges of the Great Basin, in which the author deals with the effects of erosion on faulted mountain-blocks.

THE surface geology of Cheshire in its relation to agriculture is dealt with by Mr. William Edwards (*Proc.* Liverpool Geol. Soc., vol. ix. part iii.). He refers to the Drift soils, but more especially to those derived from Triassic rocks. The Keuper Marls yield some of the best soils, owing to their mineral ingredients, to their physical properties, and in part to their colour. The author observes that most of our best soils have a deep red colour, and probably the value of this colour depends upon its power to absorb the heat rays of the sun.

THE general report of the work carried on by the Geological Survey of India for the year 1902–1903 has been drawn up by the new director, Mr. T. H. Holland. Economic inquiries have been made with regard to coal, chromite, fire-clay, gold, iron, manganese, lead, petroleum, &c. Field-work was carried out in seven districts. In the report on the Punjab area, reference is made to evidence brought forward by Dr. Noetling, that in the Salt Range the sedimentary series from Cambrian to Tertiary has been thrust bodily in a southerly direction over the salt-marl, and that the marl is not pre-Cambrian, but simply belongs to the Tertiary salt-bearing formation, like that represented at Kohat.

WE have received from Messrs. Darbishire and Stanford, of the Oxford Geographical Institute, Oxford, specimens of a new series of outline maps which they are issuing under the title of the "Autograph Handmaps," at the price of one penny each. The feature of the series is that, besides showing the coast lines and the principal rivers, the chief hill features of the country are indicated by a very expressive scheme of shading, which renders the pictorial value of the maps, and therefore their value in elementary teaching, decidedly greater than is the case where contour lines are employed. The execution is somewhat unequal, but generally good; the maps of the British Isles, Scotland, and Ireland are the best. We note that in most cases the name of the projection on which the map is drawn, the natural scale, and scales of miles and kilometres, are given. The maps are printed in a dull brown colour, so that additional matter introduced by teacher or pupil stands clearly out. The maps are a valuable addition to the equipment available for teaching geography, and as such should be heartily welcomed.

IN the Cracow *Bulletin*, Mr. Ed. Janczewski proposes a new classification of the species belonging to the genus Ribes. The author distinguishes six subgenera, four of which (Ribesia, Berisia, Grossularioides, and Grossularia) are characterised by scarious scales, while in the other two (Calobotrya and Coreosma) the scales are herbaceous.

THE early cell divisions in the germinating spore of the liverwort Pellia form the subject of a paper by Mr. C. J. Chamberlain in the *Botanical Gazette*. As Prof. Farmer originally showed, interest attaches to the nuclear divisions at this stage owing to the appearance of a centrosphere and radiations. Mr. Chamberlain holds the opinion that the radiations represent lines of streaming material.

IT is known that the red and blue colours of many flowers and fruits are due to the pigment anthocyanin, which occurs in the cell sap. Mr. T. Ischimura has examined its formation in hydrangea flowers, and describes the results in the *Journal* of the College of Science, Tokio. In conformity with the reactions obtained the author concludes that anthocyanin is a tannin, or a tannin derivative, and shows that besides tannin, light, and generally sunlight, is necessary for its formation.

IN the report for the year 1902–3, the director of the Botanical Survey of India announces the retirement of Mr. J. F. Duthie, who held the post of director of the Botanical Department of Northern India. The investigations of the various kinds of Indian yams are being continued, and cultivations of fibre plants are being undertaken in order to determine the sources of the fibres classed as Indian hemp. Mr. C. A. Barber refers to a disease known as "spike" which is destroying the sandal wood plantations of Mysore and Coorg, and also reports the appearance of a species of fungus on cholam leaves, similar to one which is very destructive to the sugar cane.

A USEFUL little book on "Hardy Perennials," by Mr. D. S. Fish, has been published in the Rural Handbook Series by Messrs. Dawbarn and Ward, Ltd. Amateur gardeners will find in the book practical hints on the selection, arrangement, and cultivation of many hardy garden flowers.

MESSRS. ROSS, LTD., have issued recently an abridged catalogue for 1903, and a new edition of their "C" catalogue. Both lists are beautifully illustrated with reproductions of photographs taken with Ross, Ross-Zeiss, and Ross-Goerz lenses, and contain full information of photographic and other optical apparatus.

WE have received a second edition of the discourses by Dr. Stephan Waetzoldt bearing the title "Die Jugendsprache Goethe's" and "Goethe und die Romantik," the first edition of which was printed in 1888. An addition has now been made in the form of a third discourse dealing with the ballads of Goethe and their origin.

ALL photographers will find something of value and interest in the first number of the *Practical Photographer*—that for October. Not only is photography regarded from

its scientific side by chemists and others, but the artistic aspects of the photographer's work are dealt with in a helpful manner by experienced writers. The magazine is admirably illustrated by a profusion of well executed plates, and is published by Messrs. Hodder and Stoughton.

MESSRS. F. E. BECKER AND Co., of Hatton Wall, London, are manufacturing cheap electric switchboards for use in physical laboratories supplied with continuous current, designed by Mr. William Bennett, of the Gravesend Technical School. It is claimed that by this method it is impossible for students to short circuit the mains, as only one wire is carried round the room. A switch block is provided in each working place, and all students have the same current, but any student can switch the current on or off without interrupting others. The boards are supplied with resistances, instruments for measuring current, and other necessary adjuncts.

WE have received the thirty-sixth volume, that for 1902, of the *Journal and Proceedings* of the Royal Society of New South Wales. The original papers contained in the first part of the volume are seventeen in number, and many of them are illustrated by plates, of which there are no less than twenty-one. The volume concludes with the annual address delivered to the engineering section of the Society, and two papers also read to the same section. As abstracts of the papers read before the Society are periodically published in NATURE, it only remains to be said that the scientific work of the Society, as represented by the contents of the volume before us, does honour to the colony of New South Wales.

THE additions to the Zoological Society's Gardens during the past week include two Black Lemurs (*Lemur macaco*) from Madagascar, presented by Mr. Walter Barnes; a South African Hornbill (*Bucorvus cafer*) from South Africa, presented by Mr. W. Champion; two Larger Patagonian Conures (*Cyanolyseus byroni*) from Chili, presented by Mr. E. C. Davids; two Grey-winged Ouzels (*Merula boulboul*) from India, an Adelaide Parrakeet (*Platycercus adelaidae*) from Australia, three Derbian Sternotheres (*Sternothaerus derbianus*) from West Africa, two Adorned Terrapins (*Chrysemys ornata*) from Central America, four Brazilian Tortoises (*Testudo tabulata*), four Orbicular Horned Lizards (*Phrynosoma orbiculare*) from Brazil, deposited.

OUR ASTRONOMICAL COLUMN.

REPORTED DISCOVERY OF A NOVA.—A telegram received from the Kiel Centralstelle on October 5 announced that Prof. Wolf had discovered what was probably a new star on the evening of September 21. He found the position of the object, reduced to the equinox of 1903, to be R.A. = 20h. 14m. 6·8s., Dec. = $+37^\circ\ 9'\ 49''$, and reported that its spectrum was of the nebular type.

A further communication received from Kiel announces, however, that a telegram received from Prof. Pickering states that the object is not a Nova, but a variable having a spectrum of the fourth type, whilst another telegram from Prof. Hale announces that Barnard has identified the supposed Nova with the star B.D. $+37^\circ$·3876 (R.A. = 20h. 14m. 6.8s., Dec. = $+37^\circ\ 9'\ 47''$), and found the colour to be "very red." Dr. Parkhurst determined the magnitude of the variable on October 5, and found it to be 10·6.

1903–4 EPHEMERIS FOR WINNECKE'S PERIODICAL COMET.—The elements and ephemeris of Winnecke's comet for its appearance during 1903–4 have been calculated by Herr C. Hillebrand, of Graz, and are published in No. 3907 of the *Astronomische Nachrichten*. The elements and part of the ephemeris are given below:—

Epoch = 1904 *Jan.* 24·0 (M.T. *Berlin*).

$$M = 0^\circ\ 28'\ 1''\!\cdot\!61$$

$$\left.\begin{aligned} \pi &= 274\ \ 19\ 45\cdot40 \\ \Omega &= 104\ \ 12\ 36\cdot44 \\ i &= 16\ \ 59\ 54\cdot78 \end{aligned}\right\} 1903\cdot0 \qquad \begin{aligned} \phi &= 45^\circ\ 38'\ 0''\cdot12 \\ \mu &= 608''\cdot801706 \end{aligned}$$

Perihelion = 1904 Jan. 21·24

Ephemeris 0h. (*M.T. Berlin*).

1903	α app. h. m. s.	δ app. ° ′ ″	log r	log Δ

DIAMETER OF NEPTUNE.—Herr C. W. Wirtz, Strassburg, publishes the results of a series of measurements of the diameter of Neptune, made by him during the period December, 1902–March, 1903, in No. 3907 of the *Astronomische Nachrichten*. As the mean result of forty-nine measurements, made on twenty-six evenings, he obtained 2″·303 with a possible error of ±0″·044 for the value of the diameter.

Taking the value of the solar parallax as 8″·80, and Bessell's dimensions for the earth, this gives the actual diameter of Neptune as 50,251 km. and the mean density of the planet as 1·54, the density of the earth being taken as 5·53.

THE OPPOSITION OF EROS IN 1905.—In No. 73 of the Harvard College Observatory *Circulars* Prof. Pickering publishes an ephemeris for Eros during the opposition of 1905.

This ephemeris gives the Julian Day, the date, the R.A. (1900) and Dec. (1900), the logarithms of the distances from the sun and earth respectively, and the computed magnitude for every tenth day from November 21, 1903, to December 20, 1905; it has been obtained by interpolation from an ephemeris, for intervals of forty days, computed by Mr. F. E. Seagrave from the elements published in the *Berliner Jahrbuch* for 1905.

As seen from the ephemeris, the opposition of Eros during 1905 will be one of the most unfavourable oppositions that can possibly occur, for the computed magnitudes never exceed the twelfth. Prof. Pickering recommends that observations of the light variations, both photographic and visual, should be made during the opposition, although Prof. Bailey, working with the 13-inch Boyden telescope at Arequipa during the present year, has obtained an excellent set of light-curves of this planet. In general the position of the planet in the sky, during the 1905 opposition, will be nearly opposite to that which it occupied during the spring of 1901, when its variability was discovered.

THE ROYAL UNIVERSITY OBSERVATORY, VIENNA.—The sixteenth annual volume of the Vienna Observatory *Publications* contains the details of the "zone observations" for the zone −6° to −10°, made in accordance with the programme of the Astronomische Gesellschaft for its star catalogue, and collected by Dr. Johann Palisa. The observations were made with the 11½-inch Clark refractor, and the tables give the position for 1875·0, together with the usual reductions.

The same instrument was also used by Herr J. Rheden for observing the opposition of Mars during the period December 21, 1898–March 16, 1899, and the results of these observations, including eight excellent coloured reproductions of Herr Rheden's drawings, form the second part of the publication.

The third and last section is devoted to the meteorological observations made during the years 1897, 1898, 1899 and 1900.

THE BRITISH ASSOCIATION.

SECTION L.

EDUCATIONAL SCIENCE.

Opening Address by Sir William de W. Abney, K.C.B., D.C.L., D.Sc., F.R.S., President of the Section.

The Section over which I have the honour to preside deals with every branch of education. It is manifest that in an Address your President cannot deal with all of them, and it remained for me to choose one on which I might remark with advantage. As my official work during the last thirty-three years has been connected with education in science, I think I cannot do better than take as my subject the action that the State has taken in encouraging this form of education, and to show that through such action there has been a development of scientific instruction amongst the artisan population and in secondary day schools. The development may not indeed have been to the extent hoped for, but it yet remains that solid progress has been made.

I have chosen the subject deliberately, as I find that there are very few of those who have the interests of education strongly at heart, or who freely criticise those who have borne the burden of the past, that have any knowledge of the trials and difficulties (some of its own creating, but others forced on it by public opinion) which the State, as represented by the now defunct Science and Art Department, had to contend with in its unceasing missionary efforts in the cause of scientific instruction. I shall not attempt to do more than show that whatever its defect may have been in tact, whatever its shortcomings in method, that Department still deserved well of the country for the work that it did in regard to the fostering of scientific instruction in the country at large.

As far back as 1852 the Government of the day, influenced very largely by the Prince Consort, realised that it had an educational duty to perform to the industrial classes. Whether it was influenced by philanthropic motives or from the evidence before it that if Great Britain was to maintain its commercial and industrial supremacy scientific instruction was a necessity, it matters little. The fact remains that it determined that the industrial classes should have an opportunity of acquiring that particular kind of knowledge which would be of service to them as craftsmen. In this year 1852 the Speech from the Throne contained these words: "The advancement of Fine Arts and of Practical Science will be readily recognised by you as worthy of a great and enlightened nation. I have directed that a comprehensive scheme shall be laid before you, having in view the promotion of those objects towards which I invite your aid and co-operation."

It is somewhat remarkable that the then Ministry, of which Lord Derby was the chief and Mr. Disraeli the Chancellor of the Exchequer, did not survive to promulgate the scheme, which proposed theoretical rather than practical science, but that their successors, under Lord Aberdeen, issued it and commenced to carry it into effect. In 1853 the Department of Science and Art was established under the direction of Mr. Cole. Since 1835 so-called Schools of Design had been in being. These came under the new Department, and it was determined to establish science classes for instruction in science, Dr. Lyon Playfair, the well-known chemist, being charged with the duty. Playfair resigned in 1858, and in 1859 Mr. Cole induced a young Engineer officer, Lieut. Donnelly, to undertake the inspection and organisation of science instruction throughout the country. It was through this officer's untiring energy and zeal that the classes in science flourished and were added to at this early stage of the new Department's history. The same energy was displayed by Donnelly during the whole of his long career in the service of the State, and I feel that it was fortunate for myself to have served so many years as I did under one to whom the country at large owes a deep debt of gratitude.

Not long ago he passed away from us, and there will be no more lasting memorial to him than that which he himself erected during his lifetime in the fostering of that form of education which is of such vital importance to the national well-being.

To revert to history, I may record that the first science examinations conducted by the State took place in May, 1861, and, the system of grants being made on the results of examination having been authorised, the magnificent sum of 1300*l.* was spent on this occasion on the instruction of 650 candidates, that number having been examined. Thus early was the system of examination commenced in the Department's career, and the method of payments on the results of these examinations stereotyped for many years to come. There is reason to believe that the educational experts of that day considered that both were essential and of educational value, a value which has since been seriously discounted. Employers of labour in this country were not too quick in discerning the advantages that must ultimately ensue from this class of education if properly carried out and encouraged. Theoretically they gave encouragement, but practically very little, and this survives to some extent even to the present day. Some of the foremost employers, however, gave material encouragement to the formation of classes, insisting on their employees attending evening instruction; but conspicuous above all was Mr. Whitworth, who, in 1868, placed in the hands of the Department the sum of 100,000*l.*, to be devoted to the creation of scholarships, which were to be awarded at the annual May examinations. The proviso made by him was that all competitors were to have had experience in practical work in an engineering establishment. Such candidates, it was evident, must have found out their own weakness in education, and, by working in science classes, could make up their deficiencies, and the award of these scholarships would enable them to study further. Sir J. Whitworth was far-seeing and almost lived before his age, but the benefits that he has conferred, not only on individuals, but on science and industries, by his generosity will make his name to be remembered for generations to come. To have been a Whitworth scholar gives an *entrée* into various Government and engineering posts, and we have in the front rank of science men who have held these scholarships and whose names stand prominent in the development of engineering.

Incidentally, I may say that no country but this, for very many years, considered that instruction in science for the artisan was a large factor in maintaining and developing industry. The educational interests of the employer and the foreman were, in some countries, well provided for, but the mechanic was merely a hand, and a "hand" trained in merely practical work he was to remain. He could not aspire to rise beyond. We may congratulate ourselves that such a "caste" system does not exist amongst ourselves.

For the first twenty-five years of the Department of Science and Art the grants given by Parliament for science instruction were distributed almost entirely amongst those who were officially supposed to belong to the industrial classes, and no encouragement was offered to any higher class in the social scale.

It would take me too long to show that at first the industrial classes were very shy of seizing on the advantages offered them. Suffice it to say that they had to be bribed by the offer of prizes and certificates of success to attend instruction, and it was not for several years that the evening classes got acclimatised and became popular.

The evening instruction was then largely attended by adults. That this was the case may be judged by the fact that the average age of candidates who obtained successes in advanced chemistry was about twenty-five and in elementary chemistry about twenty-one. I have alluded to the apathy displayed by employers and by the artisans in the early days of the Department of Science and Art. The causes which dispelled it in both employers and employed, in regard to science instruction, will be found in the following extract from a report by the Department of Science and Art:—

"The Paris Exhibition (1867) caused the work of this country to be brought into close comparison with that of the rest of the Continent, and in many points both of manufacture and of skilled labour it was found England did not stand in such a good position as she had done a few years back. Dr. Playfair, in a letter to the *Times*, drew attention to this, attributing much if not all the evil to the deficiency of our technical education among the artisan class. The substance of this letter was taken up by many

persons of influence during the autumnal recess, and it led to a sort of educational panic, the cry for technical education becoming quite the absorbing topic among all circles and forming a considerable portion of the contents of all periodicals. Meetings were convened and addresses delivered all over the country, and the question was so much ventilated that important changes were anticipated in the educational arrangements of the country during the coming session of Parliament, which unfortunately were put off on account of the debates on the Reform Bill of 1868.

"The agitation necessarily brought forward the work of the Science Division of the Science and Art Department, and it is not a little remarkable how completely the system which had been growing up since 1860 seemed to meet all the requirements of the case, and at the same time how few persons had any idea of its provisions in spite of all that had been done to spread a knowledge of the scheme.

"There can be no doubt, however, but that this six years' work had silently, though materially, effected a change in the general tone of feeling on the subject of scientific education, and had been the means of preparing the country for the 1867 agitation. The different feeling among the working-classes on the subject is forcibly shown in the Annual Report of the Science and Art Department. From this it appears that in 1860 a pupil in one of the science classes in Manchester, a town usually looked upon as in advance of others, could hardly continue his attendance at the class owing to the taunts of, and ill-treatment by, his companions. Nevertheless, in the autumn of this year, 1867, hardly enough could be said or done to satisfy the desire for science classes being formed for those very persons who, but six years before, had considered attendance at a Government science school as almost against the rules of their trade."

Such was the account of 1867 given by Mr. G. C. T. Bartley (now Sir G. Bartley, M.P.). The plan adopted by the Science and Art Department for encouraging instruction in science was perhaps the best that could be devised at the time, though we now know that it was capable of improvement. It may be mentioned that an improvement in it was made the next year by the introduction of a very large system of scholarships, scholarships which have enabled the possessors in some instances to continue their studies at universities, and several distinguished men owe their positions to this aid. It was in this same year that Mr. Whitworth established his scholarships, as before described.

I have endeavoured to give a brief *résumé* of what was done during the first fifteen years of the existence of the Science and Art Department, and it continued to expand its operations after 1868 on the same lines for another ten years. In 1876 your President became connected with the Department as a Science Inspector. I am sure the Section will forgive me if I am somewhat personal for a few moments. During the previous eight years I had had the honour of being a teacher of some branches of physical science at the School of Military Engineering, and my own training was such that I had formed a very definite opinion as to how science instruction should be imparted, both to those who had a good general education and also to those who had not. The method was the same in both cases: it should be taught practically. I may say that though I had not myself had the advantage of being taught it at school, I had learned all the science I knew practically, and I entered the Department fully impressed with this view. Whenever possible I have until the present time endeavoured to impress this view on all who were interested in the work of the Department. Much of the science that was taught in State-supported classes was largely book work and cram, and the theoretical instruction as a rule was unillustrated by experiment. This was undoubtedly due to the system of payments being based on success at the examinations. I must here say that there were honourable exceptions to this procedure. There were teachers, then as now, who knew the subjects they taught, and who were inspired by a genuine love of their calling. I can in my mind's eye recall many such, some of whom have joined the majority and others who are still at work and as successful now as then in rousing the enthusiasm of their students.

I am not one of those who think, as some do, that cramming is entirely pernicious. A good deal of what used to be taught at public schools in my days was cram. It served its purpose at the time in sharpening the memory, and was a useful exercise, and it did not much matter if in after years much of it was forgotten. If the cramming is in science, a few facts called back to mind in after life are better than never having had the chance at all. In fact, as the faded beauty replied to the born plain friend, it is better to be one of the "have beens" than a "never wasn't."

It was determined to make a vigorous onslaught against teaching that was unillustrated by experiment and to encourage practical teaching as far as could be done. Proper apparatus for illustrating lectures was insisted upon, and, with aid from the Department, was eventually provided, though in some instances several years' pressure had to be exercised before it was obtained. I am bound to say that in many instances after it had been procured a surprise visit by the inspector during the hours of instruction often found that the lecture table was free from all encumbrance, and that the dust of weeks was upon the apparatus that should have been in use. This was sometimes due to the inability of the teacher to use the apparatus rather than to a wish to disregard the rules laid down by the Department; but usually it was due to the fact that the teacher found cram paid best. I should like to say here that this state of things does not exist at the present time, and that the training of science teachers by the Royal College of Science and by other institutions has completely broken down the excuses that were often offered at that time.

The first grants for practical teaching were paid for chemistry. The practical work had to be carried out in properly fitted laboratories. There were not half-a-dozen at the time which really answered our purpose, and one of the earliest pieces of work on which I was engaged was in assisting to get out plans for laboratory fittings. These were very similar to those which I had designed for the School of Military Engineering several years before. Thanks to the Education Act of 1870 (I speak thankfully of the work that some of the important School Boards have done in the past in taking an enlightened view of science instruction) there were some localities where the idea of fitting up laboratories was received with favour, and it was not long before several old ones were refitted, in which instruction to adults was given, and new ones established in Board Schools for the benefit of the Sixth Standard children. At that time an inspector's, like the policeman's, lot was not a happy one. We had to refuse to pass laboratories which did not fulfil conditions, though we left very few "hard cases."

Until after the passing of the Technical Instruction Act in 1887 the Department aided schools in the purchase of the fittings of laboratories (both chemical and others), and year after year this help, which stimulated local effort, caused large numbers of new laboratories to be added to the recognised list. After six or seven years we had a hundred or more laboratories at work of what I may call "sealed-pattern efficiency." I am not very partial to sealed patterns, but they are useful at times, for they tell people what is the least that is expected from them. The pattern was not without its defects; but laboratories, like other matters, follow the law of evolution, and the more recently fitted ones show that the experience gained whilst teaching or being taught in a sealed-pattern type has led to marked improvements. Personally I am of opinion that only necessaries should be required, and I rebel against luxuries; for a student trained by means of the latter will, as a rule, in after life fail to meet with anything beyond the mere essentials for carrying on his scientific work.

The sealed pattern is practically in abeyance, though it can be trotted out as a bogey, and any properly equipped laboratory is recognised so long as it meets the absolute necessities of instruction.

The half-dozen chemical laboratories which existed in 1877 have now expanded to 349 physical and 774 chemical laboratories. These are spread over all parts of England. I leave out Scotland and Ireland, as the science teaching is no longer under the English Board of Education.

It is only fair to say that many of this large number of laboratories are at present in secondary schools, regarding which I shall have to speak more at length. But the fact remains that in twenty-seven years there has been such a growth of practical science teaching that some 1120

laboratories have come into being. My predecessor in the Chair likes to call laboratories "workshops." I have no objection, but the reverse; for the word "laboratory," like "research," sounds too magnificent for what is really meant, and all education should more or less be carried out in workshops.

The increase is as satisfactory as it is remarkable. It was only possible to increase the numbers in early days by gentle pressure and prophesying smooth things which, happily, did eventually come to pass. In later days the increase has been almost automatic. The Technical Instruction Act has called into being technical instruction committees who in many cases have taken up science instruction in their districts in earnest. They, too, have had public money to allocate, and not a little has gone in the encouragement of practical education. It may, however, be remarked that had it not been for the preliminary work that had been done by the Science and Art Department it is more than probable that the Technical Instruction Act of 1887 would never have seen the light.

A reference must now be made to the removal of what anyone will see was a great bar to the spread of sound instruction in every class of school where science was taught. So long as the student's success in examination was the test which regulated the amount of the grant paid by the State, so long was it impossible to insist on all-round practical instruction. It was impracticable to hold practical examinations for tens of thousands of students in some twenty different subjects of science. The practical examination in chemistry told its tale of difficulties. It was only when the Duke of Devonshire and Sir John Gorst in 1898 substituted for the old scheme of payments payment for attendance, and in a large measure substituted inspection for examination, that the Department could still further press for practical instruction. For all elementary instruction the test of outside examination does more harm than good, and any examination in the work done by elementary students should be carried out by the teacher, and should be made on the absolute course that has been given. It seems to be useless or worse that an examination should cover more than this. Instruction in a set syllabus which for an outside examination has to be covered spoils the teaching and takes away the liberty of method which a good teacher should enjoy. The literary work involved of answering questions, for an outside examiner, is also against the elementary student's success, and cannot be equal to that which may properly be expected from him a couple of years later.

Advanced instruction appears to be on a different footing. The student in advanced science must have gradually obtained a knowledge of the elementary portions of the subject, and it is not too much to ask him beyond the inspection of his work to express himself in decent English and to submit to examination from the outside; but even here the payment for such instruction should be by an attendance grant tempered in some degree by the results of examination, since examiners are not always to be trusted.

The attendance grant was not viewed by some with great favour at first, and protests were received against its adoption, a favourite complaint being that it was sure to entail a loss of grant. One became suspicious that some of those who protested were aware that the last bulwark which defended the earning of grants by cram was being removed, and that inspection might prove more irksome than examination. This is past history now, and the new system works as smoothly as the old and with not more complaints than are to be always expected.

As I have said, grants were for very many years supposed to be confined to aiding the instruction of the industrial classes, but this limitation was more nominal than real. It might probably be imagined that it was no very difficult task to distinguish an artisan and his children from students who belonged to the middle classes. This was not the case, however. Children belonging to the industrial class were, on joining a science class, obliged to state the occupation of the father, and it was no uncommon thing for fathers to be given brevet-rank by their children. Thus, a bricklayer's son would describe his father as a "builder," which, if true, ought to have brought him into the ranks of the middle class. These unauthorised promotions were one of the difficulties the inspector had to face when judging as to the status of the parents. This difficulty was largely met by a rule that all those who attended evening classes were supposed to be of the industrial class; but as day classes increased the numbers of those who by no possibility could be of the artisan class also increased, and it became a very invidious duty of the inspector to put M.C. (Middle Class) against the names of many. It was determined by superior authority that only those students or their parents who could claim exemption from income-tax should be reckoned as coming within the category of industrial students. In early days the qualification for abatement on income-tax was a much lower figure than it is to-day, and almost each succeeding Chancellor of the Exchequer has raised the figure of the income on which the abatement could be claimed. To-day it is, I believe, 700*l.* a year, bringing the official definition as to membership of the industrial classes to an absurdity. It became evident to the official mind, which some people are good enough to say works but slowly, that the definition must be amended or the limitation abolished. The progress of events happily made the abolition the better plan, and was the means of allowing inroads of science instruction to be made into secondary day schools.

The history of these inroads I shall now give. Instruction given in so-called organised science schools was originally aided by the Department by means of a small Capitation Grant. These schools were supposed to give an organised course of science instruction, and the successes at examination determined the payment. They were not satisfactory as at first constituted, and they so dwindled away in numbers that in 1890 only some one or two were left. A small increase in Capitation Grant in 1892 revived some of them, and a fair number existed in the following year. There was no doubt, however, that the conditions under which they existed were most unfavourable for a sound education, which ought not only to include science but also literary instruction. The latter was, in many schools, wholly neglected, owing to the fact that the grants earned depended on the results of examination, and so all the school time was devoted to grant earning.

Mr. Acland, at this time Minister for Education, was made aware of this neglect to give a good general education, and as I was at that time responsible for science instruction I was directed to draw up a scheme for reorganising these schools and forcing a general as well as scientific education to be carried out. Baldly the scheme abolished almost entirely[1] payments on results of examination, and the rate of grant depended on inspection and attendance. Further, a certain minimum number of hours had to be given to literary subjects, and another minimum to science instruction, a great deal of it being practical and having to be carried out in the "workshop." The payments for science instruction were to be withheld unless the inspector was satisfied that the literary part of the education was given satisfactorily.

The scheme was accepted and promulgated whilst the Royal Commission on Secondary Education was sitting, and, if I may be allowed to say so, Mr. Acland's tenure of office would be long remembered for this innovation alone, since in it he took a wide departure from the traditional methods of the Department and created a class of secondary school which differed totally from those then existing. Needless to say the scheme was not received with favour on all sides, more especially by those who thought that serious damage would be done to secondary schools by the competition from this new development of secondary education. I am not ashamed to say that the disfavour shown on some sides made me rejoice, as it indicated that a move had been made in the right direction. At first it was principally the higher-grade Board Schools that came under the scheme, and in the first year there were twenty-four of them at work. This type of school gradually increased until about seventy of them, and chiefly of a most efficient character, were recognised in 1900. Their further increase was only arrested by the Cockerton judgment, now so well known that I need only name it. But here we come to a most interesting development. State aid, as already said, was at first limited to the instruction of the industrial classes, but no limitation as to the status of the pupil was made in this new scheme for the schools of science, and logically this freedom was extended in 1897 to all instruction aided by the Department—the date when all limitation

[1] Within the next four years they will entirely cease.

as to the status of the pupil was abolished, the only limitation being the status of the school itself. Thus, if a flourishing public school, charging high fees for tuition, were to apply to participate in the grant voted by Parliament, it may be presumed, it would have to be refused. The abolition of the restriction as to the status of the pupils left it open to poorly endowed secondary grammar schools to come under the new scheme. To a good many the additional income to be derived from the grant meant continuing their existence as efficient, and for this reason, and often, I fear, for this reason alone, some claimed recognition as eligible.

Such is an outline history of the invasion of science instruction into certain secondary schools—an invasion which ought to be of great national service. In my view no general education is complete without a knowledge of those simple truths of science which speak to everyone, but usually pass unheeded day by day. The expansion of the reasoning and observational powers of every child is as material to sound education as is the exercise of the memory or the acquisition of some smattering of a language. I am not going into the question of curricula in schools, as I hope, regarding them, we shall have a full discussion. But of this I am sure, that no curriculum will be adequate which does not include practical instruction in the elementary truths of science. The President of the Royal Society, in his last Annual Address, alluded to the mediæval education that was being given in a vast number of secondary schools. Those who planned the system of education of those times deserve infinite credit for including all that it was possible to include. Had there been a development of science in those days, one must believe that with the far-seeing wisdom they then displayed they would have included that which it is the desire of all modern educationists to include. Observational and experimental science would have assuredly found a place in the system.

One, however, cannot help being struck by the broadening of views in regard to modern education that has taken place in the minds of many who were certainly not friendly to its development. Perhaps in the Bishop of Hereford, when headmaster of Clifton, we have the most remarkable early example of breadth of view, which he carried out in a practical manner, surrounding himself with many of the ablest teachers of science of the day. There are other headmasters who, though trained on the classical side, have had the prescience to follow in his footsteps, and of free will; but others there are who have neither the desire nor the intention, if not compelled to do so, to move in the direction which modern necessities indicate is essential for national progress. I am inclined to think that the movement in favour of modernising education has been very largely quickened by the establishment of schools of science in connection with endowed schools and the desire for their foundation by the Technical Instruction Committees, who had the whisky money at their disposal, and who often more than supplemented the parliamentary grants which these schools were able to earn. It was the circumstance that the new scheme was issued when many endowed schools were in low water that made it as successful as it has been.

The number of schools of science increased so rapidly that it appeared there might be a danger of too many of this type being started on sufficient educational grounds. Science instruction was carried in them to such an advanced point and so many hours of the week were spent on it that they became in some degree specialised schools. At least eight hours a week had to be devoted to science, ten to literary instruction, and five to mathematics—any further time available could be spent on any section that was considered desirable. For some pupils the time devoted to science is barely enough, but for others who intend to follow careers in which the literary section should predominate it appeared that some curtailment of hours in the science section might be usefully allowed, and it became a question how far such instruction might be shortened without impairing its soundness. After much anxious thought it was considered that four hours per week, besides mathematics, was the very least time that ought to be devoted to such instruction, and that the latter part of it should be practical work. A scheme embodying this modification was approved by the Lord President and the Vice-President whilst I was Principal Assistant Secretary for Secondary Education, and smaller grants than those for schools of science were authorised in 1901 for those schools which were prepared to adopt it. By the scheme instruction has to be given only in such subjects and to such an extent as is really necessary to form part of that general education of ordinary students who might not have to follow in industrial pursuits. This modified and shortened course has met with unqualified success. Some 127 schools came under the scheme the first year, and I gather that there will be a considerable increase in numbers in the future. The establishment of schools of science and of these schools may be considered to be a great step taken in getting practical instruction in natural knowledge introduced into secondary schools. The leaven has been placed in some 300 of them, and we may expect that all schools which may be eligible for State aid will gradually adopt one scheme or the other. Though it is said that there is nothing in a name, I am a little doubtful as to whether the earmarking of science education as distinct from secondary education is not somewhat of a mistake at the present day. For my own part, I should like to think that the days have passed when such an earmarking was necessary or advisable. The science to be taught in secondary schools should be part and parcel of the secondary education, and it would be just as proper to talk of Latin and Greek instruction apart from secondary education as it is to talk of science instruction. One of the causes of the unpopularity of the Science and Art Department was its too distinctive name. At the same time it would be most unwise at the present time, when the new Education Committees are learning their work and looking to the central authority for a lead, for the State to alter the conditions on which it makes its grants to these schools. It will require at least a generation to pass before modernised education will be free from assault. If science instruction is not safeguarded for some time to come it runs a good chance of disappearing or being neglected in a good many schools. As to the schools which have no financial difficulties, it is hard to say what lines they may follow. Tradition may be too strong in them to allow any material change in their courses of study. If it be true that the modern side of many a public school is made a refuge for the "incapables," and is considered inferior to the classical side, as some say is the case, such a side is practically useless in representing modern education in its proper light. Again, one at least of the ancient universities has not shown much sympathy with modern ideas, and so long as she is content to receive her students ignorant of all else but what has been called mediæval lore, so long will the schools which feed her have no great inclination to change their educational schemes.

If we would only make the universities set the fashion the public schools would be bound to follow. The universities say that it is for the public schools to say what they want, and *vice versâ*, and so neither one nor the other change. It appears to me that we must look to the modern universities to lead the movement in favour of that kind of education which is best fitted for the after life of the large majority of the people of this country. If for no other reason, we must for this one hail the creation of two more universities where the localities will be able to impress on the authorities their needs. The large majority of those whose views I share in this matter are not opposed to or distrust the good effects of those parts of education which date from ancient times. The great men who have come under their sway are living proofs that they can be effective now as they have been in times past, but we look to the production of greater men by the removal of the limitations which tradition sets. I myself gratefully acknowledge what the public school at which I had my early education did for me, but I think my gratitude would be more intense had I been given some small elementary instruction in that natural knowledge which has had to be picked up here and there in after life.

There is one type of college which I have not alluded to before, and that is the technical institutes. These have been fostered by the localities in which they are situated, and been largely supported by the whisky money, supplemented by Government aid. I am glad to see that in the last regulations of the Board of Education these colleges will receive grants for higher scientific instruction, and I have no doubt that in the near future such institutions and schools of science will receive a block grant, which will

give them even still greater freedom than they now enjoy. These are colleges to which students from secondary schools will gradually find their way, where they wish for higher education of a type different from that to be gained at a university.

I have endeavoured to give a brief historical sketch of what the State has done in helping forward instruction in natural knowledge amongst the industrial classes, adults and children, and how gradually its financial aid has been extended to secondary schools. I have also endeavoured to indicate the steps by which practical instruction has been fostered by it. I have done this because I am confident that ninety-nine educationists out of every hundred have but little idea what the State has been doing for the last fifty years. Some connected with secondary schools—I have personal knowledge—were until lately ignorant that the State had offered advantages to them of a financial nature. I may say that the work of the late Science and Art Department was largely a missionary work. It was abused, sometimes rightly but more often wrongly, for this very work, and it had more abusers at one time probably than any other Government Department. Even friends to the movement of modernising education found fault with it as antiquated and slow, but I can assure you that no greater mistake can be made in pressing forward any movement by any hurried change of front or by endeavouring to push forward matters too rapidly. In the first place, the Treasury naturally views untried changes with suspicion, and this fact has to be dealt with more particularly when there is no great expression of public opinion to reckon with. At the same time it cannot be stated too strongly that the Treasury has in recent years dealt in a friendly and enlightened spirit with all matters which could affect the spread of science. Again, there is a hostility to great and rapid changes in the minds of those whom such changes affect.

The policy must always be to progress as much as is possible without rousing too great an opposition from any quarter, and I think it will be seen that the progress made during the last twenty-five years has, by the various annual increments, been perhaps more than could have been hoped for, and gives a promise for even more rapid advances in the future.

As an appendix to this Address I have given a brief epitome of the increases in students, in schools, in laboratories, and in grants which have taken place since 1861. If to the last be added the amount spent out of the whisky money an additional half million may be reckoned.

It will be seen that the progress made has been gradual, but satisfactory, and that, if we showed some of the results graphically, weighted according to the circumstances of their date, and dared make an extrapolation curve of future results, we should have a complete justification for prophesying hopefully.

The question of the supply of science teachers has already been referred to. My remarks I should like to supplement by saying that in the greater number of schools teachers are to be found who have been trained at the Royal College of Science, and mostly at public expense—some through scholarships gained by competition and some through training selected teachers. The success of the movement for the introduction of science instruction in schools depended on the proper supply of teachers, and even now the demand for men possessing the highest teaching qualifications in science is greater than the supply. It may be said, I think, that our science teachers from the college have one special qualification, and that is, that besides the knowledge of science, practical and theoretical, that they have acquired they have lived in an atmosphere of what is called research, and which might be called original investigation. Professors, assistants, and students alike are impregnated with it, and when the teacher so trained takes up his duties in his school he still retains the "reek" of it. True instruction in science should, as I have before said, be practical, and practical instruction should certainly include original inquiry into matters old or new. The teacher who retains the "reek" is the teacher who will prove most successful. It will thus be seen that the State had the task before it, not only of introducing instruction in science, but of training teachers to give such instruction. This problem is the same as now exists in Ireland, and the experience gained in England cannot but be of the greatest use to those at the head of Irish technical education.

Before concluding there is one subject that I must lightly touch upon, and that is the supply of teachers other than science teachers. The Education Act of 1870 gave the power to elementary schools to train pupil teachers, who in the process of time would become teachers, either by entering into a training college by means of a King's Scholarship or, less satisfactorily, by examination. In large towns the need of a proper training for pupil teachers has been felt, and gradually pupil teacher centres were established, principally by School Boards, where the training could be carried out more or less completely; but in the rural districts and smaller towns the pupil teacher has had to be more or less self-taught, and except in rare cases "self-taught" means badly taught. The Training College authorities make no secret of the fact that one of the two years during which the training of the teacher is carried out has to be devoted more or less to instructing the pupils in subjects they ought to have been taught before they entered the college. Thus all the essential and special instruction which is given has to be practically shortened, and the teacher leaves the college with less training than he should have.

The new Education Act has put it in the power of the educational authorities to rectify the defects in the training of pupil teachers. It is much to be hoped that Councils will separately or in combination either form special centres for the training of all pupil teachers or else give scholarships (perhaps aided by the State) to them, to be held at some secondary school receiving the grant for science and recognised by the Board of Education as efficient. The latter plan is one which commends itself, as it ensures that the student shall associate with others who are not preparing for the same calling in life, and will prevent that narrowness of mind which is inevitable where years are spent in the one atmosphere of pedagogy. The non-residential training college, where the training of the teacher is carried on at some university college, is an attempt to give breadth of view to him, but if attempted in the earliest years of a teacher's career, it will be even more successful. All teaching requires to be improved, and the first step to take in this direction is to educate the pupil teacher from his earliest day's appointment, for his influence in after years will not only be felt in that elementary, but will also penetrate into secondary education. In regard to the additions which are required in elementary education, and which require the proper training of the pupil teacher, I must refer you to a report which will be presented to the Section. The task of training pupil teachers is one which requires the earnest and undivided thought of the new Education Committees.

In the earnest Address given by my predecessor in this Chair he brought forward the shortcomings of secondary education and of the requirements for a military career in a trenchant manner and with an ability which I cannot emulate. With much of what he said I agree heartily, but I cannot forget that, after all, the details of education are to some extent matters of opinion, though the main features are not. We must be content to see advances made in the directions on which the majority of men and women educational experts are agreed. Great strides have already been made in educating the public both in methods and subjects, but a good deal more remains to be done.

It may be expected, for instance, that the registration of teachers will lead to increased efficiency in secondary schools, and that the would-be teacher, fresh from college, will not get his training by practising on the unfortunate children he may be told off to teach. It may also be expected that such increased efficiency will have to be vouched for by the thorough inspection which is now made under the Board of Education Act, by the Board, by a university, or by some such recognised body. It again may be expected that parents will gradually waken up to the meaning of the teacher's register and the value of inspection, and that those schools will flourish best which can show that they too appreciate the advantages of each.

I have to crave pardon for having failed to give an Address which is in any way sensational. I have thought it better to review what has been done in the past within my own knowledge, and with this in my mind I cannot

but prophesy that the future is more than hopeful, now that the public is beginning to be educated in education. It will demand, and its wants will be supplied.

APPENDIX.

Number of Schools of Science and their Grants.

Year	Higher Grade Schools	Endowed Secondary Schools	Technical Institutes	Total Schools	Total Grants
					£
1895	53	30	29	112	39,163
1898	69	50	49	168	98,849
1901	63	106	43	212	118,833
1903	50	119	57	226	Not yet known[1]

Number of Schools teaching Shortened Course of Science.

Year	No.
1902	127
1903	184

Number of Laboratories recognised.

Year	Chemistry	Metallurgy	Physics	Biology	Mechanics

1885	63,364		

[1] In 1902 124,300*l.* was paid.

THE GERMAN ASSOCIATION AT CASSEL.

THE seventy-fifth meeting of the German Association for the Advancement of Science and Medicine took place in brilliant weather in the picturesque town of Cassel. By Saturday evening, September 19, members and associates began to arrive, and on Sunday a large number of gaily coloured "rosettes" were visible in the streets. Advantage was taken of this gathering of men of science to present to Prof. Graebe, of Geneva, an address on the completion of the twenty-fifth year of occupancy of his chair of chemistry, and M. Moissan, of Paris, on behalf of the Chemical Society, conveyed to him the Lavoisier medal of the Institute of France. Prof. Graebe, who, in conjunction with Prof. Liebermann, of Berlin, achieved the first important chemical synthesis—that of artificial alizarine—was an old assistant of Prof. v. Baeyer, of Munich, who then occupied the chair of chemistry in the Gewerbe Akademie in Berlin. Prof. v. Baeyer, in his opening address, directed special attention to the cooperation of men of science with technologists, which was the fruit of this important synthesis—a cooperation which has had enormous influence on the development both of German science and industry. The rector of the University of Geneva followed, and he mentioned that, during the twenty-five years of Prof. Graebe's tenure of the chair, he had published 196 memoirs on chemical subjects, while more than 400 papers were published by workers in his laboratory. Prof. Moissan, who, as delegate of the Académie des Sciences, handed to Prof. Graebe the Lavoisier medal, referred in an eloquent speech to the great influence which Graebe's work has had in developing synthetical organic chemistry, and after the presentation of addresses from the Royal Academy of Sciences of Bavaria, from the German Chemical Society, from the Societies of Geneva and Frankfort, and from the University of Lausanne, Prof. Graebe received from the chairman a gold plaque, engraved with his portrait, and from M. Amé Pictet, on behalf of his old students, a bound copy of his own papers. Dr. Brunck, on behalf of the "Badische" Chemical Company, of which he is managing director, added a tribute to Graebe from the point of view of technology, and in an eloquent reply Prof. Graebe expressed his gratitude and thanks. About sixty of the audience remained to a dinner given in honour of Prof. Graebe, at which numerous toasts were drunk, and the proceedings were kept up until a late hour.

The members and associates met for the first time on Sunday evening, September 20, in the grounds of the Hessian Brewery, where a large hall had been adapted for the purpose of the general meetings, and on Monday morning, after words of welcome from Prof. Hornstein, of Cassel, the local secretary, from President von Trott zu Solz, from the mayor and others, the president of the Association, Prof. van 't Hoff, returned thanks in the name of the Association. An address was then delivered by Prof. Ladenburg on the influence of science on our views of life. The address treated of the gradual development of scientific knowledge and its opposition by the church; the necessity of education in the phenomena and laws of nature, and the insignificant position of man among natural phenomena; the doctrine of the immortality of the soul and the dicta of science on the subject. He contended that Christianity alone had been unable to induce mankind to accept the doctrine of liberty, equality, and fraternity, and that this doctrine, indispensable for our future progress, must be the future object of scientific endeavour. The general opinion of the audience appeared to be that Prof. Ladenburg's address was unnecessary, and that he had assumed for science an infallibility similar to that claimed by the Apostolic See. The second address, by Prof. Ziehen, of Utrecht, treated of impressions and sensations, and their connection with the surface of the brain. Sensations may be termed positive or negative, according as they produce pleasant or unpleasant emotions, and their intensity depends less on the degree of excitability of the regions of the brain affected than on the capacity for "discharge" or communication with other regions. "Negative" sensations are more numerous than positive; the lecturer attempted to prove this by the fact that, in German, words denoting unpleasant are more numerous than those which denote pleasant sensations. But up to now it had been impossible to bridge the gap between the mechanism of the brain and the sensations and perceptions.

In the afternoon the sections met, and in the evening the opera of "Tannhäuser" was well performed in the theatre. September 21 was devoted to sectional meetings, and in the evening the members and associates dined together in the "Festhalle," and many toasts were proposed. On the morning of the next day addresses were delivered by Prof. Penck, of Vienna, on geological time; by Prof. Schwalbe, of Strassburg, on the early history of man; and by Dr. Alsberg, of Cassel, on inherited degeneration as a consequence of social influences. On the morning of September 24 the medical side of the congress was represented by Dr. Allan Macfadyen, who gave an address on intercellular toxines; by Dr. Paul Jensen, on the physiological action of light; and by Dr. Rieder, on the curative results obtained by treatment with light.

Later in the morning, in order to open a discussion on the place of mechanics in our views of nature, papers were read by Dr. Schwarzschild, of Göttingen, on astronomical mechanics, by Prof. Sommerfeld on technical mechanics, and by Prof. Otto Fischer on physiological mechanics. Dr. Schwarzschild began by stating that Newton's law of gravitational attraction still remains the leading factor in astronomy, and every observation only serves as a confirmation of its correctness. It has been proved to be correct to two parts in one hundred millions. The chief aim of astronomical mechanics is to represent exactly the actual path of the planets. But the classical "Mechanics of the Heavens" fails, if it is applied to very long periods of time. The formulæ which are applied would, if extended, point to a destruction of the planetary system. There are, however, two reasons for believing that such a conclusion would be incorrect. The problem of "secular disturbances" was solved by Lagrange, and that of "commensurabilities"

has made great progress during the last thirty years. Under the last head may be grouped periodic and asymptotic paths, the problem of the gaps in the asteroids and the ring of Saturn, and the theory of the libration of the moons of Jupiter and Saturn. When these are carefully considered, they appear to point to the stability of the planetary system for all time. This conclusion is, indeed, rendered less general by Poincaré's proof of the divergence of series in the theory of disturbances, but it can nevertheless be shown that, during a long period of time, for which it is possible to give a lower limit, changes in the planetary system are unimportant. The problems which still face the astronomer who undertakes similar investigations were exemplified by Lexell's comet and Darwin's periodic paths.

Prof. Sommerfeld, in indicating the direction in which mechanics comes into technical use, spoke of the confirmation of experimental principles and the greater use of theory. He gave an account of the teaching of mechanics in the universities and Polytechnika of Germany, entering somewhat into detail as regards the order of presentment of various conceptions. Dr. Otto Fischer discussed the necessity of determining the dimensions, the mass, the centre of gravity, and the moment of inertia of various portions of the living body, and the effects of external and internal forces in altering these properties.

On the morning of September 25 Sir William Ramsay lectured on the periodic system of the elements, Prof. Griesbach on school hygiene, and Prof. von Behring on the fight against tuberculosis. Ramsay spoke of the various attempts which have been made to ascertain whether mass and inertia, on the one hand, are invariable, or, on the other, whether the atomic weights show signs of variation. On the whole, the evidence is negative. He then described the spontaneous change of the emanation from radium bromide into helium, and concluded with some speculations as to the possible formation and decomposition of what are at present regarded as elementary bodies. The subject of school hygiene, though a very important one, has little scientific interest, but the lecture of von Behring was listened to with the greatest attention. Prof. von Behring has a large estate at Marburg where experiments on tuberculosis are carried out on animals. For example, he has rendered it very probable that vaccination of cows with the tuberculosis antitoxin renders their milk immune, and that the milk, in its turn, may render human beings immune. He believes to have shown that infants acquire tuberculosis through milk, and that even before birth the skin of infants is penetrable by the tubercular bacillus. If such infants are nourished on the milk of cows which have been injected with tubercular bacillus, the milk contains an antitoxin, and the tendency towards tuberculosis is obviated. He advocated the view that adults seldom acquire tuberculous diseases unless they are early predisposed to receive them by infection as infants. But this tendency can be combated by feeding infants with milk from cows which, through vaccination with tubercular matter, have developed the suitable antitoxin.

Prof. van 't Hoff, the president of the Association, then concluded by giving a short account of the most important papers which had been communicated to the sections, after which he thanked the town of Cassel, in the name of the Society, for its hospitable reception.

The German "Naturforscherversammlung," unlike the British Association, includes many sections which treat of medical subjects. Only those lectures which are of general interest are delivered before the Association as a whole. The proceedings of the medical sections will doubtless find their way into the medical journals, and only the proceedings of scientific interest will be treated of here. Through the courtesy of the president and of Prof. Rassow, of Leipzig, abstracts of the more noteworthy of the papers in each section were furnished to the writer.

Of the mathematical section, it was merely stated that in all five meetings were held, in which twenty-eight papers were read, three being of some length. It would appear that mathematicians are too modest to thrust their views on the scientific brethren, or perhaps they doubt if they would be understood.

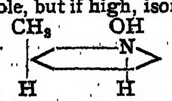
The most noteworthy papers in the physical section were, first, a confirmation by Prof. Rubens of Maxwell's theory by experiments on the optics of metals—their refractivity, and behaviour to electric currents; and, second, a paper by Prof. Nernst, in which he described and showed his iridium apparatus, by means of which a temperature of 2000° C. has been attained, and determinations of vapour density carried out. Nernst's "furnace" consists of an iridium tube about 10 inches long and 1½ inches diameter. By means of a powerful current which passes through the walls of the tube the temperature can be raised to any desired degree, short of the melting point of iridium. A small "bulb" of iridium, similar to that used for Victor Meyer's density apparatus, hangs inside the tube, and attains the temperature of the iridium tube. Nernst's balance, by means of which a couple of milligrams of substance can be correctly weighed to within a half per cent., consists of a glass fibre suspended by a quartz fibre at right angles to it; from one end hangs a small iridium capsule counterpoised by a small weight; the other end of the glass fibre projects over a mirror-scale; the balance acts partly by torsion of the quartz fibre, partly like a steelyard. The density of vapours of "non-volatile" substances is determined exactly as with a Victor Meyer apparatus, and while that of sulphur was found to correspond to S_1, that of phosphorus gave negative results in an atmosphere of nitrogen, due, no doubt, to the formation of a compound of phosphorus with nitrogen, stable only at a high temperature. Nernst also described his method of measuring high temperatures by noting the intensity of the radiation from the interior of the tube.

In the section of applied mathematics, Dr. Otto Thilo spoke of the necessity of a knowledge of mechanics for the investigator. By help of preparations and models he demonstrated the relation of sinews to bones, especially those which confine the motion to one plane, the mechanism for getting over the "dead-point," and those for restraint, so that muscular power is saved, for example, when a man is standing erect. He further went on to demonstrate the mechanism by which the pressure of air in the swimming-bladder of fishes is communicated to the brain. His contention was that even biologists must be instructed in mechanics if they wish to study the movements of living organisms.

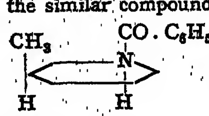
In the chemical section, Prof. Biltz spoke about the precipitation of colloids by salts. He advanced the theory that a colloidal solution consists of a colloid suspended in an electrolyte; when a precipitant is added a new form of combination occurs, for instance:—

Electrolyte – colloid + colloid-precipitant =
colloid – colloid-precipitant + electrolyte.

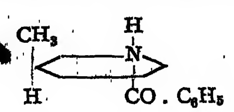
The precipitation of the iodine-starch substance by means of alumina was illustrated, and also of the meta-phosphoric acid-albumen couple. Prof. Ostwald suggested that the precipitation depends on the relative velocity of the two reactions, and that that reaction which takes place most rapidly gives rise to the formation of stable substances. Prof. Wedekind showed isomeric organic ammonium salts containing radicals of high molecular weight, and Prof. Ladenburg also read a paper on asymmetric nitrogen. Prof. Wallach mentioned a new instance of optical isomerism, in which, if the molecular weight of the substituting group is low, no isomerism is noticeable, but if high, isomerism exists. For example, the compound



gives us isomerides (the benzene nucleus is here seen in perspective), while the similar compounds



and



are isomeric.

Prof. Nernst read a paper on the theory of ozone formation. The potential difference between the system O_3, O_2|electrolyte|O_2 is 0·57 volt, and this corresponds with the heat of formation of ozone, for the couple has practically no temperature-coefficient. He calculated that if oxygen is heated to 6400° it should contain 10 per cent. of ozone, at 3230° 1 per cent., and at 2183° 0·1 per cent. In the sun the oxygen must be wholly in the state of ozone, owing to the high temperature and the enormous gravitational pressure. Prof. Abegg spoke of two cases of heterogeneous

equilibrium, and other papers treated of the ring formula for benzene, the use of the spectroscope in the determination of atomic weight (Runge), fluorescence and chemical constitution (Richard Meyer), &c.

In the section of applied chemistry, Prof. König spoke of the determination of fibre, cellulose, and lignin in plants, and of the decomposition of fodder by microbes, and Dr. Marquart, of Cassel, gave an account of Dr. Schenck's red-phosphorus. This variety is produced at a comparatively low temperature—about 180°—by heating a solution of yellow phosphorus in phosphorous bromide. It is precipitated out of the solution, and must be filtered off and washed with carbon disulphide to free it from yellow phosphorus. Its point of inflammation is that of ordinary red phosphorus, but it is in a state of such fine division as to be readily set on fire by rubbing if it be mixed with potassium chlorate; at the same time it gives off no fumes, and is therefore harmless to operatives who dip matches. The light red powder is soluble in caustic soda (for it probably contains an atom of replaceable hydrogen), and is reprecipitated by acids. Dr. Marquart spoke especially of the future of this substance in the manufacture of matches which ignite when rubbed on any surface, and which, at the same time, are without danger to workpeople.

In the section of geophysics, Dr. Mansing exhibited an apparatus for determining the ebb and flow, and also the direction and velocity, of currents, and likewise the pressure in deep water. The apparatus is electrically connected with a ship, and registers for thirty days. The advantage over apparatus which registers only in shallow water is obvious. Dr Nippolt read a paper on terrestrial magnetic variations, citing observations made partly by himself, but mainly by others. The curves which he obtained point to changes which occur simultaneously at different spots of the earth's surface; he interprets such changes as significative of changes in the internal nucleus of the earth, and of displacements of the relative positions of the earth's crust and the magma which he believes to exist in the interior. Prof. Krebs treated of subaqueous volcanic regions, and suggested that they may be points of connection between the sea-water and the earth's internal magma; he advocated that their position and nature deserve careful investigation on account of danger to passing ships. In another paper Dr. Krebs believed he had found an explanation of the inundations in Silesian Austria, in certain long areas of low barometric pressure from which regions of low pressure in Silesian Galicia can be deduced.

Dr. Wolkenhauer, in the geographical section, spoke of the oldest German maps, which he ascribed to the fifteenth and sixteenth centuries. The oldest maps are by Erhard Etzlaub; those of Cuza, which were formerly believed to have been published in 1491, appear to be as late as 1530. The attendance in this section was very small, owing to the meeting this year of geographers at Cologne.

In the botanical section the most important papers were by Prof. Kohl, who offered a proof that the central bodies of the Cyanophyceæ cells possess the properties of cell nuclei, and he expressed the belief that in the closely allied Schizomycetæ a similar proof could be found. Numerous experiments on Mycorrhizen, an account of which was given by Prof. Möller, proved that the existence of fungi on the roots of plants must be regarded as a case of parasitic existence, but not of symbiosis. Prof. Drude, who has made numerous experiments in the botanic garden at Dresden, contended that mutation cannot be sharply distinguished from variation, as De Vries believes, but that the difference is only one of degree. To prove his contention, he exhibited living specimens of *Oenothera Lamarckiana*, grown from seed which De Vries had given him.

In the zoological section only one meeting was held, at which lectures were delivered by Prof. Klunziger, Dr. Thilo, Dr. Eysell, and Dr. Basse. They were illustrated by demonstrations, but appear not to have contained any specially new matter.

The anthropological section excited a good deal of interest. Among the more important papers was one by Prof. Hagen, in which he demonstrated that the eight months' fœtus of the Malay and Melanesian races differed from the European fœtus by the shortness of the body compared with the limbs, and the greater diameter of the body in the region of the false ribs, &c. The Melanesian fœtus showed peculiarities from which he deduced the conclusion that the genus man became differentiated from other mammals at a very early period of history. On the other hand, Prof. Schwalbe, from investigation of the frontal sutures of apes and their comparison with those of man, contended that there is a close relationship to be observed between man and old-world apes. Prof. Gojanovic-Kramberger had examined human remains recently discovered in Croatia—the so-called *Homo crapinensis*—and concluded from his researches that in the Ice age two races were alive; the differences in the form of the jaws and teeth, the shape of the collar-bone, the upper arm and parts of the skull, were adduced as proof of his view. One of these races, he believed, showed analogy with the owner of the Neanderthal skull and the skeleton from the grotto of the Spy, so far as the morphological relationship could be traced.

One of the sections dealt with the teaching of mathematics and science in schools, and there Prof. Grimsell demonstrated the use of new apparatus designed to illustrate terrestrial magnetism and the mechanical equivalent of heat, and he showed a lantern which gave good images with an ordinary incandescent gas flame. Prof. Schotten gave a lecture which was largely attended, and at which much discussion took place on the suitability of zoology as a school subject. While most of the speakers agreed on its being easily taught and useful, doubt was expressed whether it was wise to add another subject to the already heavy load which a German boy is expected to carry. On the whole, the latter opinion was the more widely held.

After the meeting the members made excursions to objects of interest in the neighbourhood of Cassel. About seventy chemists and physicists visited Göttingen and inspected the laboratories of Profs. Nernst, Voigt, Rieke, and Wiechert; the last has been created only a few years, and is devoted to the investigation of the problems of "terrestrial physics." It is furnished with seismographs, instruments for investigating terrestrial magnetism, atmospheric electricity, &c., and good work is already being done in it. It is a handsome building at some distance from the town, and it may be held up as an example of the way in which the Germans leave no stone unturned to be first in the investigation of natural phenomena of all kinds. Some of the associates, chiefly medical, visited Marburg, in order to inspect Prof. von Behring's institute for the study of tuberculosis. The buildings and equipment must be characterised as magnificent. Here, again, is an instance of the cooperation of the scientific man and the manufacturer, for Dr. von Behring was for long scientific adviser to the firm of Höchst, which erected the laboratories, and undertook the manufacture of the antitoxin serum. Would that a similar spirit of cordial cooperation between English men of science and "practical" men could become more common!

W. R.

FORTHCOMING BOOKS OF SCIENCE.

MR. F. ALCAN (Paris) gives notice of:—"Essai sur le Langage intérieur et la Fonction endophasique à l'État normal et dans les États pathologiques," by Dr. G. Saint-Paul; "Travail et Plaisir," by Dr. Ch. Féré; "La Philosophie pratique de Kant," by V. Delbos; "Manuel d'Histologie pathologique," by Cornil, Ranvier, Brault et Letulle, Tome iii.; "Mécanisme et Éducation des Mouvements," by G. Demeny; "Les Défenses de la Vie," by Dr. J. Laumonier; "Histoire de l'Habillement et de la Parure, depuis les Temps préhistoriques jusqu'à nos Jours," by L Bourdeau; "Traité de Sylviculture—Exploitation et Aménagement des Bois," by Prof. P. Mouillefert; "L'Éducation," by C. A. Laesant."

Mr. George Allen promises:—"Ideals of Science and Faith," nine essays by Sir Oliver Lodge and various other writers, edited by Rev. J. E. Hand.

Mr. Edward Arnold's announcements include:—"The Chemical Synthesis of Vital Products and the Inter-relations between Organic Compounds," by Prof. R. Meldola, F.R.S.; "The Strength and Elasticity of Structural Members," by R. J. Woods; "The Evolution Theory," by Prof. A. Weismann, translated by Prof. J. A. Thomson, two volumes, illustrated; "Nature Study," by

Prof. L. C. Miall, F.R.S.; and a third series of "Memories of the Months," by Sir Herbert Maxwell, Bart.

Messrs. Baillière, Tindall and Cox announce:—"Health of Armies in the Field," by Major R. Caldwell; "The Nutrition of the Infant," by Dr. R. Vincent; and "Students' Aids to Chemistry," by T. A. Henry.

Messrs. A. and C. Black direct attention to:—"Trout Fishing: an Essay in the Study of Natural Phenomena," by W. Earl Hodgson, illustrated; "The Direction of Hair in Animals and Man," by Dr. W. Kidd, illustrated; and a new edition of "Text-book of Operative Surgery," by Dr. T. Kocher, translated by Dr. H. J. Stiles.

The list of the Cambridge University Press includes:—"Micro-cosmographie, or, a Piece of the World discovered; in Essays and Characters," by John Earle, printed from the sixth augmented edition of 1633; "Principia Ethica," by G. E. Moore; "The Algebra of Invariants," by J. H. Grace and A. Young; "The Collected Mathematical Papers of James Joseph Sylvester, F.R.S.," edited by Dr. H. F. Baker, F.R.S.; "Radio-activity," by Prof. E. Rutherford, F.R.S.; "The Fauna and Geography of the Maldive and Laccadive Archipelagoes. Being the Account of the Work carried on and of the Collections made by an Expedition during the years 1899 and 1900 under the leadership of J. S. Gardiner," vol. ii. part ii., illustrated; "Reports of the Anthropological Expedition to Torres Straits by the Members of the Expedition," edited by Dr. A. C. Haddon, F.R.S.; "Immunity in Infectious Diseases," by Prof. É. Metchnikoff, authorised English translation by F. G. Binnie, illustrated; "Rabies, its Place amongst Germ-diseases, and its Origin in the Animal Kingdom," by Dr. D. Sime; "The Natural History of some Common Animals," by O. H. Latter; "A Systematic Account of the Seed-Plants," by Dr. A. B. Rendle, vol. i.; "Fossil Plants, a Manual for Students of Botany and Geology," by A. C. Seward, F.R.S., vol. ii.; "The Morphology of Plants," by J. C. Willis; and new editions of Scott's "A Treatise on Determinants," by G. B. Mathews, F.R.S.; and "A Manual and Dictionary of the Flowering Plants and Ferns," by J. C. Willis.

The list of Messrs. Cassell and Co., Ltd., contains:—"Wild Nature's Ways," by R. Kearton, illustrated; "Nature's Riddles; or the Battle of the Beasts," by H. W. Shepheard-Walwyn, illustrated; and new editions of "The Automobile: its Construction and Management," edited by P. N. Hasluck; "A Manual of Operative Surgery," by Sir F. Treves; and "Elements of Surgical Diagnosis," by A. P. Gould.

Messrs. W. and R. Chambers, Ltd., will issue:—"Medicine, Surgery, and Hygiene in the Century," by Dr. E. H. Stafford; "Discoveries and Explorations of the Century," by Prof. C. G. D. Roberts; "Progress of Education in the Century," by J. L. Hughes and Dr. L. R. Klemm; "Progress of Science in the Century," by Prof. J. A. Thomson; and a new edition of "Practical Mathematics," revised under the supervision of Drs. C. G. Knott and J. S. Mackay.

Messrs. Chapman and Hall, Ltd., direct attention to:—"Man's Place in the Universe, a Study of the Results of Scientific Research in Relation to the Unity or Plurality of Worlds," by Dr. A. R. Wallace, F.R.S., with diagrams; "China, Past and Present," by E. H. Parker, with a map of China; "Life and Sport in China," by O. G. Ready, illustrated; "The Gun, Afield and Afloat," by H. Sharp, illustrated; "Æther and Gravitation," by W. G. Hooper, with diagrams; "A Short Memoir of Isaak Walton and his Friends," by S. Martin, illustrated; and "The Worship of the Dead, the Origin, Nature and History of Pagan Idolatry," by Colonel J. Garnier, R.E., illustrated.

The list of the University of Chicago Press (Chicago) contains:—"The Mental Traits of Sex," by H. B. Thompson; "The Psychology of Child Development," by I. King; "Animal Education," by J. B. Watson; "A History of Matrimonial Institutions," by G. E. Howard, three volumes; "Studies in Logical Theory," edited by J. Dewey; "Physical Chemistry in the Service of the Sciences," by Prof. J. H. van 't Hoff, translated by A. Smith; and "Studies in General Physiology," by J. Loeb, two parts.

Messrs. J. and A. Churchill announce new editions of Bloxam's "Chemistry," revised by Prof. J. M. Thomson and A. G. Bloxam; and "Elementary Practical Chemistry," by Profs. Clowes and Coleman, two parts.

The Clarendon Press will publish:—"The Theory of Continuous Groups," by J. E. Campbell; "Notes on Analytical Conics," by Dr. A. C. Jones; "The Logic of Arithmetic," by Mrs. M. Boole; "Index Kewensis Plantarum Phanerogamarum." Supplementum Secundum, confecerunt T. Durand et B. D. Jackson; Goebel's "Organography of Plants," authorised English edition, by Prof. I. Bayley Balfour, F.R.S., vol. ii.; Pfeffer's "Physiology of Plants," translated by Dr. A. J. Ewart, vol. ii.; and "Plant Geography upon a Physiological Basis," by the late Dr. A. F. W. Schimper, the authorised English edition by Prof. W. R. Fisher, revised by Prof. P. Groom, in four monthly parts, illustrated.

Messrs. Archibald Constable and Co., Ltd., give notice of:—"Motor Vehicles and Motors," by W. W. Beaumont, vol. ii., illustrated; "The Motor Pocket Book," by M. O'Gorman and Cozens-Hardy; "The Engineer in South Africa," by S. Ransome, illustrated; "Liquid Fuel and its Combustion," by W. H. Booth, illustrated; "Dust Destructors," by W. F. Goodrich, illustrated; "Construction in Reinforced Concrete," by C. F. Marsh, illustrated; "Air Engines and Machinery," by G. Halliday, illustrated; "The Lymphatics," by G. Delamere, P. Poirier, and B. Cunéo, illustrated; and "New Methods of Treatment," by Dr. Laumonner, edited by Dr. Sayers.

The *Electrician* Company, Ltd., announce:—"Handbook of the Electrical Laboratory and Testing Room," by Dr. J. A. Fleming, second volume, illustrated; and new editions of the "International Telegraph Convention and Telegraph and Telephone Service Regulations," and "Localisation of Faults in Electric Light Mains," by F. C. Raphael.

Messrs. R. Friedländer and Son (Berlin) give notice of:—"Käferfauna der Balkanhalbinsel," by V. Appelbeck, *Berichte* der Deutschen Chemischen Gesellschaft, reprint of vols. i.–vi., 1868–73; "Die Vögel der palaearktischen Region," by E. Hartert; and "Das Tierreich," Lief. 20.

Messrs. Funk and Wagnalls announce:—"A Guide to Electro-Diagnosis and Electro-Therapeutics," by Dr. T. Cohn.

Messrs. Gibbings and Co., Ltd., promise:—"Science in Arcady," by Grant Allen; "Man and Beast," by Rev. C. Wood; "Geological Stories," by J. E. Taylor; "British Fossils," by J. E. Taylor; "Playtime Naturalist," by J. E. Taylor; and "Sagacity and Morality of Plants," by J. E. Taylor.

The list of Messrs. Charles Griffin and Co., Ltd., includes:—"The Metallurgy of Steel," by F. W. Harbord, with a section on "The Mechanical Treatment of Steel," by J. W. Hall, illustrated; "Precious Stones: their Properties, Occurrences, and Uses," by Dr. M. Bauer, translated by L. J. Spencer, illustrated; "Cyaniding Gold and Silver Ores," by H. F. Julian and E. Smart, illustrated; "The Principles and Practice of Dock Engineering," by Brysson Cunningham, illustrated; "Electricity Control, a Treatise on Electricity Switchgear and Systems of Transmission," by L. Andrews, illustrated; "The Micrography of Steel, a Handbook of the Methods Employed in the Investigation of the Microstructure of Steel and its Constituents," by F. Osmond and J. E. Stead, F.R.S., with an appendix including Mr. Stead's latest researches, illustrated; "The Elements of Mining and Quarrying," by Prof. C. Le Neve Foster, F.R.S., illustrated; "Fire and Explosion Risks, a Handbook of the Detection, Investigation, and Prevention of Fires and Explosions," by Dr. von Schwartz, translated from the revised German edition by C. T. C. Salter; "Applied Anatomy: a Treatise for Students, House Surgeons, and for Operating Surgeons," by Dr. Edward H. Taylor, illustrated; "The Chemistry and Pathology of the Urine," by Dr. J. D. Mann, illustrated; "Methods and Calculations in Public Health and Vital Statistics," by Dr. H. W. G. Macleod, illustrated; "Milk: its Production and Uses, with Chapters on Dairy Farming, the Diseases of Cattle, and on the Hygiene and Control of Supplies," by Dr. E. F. Willoughby, illustrated; "A Text-book of Physics," by Profs. J. H. Poynting, F.R.S., and J. J. Thomson, F.R.S., vols. on heat, light, magnetism and electricity; and new editions of "The Cyanide Process of Gold Extraction, a Text-book for the

Use of Metallurgists and Students at Schools of Mines, &c.," by Prof. J. Park, illustrated; "A Manual of Marine Engineering: Comprising the Designing, Construction, and Working of Marine Machinery," by A. E. Seaton, illustrated; and "Central Electrical Stations: their Design, Organisation, and Management," by C. H. Wordingham, illustrated.

Messrs. Gurney and Jackson will issue vol. i., containing parts i. and ii., of an enlarged edition of Dr. G. Lunge's "Theoretical and Practical Treatise on the Manufacture of Sulphuric Acid and Alkali."

Mr. W. Heinemann's list includes:—"The Regions of the World," edited by H. J. Mackinder, vol. iv., India, by Colonel Sir T. Holdich, vol. v. North America, by I. C. Russell; "The Founder of Mormonism, a Psychological Study of Joseph Smith, jun.," by J. W. Riley; "The Nature of Man, Studies in Optimistic Philosophy," by Prof. E. Metchnikoff, authorised English translation, edited by Dr. P. C. Mitchell, illustrated; and in the Dainty Nature Series, "The Brook Book," by M. R. Miller, illustrated.

Mr. R. Brimley Johnson promises:—"Mrs. Piper and the Society for Psychical Research," by M. Sage, translated.

Mr. Henry Kimpton's list is as follows:—"Bacteriology, a Manual for Students and Practitioners," by Dr. F. C. Zapffe, illustrated; and new editions of "The Physiological Feeding of Infants," by Dr. E. Pritchard; "The Treatment of Disease by Electric Currents," by Dr. S. H. Monell, illustrated; "Elements of Correct Technique," by Dr. S. H. Monell; "Medical German, a Manual Designed to Aid Physicians in their Intercourse with German Patients and in Reading Medical Works and Publications in the German Language," by S. Deutsch.

Mr. John Lane gives notice of:—Handbooks of practical gardening, edited by H. Roberts, illustrated: "The Book of Herbs," "The Book of Shrubs," "The Book of the Daffodil," "The Book of the Lily," "The Book of Topiary," "The Book of Town and Window Gardening," "The Book of Rarer Vegetables," "The Book of the Iris," and "The Book of Garden Furniture."

Mr. F. Lehmann (Stuttgart) announces:—"Das Mineralreich," by Prof. R. Brauns.

Messrs. Crosby Lockwood and Sons direct attention to:—"Watch Repairing, Cleaning, and Adjusting," by F. J. Garrard, illustrated; "An Elementary Treatise on Hoisting Machinery, including the Elements of Crane Construction and Descriptions of the Various Types of Cranes in Use," by J. Horner; "Gas and Oil Engine Management, a Handbook for Users, being Notes on Selection, Construction, and Management," by M. P. Bale; "An Introduction to Pure and Applied Geometry," by E. Sprague, illustrated; and new editions of "Clocks, Watches, and Bells for Public Purposes," by E. Beckett, Lord Grimthorpe, illustrated; and "The Elements of Electrical Engineering, a First Year's Course for Students," by T. Sewell, illustrated.

The announcements of Messrs. Longmans and Co. include:—"A Social History of Ancient Ireland, Treating of the Government, Military System and Law, Religion, Learning and Art, Trades, Industries and Commerce, Manners, Customs and Domestic Life of the Ancient Irish People," by Dr. P. W. Joyce, 2 vols., illustrated; "The Great North-West and the Great Lake Region of North America," by P. Fountain; "First Lessons in Observational Geometry," by Mrs. W. N. Shaw; "Education as Adjustment, Educational Theory Viewed in the Light of Contemporary Thought," by Prof. M. V. O'Shea; "Queries in Ethnography," by Dr. A. G. Keller; and "Steam Boilers, their Theory and Design," by Prof. H. de B. Parsons, illustrated.

Messrs. Luzac and Co. will issue:—"The History of Philosophy in Islam," by T. J. de Boer, translated by E. R. Jones; and "The Indian Sect of the Jainas," by T. G. Bühler, translated by Dr. J. Burgess.

Messrs. James Maclehose and Sons (Glasgow) announce:—"The Principal Navigations, Voyages, Traffics, and Discoveries of the English Nation made by Sea or Overland to the Remote and Farthest Distant Quarters of the Earth at any Time within the Compass of these 1600 Years," by Richard Hakluyt, preacher and sometime student of Christ Church in Oxford, in 12 vols.; "Museums, their History and their Use, with a Bibliography and List of Museums in the United Kingdom," by Dr. D. Murray, 3 vols.

In the announcements of Messrs. Macmillan and Co., Ltd., we notice:—"The Life of Sir William Henry Flower, F.R.S.," by C. J. Cornish, with photogravure portraits; "The Native Tribes of the Northern Territory of Australia," by Prof. B. Spencer, F.R.S., and F. J. Gillen, illustrated; "Wild Tribes of the Malay Peninsula," by W. W. Skeat, illustrated; Cambridge Natural History, illustrated: vol. vii., "Balanoglossus, &c.," by Dr. S. F. Harmer, F.R.S., "Ascidians and Amphioxus," by Prof. W. A. Herdman, F.R.S., "Fishes," by Dr. W. Bridge and G. A. Boulenger, F.R.S.; vol. i., "Protozoa," by Prof. M. Hartog, "Sponges," by Prof. W. J. Sollas, F.R.S., "Jelly-fish, Sea-anemones, &c.," by Prof. S. J. Hickson, F.R.S., "Star-fish, Sea-Urchins, &c.," by Prof. E. W. MacBride; vol. iv., "Spiders, Mites, &c.," by C. Warburton, "Scorpions, Trilobites, &c.," by Dr. M. Laurie, "Pycnogonids," by Prof. D'Arcy W. Thompson, "Linguatulida and Tardigrada," by A. E. Shipley, "Crustacea," by Prof. W. F. R. Weldon, F.R.S.; "Education, and other Subjects," by the Right Hon. Lord Avebury, F.R.S.; and new editions of "A Handbook of Metallurgy," by Prof. C. Schnabel, translated and edited by Prof. H. Louis, 2 vols., illustrated; and "A Systematic Survey of the Organic Colouring Matters," by Drs. G. Schultz and P. Julius, translated and edited, with extensive additions, by A. G. Green.

Messrs. Methuen and Co.'s list contains:—"The Gods of Egypt," by Dr. A. E. W. Budge, 2 vols., illustrated; "The Elements of Metaphysics," by A. E. Taylor; "The Way to be Healthy and Wealthy and Wise; What to Wear and the Way to Wear it," by Mrs. C. Muller; and "Prehistoric Man in England," by Dr. B. C. A. Windle, F.R.S., illustrated.

Mr. G. A. Morton (Edinburgh) promises:—"The Life History of British Lizards," by Dr. G. Leighton, illustrated.

Mr. Murray promises:—"A Manual of Pathology," by Prof. S. Martin, illustrated; "Eleanor Anne Ormerod, LL.D., Economic Entomologist, Autobiography and Correspondence," edited by Prof. R. Wallace, illustrated; "Some Indian Friends and Acquaintances," by Lieut.-Colonel D. D. Cunningham, F.R.S. This volume deals with the habits of some of the commoner bird and animal inmates of the streets and gardens of Indian towns as observed during a residence of nearly thirty years' duration in Bengal; "The Bacteriology of Milk, with Special Chapters on the Spread of Disease by Milk and the Control of the Milk Supply," by Dr. G. Newman and H. Swithinbank, illustrated; "Artillery and Explosives, Essays and Lectures Written and Delivered at Various Times," by Sir A. Noble, K.C.B., F.R.S., illustrated; "Signs of Life, a Series of Lectures on Physiology," by Dr. A. D. Waller, F.R.S., illustrated; "Heredity," by Prof. J. A. Thomson, illustrated (the Progressive Science Series); "The Home Mechanic," by J. Wright, illustrated; "Growth and Spread of Culture," by Prof. E. B. Tylor, F.R.S., illustrated; "Animal Life," by Prof. W. B. Bottomley; "Plant Life," by Prof. W. B. Bottomley; "Algebra," part ii., by E. M. Langley and S. R. N. Bradly; "Telegraphs and Telephones," by Sir W. H. Preece, K.C.B., F.R.S.; "The Calculus for Artisans," by Prof. O. Henrici, F.R.S.; "The Elements of Moral Philosophy," by Prof. M. C. Sen; and a new edition of "Primitive Culture, Researches into the Development of Mythology, Philosophy, Religion, Language, Art and Custom," by Prof. E. B. Tylor, F.R.S.

Messrs. George Newnes, Ltd., will publish:—"Beautiful and Rare Trees and Plants," by the Earl Annesley, illustrated; and in the Library of Useful Stories: "The Story of the Atlantic Cable," by C. Bright, illustrated; and "The Story of the Extinct Civilisations of the West," by R. E. Anderson, illustrated.

In the list of Messrs. C. Arthur Pearson, Ltd., we observe:—"The Romance of Modern Engineering," by A. Williams, illustrated; and a new edition of "From Franklin to Nansen," by G. F. Scott, illustrated.

Messrs. G. P. Putnam's Sons announce:—"The Law of Mental Medicine," by T. J. Hudson; "Sociology: the

Science of Human Society," by Dr. J. H. W. Stuckenberg; "Psychology and Common Life, a Survey of the Present Results of Psychical Research, with Special Reference to their Bearings upon the Interests of Everyday Life," by F. S. Hoffman; "Christopher Columbus," by J. B. Thacher, 3 vols., illustrated; and a new edition of "Thinking, Feeling, Doing," by Dr. E. W. Scripture.

Mr. Grant Richards promises:—"The Law of Evolution: its True Philosophical Basis," by J. Scouller; and a new illustrated edition of "Pioneers of Evolution," by E. Clodd.

Messrs. Rivingtons' list contains:—"Arithmetical Types and Examples," by W. G. Borchardt; and Rivingtons' Junior Mathematics, by H. G. Willis, "Arithmetic," part ii.

In the list of Messrs. George Routledge and Sons, Ltd., are to be found:—"The Management of Infancy and Childhood in Health and Disease," by Dr. H. Barratt; "Tube, Train, Tram, and Car, a non-Technical Description of Electric Locomotion," by A. H. Beavan; "Nature Study Readers," edited by J. C. Medd; "Electric Locomotion," by Sir W. Preece, K.C.B., F.R.S.; and a new edition of Morris's "British Butterflies."

The Sanitary Publishing Co., Ltd., announce:—"The Zymotic Enquiry Book," by J. Storey; "The Full Solution of the Sewage Problem, being the Presidential Address to the Association of Managers of Sewage Disposal Works at Carshalton, March 28, 1903," by W. D. Scott Moncrieff; "The *Sanitary Record* Diary and Year-Book"; "The *Sanitary Record* and Journal of Sanitary and Municipal Engineering, &c.," by Dr. W. Robertson; and new editions of "Disinfection and the Preservation of Food, together with an Account of the Chemical Substances used as Antiseptics and Preservatives," by Dr. S. Rideal; and "The Purification of Sewage and Water," by W. J. Dibden.

The Walter Scott Publishing Company, Ltd., are adding to their "Contemporary Science Series":—"Morals: a Treatise on the Psycho-Sociological Bases of Ethics," which is a translation, by W. J. Greenstreet, of Duprat's "La Morale"; "Consumption, its Nature, Causes, Prevention, and Cure," by Dr. S. de Plauzoles; "Indigestion, its Prevention and Cure," by Dr. F. H. Alderson; and a new edition of "An Introduction to Comparative Psychology," by Prof. C. Lloyd Morgan, F.R.S.

Messrs. Smith, Elder and Co., give notice of:—"A Naturalist in the Guianas," by E. André, illustrated; "Doctors and their Work, or Medicine, Quackery, and Disease," by R. Brudenell Carter.

The announcements of Messrs. Swan Sonnenschein and Co., Ltd., include:—"A History of Contemporary Philosophy," by Prof. M. Heinze, translated by Prof. W. Hammond; "Physiological Psychology," by Prof. W. Wundt. A translation of the fifth and wholly rewritten (1902–3) German edition, by Prof. E. B. Titchener, in three volumes, vols. i. and ii., illustrated; "The Philosophy of Auguste Comte," by Prof. L. L. Bruhl, translated with notes and index by the Hon. Mrs. de Beaumont-Klein; "Some Popular Philosophy," by G. H. Long; "The Student's Text-book of Zoology," by A. Sedgwick, F.R.S., vol. ii., illustrated; "The Fourth Dimension," by C. H. Hinton, illustrated; "Fatigue," by Dr. Mosso, translated by W. B. Drummond, illustrated; "Cancer: Nature's Own and Only Remedy," by Dr. C. Carillo; "Specimens of Bushman Folklore," by Dr. W. H. J. Bleek and Miss L. C. Lloyd; and a new edition of "Introduction to the Study of Organic Chemistry," by J. Wade, illustrated.

The list of the University Tutorial Press, Ltd., comprises:—"Modern Navigation," by Rev. W. Hall; "The Shilling Arithmetic"; "The Key to the New Matriculation Algebra"; "The School Arithmetic," by W. P. Workman; "Advanced Botany," by J. M. Lowson; "Graphical Representation of Algebraic Functions," by C. H. French and G. Osborn; and new editions of "The Tutorial Dynamics" and "The Tutorial Statics," by Dr. W. Briggs and Prof. G. H. Bryan, F.R.S.; "Advanced Magnetism and Electricity," by Dr. R. W. Stewart; "First Stage Magnetism and Electricity," by Dr. R. H. Jude; "Advanced Mechanics," vol. i., Dynamics; vol. ii., Statics, by Dr. W. Briggs and Prof. G. H. Bryan, F.R.S.; and "A Higher Text-book of Magnetism and Electricity," by Dr. R. W. Stewart.

Mr. T. Fisher Unwin gives notice of:—"Big Game Shooting and Travel in South and East Africa," by F. R. H. Findlay, illustrated; "The Mystics, Ascetics and Saints of India," by J. C. Oman, illustrated; "Bird Life in Wild Wales," by J. A. W. Bond, illustrated.

Messrs. Whittaker and Co. will issue:—"Electric Traction, a Practical Handbook on the Application of Electricity as a Locomotive Power," by J. H. Rider; "Electric Lighting and Power Distribution," by W. P. Maycock, vol. ii.; "Friction and its Reduction," by G. U. Wheeler; and new editions of "The Dynamo," by C. C. Hawkins and F. Wallis; "Electricity in its Application to Telegraphy," by T. E. Herbert; and "The Alternating Current Circuit and Motor," by W. P. Maycock.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The election of a professor of physiology in succession to Sir Michael Foster will take place on November 6, and the election to the chair of mechanism and applied mechanics, vacant by the resignation of Prof. Ewing, on November 14. Candidates are requested to communicate with the Vice-Chancellor.

Mr. J. M. Dodds, Peterhouse, and Mr. E. W. Barnes, Trinity, have been appointed moderators, and Mr. A. Berry, King's, and Mr. A. S. Ramsey, Magdalene, examiners for the mathematical tripos, 1904.

Mr. J. E. Wright, senior wrangler 1900 and Smith's prizeman 1902, and Mr. H. A. Webb, third wrangler 1902, have been elected to fellowships at Trinity College.

The Duke of Norfolk has contributed 8000*l.* towards the endowment of a university in Sheffield, if the charter be granted. Sir F. Mappin, Sir H. Stephenson, and the Sheffield Corporation Tramways committee have also each given 5000*l.*

In some American colleges there is a system by means of which the work done throughout the various terms of the college course is taken into account in awarding a student a degree. The plan adopted is known as the credit system. Thus in the current "Year Book" of the Michigan College of Mines, there is published an outline list of courses of instruction arranged in order of sequence, and under each main subject is given the number of attendances which must be made at the classes in different branches of that subject in order to secure certain credits. To take two instances, under the heading mathematics we find "spherical trigonometry, six times a week, five weeks; to count as three-tenths of a credit." Or, under physics, "light, six hours a week, twelve weeks; to count as two-tenths of a credit," and so on. By some such plan in this country regularity of attendance by students at their classes would be quite assured.

Mr. S. D. Chalmers has been appointed head of the new department of technical optics at the Northampton Institute, Clerkenwell. Evening classes in technical optics were started at the Northampton Institute as part of the work of the Applied Physics Department in the session 1898–99. In the first session the students largely consisted of those who desired to take the examinations of the Spectacle Makers' Company, and the work was confined to lectures and laboratory work. In the following session an optical workshop was added, and an increasing number of students engaged, professionally or otherwise, in optical work have in recent years been enrolled as students. Owing to the assistance of the London Technical Education Board, it has now become possible to separate the department of technical optics from that of applied physics, and place it in charge of a responsible head who can devote his whole time to its organisation and development.

The following entrance scholarships in connection with medical schools have been awarded:—St. Mary's Hospital Medical School—natural science scholarship, 145*l.*, G. E. Oates, St. Paul's School; natural science scholarships, 78*l.* 15*s.*, (1) J. E. L. Johnston, Epsom College and St. Mary's Hospital, (2) W. E. Haigh, Bradford Technical College; natural science scholarship, 52*l.* 10*s.*, D. W. Daniels, Wyggeston Schools, Leicester; university scholar-

ships, 63*l.*, (1) W. A. E. Dobbin, University College, Cardiff, (2) E. Beaton, Portsmouth Grammar School and Caius College, Cambridge. London Hospital Medical College—first prize, entrance science scholarship, 120*l.*, W. H. Palmer; second prize, entrance science scholarship, 60*l.*, J. E. Scudamore; third prize, entrance science scholarship, 35*l.*, J. P. Johnson; anatomy and physiology prize, scholarship open to students of Oxford and Cambridge, scholarship, 60*l.*, H. S. Souttar, University of Oxford. King's College, London (Faculty of Medicine)—medical entrance, 50*l.*, W. T. Briscoe and W. D. Sturrock (equal); Sambrooke (science), 100*l.*, E. Gauntlett; Warneford (arts), 100*l.*, O. J. W. Adamson.

PROF. E. A. SCHAFER, F.R.S., delivered the introductory address to the medical students at the Yorkshire College, Leeds, at the opening of the winter session on October 1. The object of the address was to offer practical suggestions with regard to the manner in which a medical curriculum might be mapped out in existing circumstances. It was appalling to think, said Prof. Schafer, that many people who passed as highly educated had absolutely no knowledge of any of the sciences except, perhaps, mathematics. He went on to say that, as a subject of general education, scientific knowledge was an absolutely essential preliminary to the study of medicine, and that because such knowledge was not imparted in our schools it had become necessary to incorporate into the medical curriculum, and in so far to burden it with, courses of preliminary science.

THE distribution of medals, prizes, and diplomas to the students of the Royal College of Science, South Kensington, took place on October 8, when Prof. J. B. Farmer, F.R.S., delivered an address, in the course of which he said it was still unfortunately true that many people of influence, while freely admitting the claims of science as a factor of ever-growing importance in the world of production and industry, nevertheless, when they said they wanted more technical education in the country, did not really want either science or education at all. What they did desire was merely some ready means of instruction that should adapt the knowledge already in sight to industrial and technical purposes. He believed in securing a more widespread and intelligent interest in the meaning of science and the modes by which knowledge might be really advanced. Chief among these was assuredly research.

IN distributing the prizes to the successful students of the Halifax Municipal Technical School last week, Mr. Bryce, while commending the study of commerce as a matter of science and philosophy, urged the authorities at Halifax to fix their attention principally to applied science. "But," he added, "our experience, and that of Germany and the United States, has shown that applied science, to be valuable, must be in connection with theoretical science, and in this country there must be ampler provision for teaching the higher branches of theoretical science if we are to make progress with those branches of science concerned with the practical arts. There is no reason in the world why England should not have as great a career in commerce and manufactures in the future as in the past. A country which wishes to keep abreast of modern trade must keep abreast of modern science. We have been falling behind in the study of science and its application to our industries in this modern world of ours. Science is king, and the commercial and industrial future is with the nations able most completely to master and apply the forces of nature in the most economical way."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 5.—M. Albert Gaudry in the chair.—The influence of water on the structure of the aerial roots of orchids, by M. Gaston **Bonnier**. Contact with water produces an effect on the aerial roots of many orchids, either by preventing the sclerification or lignification of the tissues of the central cylinder, a result which seems natural when compared with the modifications of the roots of aquatic plants, or by provoking a reaction tissue in the pericycle, capable of protecting the rest of the cylinder against the action of water.—On a class of linear differential equations, by M. Alexander **Chessin**.—The conditions which determine the sign and the magnitude of electrification by contact, by M. Jean **Perrin**. The contact charge between a solid and a liquid can be readily studied by means of electrical osmosis, the charge being always greater when the body is a good ioniser, such as water.—The heats of combustion of organic compounds considered as additive properties; alcohols and phenols, ether-oxides, aldehydes and ketones, by M. P. **Lemoult**. By assigning definite values to certain atomic groupings it is possible to calculate the heats of combustion of organic compounds of the above-mentioned classes with considerable accuracy.—The action of phosphorous acid upon mannite; remarks on mannide, by M. P. **Carré**. The ether

$$P_2(OH)_4.O_2(CH_2)_2.(CH.OH)_4$$

is first formed, a phosphite of mannide being ultimately produced.—Derivatives and products of oxidation of nitropyromucic acid, by M. R. **Marquis**. This acid is totally destroyed by oxidation with permanganates, chromic acid or nitric acid, but with sodium peroxide gives nitrous and fumaric acids.—Researches on the formation of azo-compounds. The reduction of ortho-nitrobenzyl-methyl ether oxide, by M. P. **Freundler**.—On the affinities of the genus Oreosoma, by M. G. A. **Boulanger**.—The action of solutions of salts of the alkalis and alkaline earths on fish, by M. Michel **Siedlecki**.—On the genus Ascodesmis, by M. P. A. **Dangeard**.—Researches on the transpiration of green leaves, either the upper or lower face of the leaf being illuminated, by M. ANCIENT CALENDARS.

Ancient Calendars and Constellations. By the Hon. Emmeline M. Plunket. Pp. xvi + 263. (London: Murray, 1903.) Price 9*s.* net.

THIS fascinating work consists of a series of reprints, arranged in logical order, of papers contributed at different times, chiefly to the *Proceedings* of the Society of Biblical Archæology. Altogether they give us an able summary of what is now known respecting the ancient calendars of the Babylonians, Egyptians, Indians, and Chinese, and a very interesting discussion of the vexed question of the origin of the ancient (especially the zodiacal) constellations, on which subject the author has succeeded in throwing fresh light, her conclusions being corroborated by approaching the question of precessional change from different points of view.

The first chapter is on the calendar of the Accadians, who possessed the country watered by the Euphrates and Tigris before the Semitic conquest. Now this calendar was sidereal, not tropical like ours; it was founded, that is to say, on the positions of the sun amongst the zodiacal constellations, not those with respect to the equinoxes. Although the importance to us in these climates of seasonal changes leads us to make our calendar conform in length to the tropical year, as it is called, yet reminiscences of the old usage remain. Thus in the "Nautical Almanac" the sun is said to enter Aries at the time of the vernal equinox, though he is really then situated in the constellation Pisces; and this having excited the surprise of some people who in these days dabble in astronomical questions without having studied them, the superintendent has, beginning with this year, tried to help them by inserting "sun enters *sign* Aries." But as it has generally been erroneously supposed that most of the ancient calendars began the year with the vernal equinox or thereabouts (in this way the old Roman usage made March the first month in the year, whence we still have September to December nominally the seventh to the tenth months), the conclusion was drawn that the zodiacal constellations were formed into a series to mark the different times of the year at an epoch when the sun was really entering Aries at the vernal equinox, which would be about three thousand years ago.

The Accadian calendar, however, it is now known, went back ages before that, and Miss Plunket puts forth the very probable theory that the true date of its commencement and of the twelve Mazzaroth (if we may use the Hebrew term for the zodiacal signs) was about B.C. 6000. That the initial sign was from the first the Ram (of the eminence of which we have so many indications in Egyptian antiquities) there seems no reason to doubt, but our author suggests that the year was made to begin, as we begin it now, about the time, not of the vernal equinox, but of the winter solstice. Eight thousand years amount to about a third part of the *annus magnus*, during which a whole round of precessional change is effected, and the sun eight thousand years ago would be at the beginning of Aries about the time of the winter solstice. This suggestion seems to be a key which unlocks the door to the explanation of many difficulties.

But we must pass on, for our hope is that nearly all our readers will study this volume for themselves. The second chapter is devoted to the constellation Aries and the importance attributed to it in ancient calendars. It is true that the surpassing importance to the Egyptians of the rising of the Nile, which takes place about the time of the summer solstice, led them in early times to transfer the beginning of the year to that season. But every student of Egyptian antiquities is constantly reminded of the prominence assigned on the monuments to the ram, or rather the head of the ram, which marks the position of the two brightest stars in the constellation. Other indications are pointed out from the orientation of the Egyptian temples of the importance attached to the stars of Aries. How this was carried afterwards into Greece is explained in the last chapter of Sir Norman Lockyer's "Dawn of Astronomy," and we may direct attention to two interesting articles by the same writer in NATURE for January 16 and May 29, 1902, on "The Farmers' Years," in which it is shown that not merely temples, but dolmens and cromlechs, were oriented to the sun when half-way between the solstices and equinoxes. Miss Plunket says:—

"As we further study the records of antiquity, now within our reach, it will, I believe, become evident that not only the Egyptians, but also all the great civilised nations of the East had traditions of a year beginning when the sun and moon entered the constellation Aries—such a year as that in use amongst the Babylonians during their long existence as a nation, and such as that which is used by the Hindus in India to this present day" (p. 41).

The ancient Median calendar is next dealt with. Its starting-point seems to have been about B.C. 3000, when the sun was in Taurus at the vernal equinox. The adoption of this by the conquering Assyrians was probably the cause of their fondness for Tauric symbolism and our present familiarity with the Assyrian bull. Miss Plunket thinks that they also adopted in part the religion they found there, on the same principle that induced Sargon, after he had repeopled the conquered kingdom of Samaria, to send one of the former priests to teach the new inhabitants "the manner of the God of the land" (2 Kings, xvii. 26). She contends that Assur, the name of the great god of the Assyrians, is, in fact, a modification of the Aryan word Asura. Several other points are elucidated in the Median calendar, and the cause of the prominence given to some ultra-zodiacal stars, particularly Altair or α Aquilæ.

We now pass on to the Indian and Chinese calendars. When Sir William Jones opened out such a flood of light upon ancient Indian lore, there were many scholars who refused to accept the antiquity of the astronomy of the Brahmins, and would have it that they derived their calendar from the Greeks after the conquests of Alexander the Great. But since that time the spade has effected as great a revolution in archæology as the spectroscope has subsequently done in astronomy. When Sir George Cornewall Lewis pub-

lished his "Historical Survey of the Astronomy of the Ancients" in 1862, he threw cold water upon the attempts which had then been made to decipher the cuneiform inscriptions. He died the year after, just forty years ago last spring; had he survived until now, very different would have been the line which he must have taken. The wealth of the material since accumulated has made it impossible to reject the conclusions of Assyriologists, and though some of the early attempts have necessarily been modified, we have enormous results now in our hands from the library of Assurbanipal and other sources which cannot in the main be gainsaid. The consequences are indirect as well as direct. For if the Assyrian and Babylonian calendars are so ancient, there is no longer any reason to call in question the antiquity also of those of India, or to suppose that they derived this knowledge from the Greeks, who themselves express great respect for the Indian lore.

Now, with regard to the Chineses, if we may follow the obsolete, but perfectly correct, form used by Milton ("Paradise Lost," iii., 438), Miss Plunket's chapter on their calendar-system is worthy, like the rest of her book, of careful perusal. In China the year is now tropical, and does not begin either at the winter solstice or the vernal equinox, but at a time midway between these. But the Gregorian length of the calendar-year was really introduced into that country by some Jesuit fathers who obtained great influence at the Chinese Court early in the seventeenth century. The date used as that of the commencement of the year began much earlier. Their old reckoning was reformed by the Emperor Tchuen about the year corresponding to B.C. 2500, and many indications point to the conclusion that it originally began, like the Accadian calendar, at the winter solstice about B.C. 6000. Miss Plunket comments on the circumstance that this is two thousand years before the creation of man according to the Ussherian chronology, formerly inserted in the margins of our Bibles; but she rightly remarks that a consideration of the variations of the readings in different ancient versions has shown that no reliance can be placed on the Ussher theory, and his dates are accordingly not inserted in the margin of our revised version.

On one point it may be worth while to take exception to a remark by our author about the Julian reformation. There is every reason to believe that it was then known that the true length of the year was several minutes short of 365¼ days, but Cæsar probably thought the insertion of a bissextile every fourth year was near enough for all practical purposes. It was unfortunate that his rule was at first misunderstood. But Pope Gregory, in 1582, not only ordered certain future centurial leap-years to be dropped, but omitted ten days from the calendar that the vernal equinox (and other seasons) might fall as at the epoch of the Council of Nicæa. Miss Plunket concludes these chapters by once more directing attention to the identity of the earliest astronomical traditions of the nations of the east, which suggests matter for reflection. Her book is excellently illustrated throughout, but the second part consists of a series of illustrations of ancient constellations with descriptive letterpress; although we have not space to enter into this at length, we cannot refrain from mentioning the ingenious suggestion that the position of Pegasus was originally upright, the horse striking the vase of Aquarius with his hoof (p. 251). The whole is very carefully printed, and a full index is provided.

W. T. L.

PHYSIOLOGICAL CHEMISTRY.

A Laboratory Manual of Physiological Chemistry. By Ralph W. Webster, M.D., Ph.D., and Waldemar Koch. Pp. 107; 21 plates. (Chicago: the University of Chicago Press; London: William Wesley and Son, 1903.) Price 6*s.* 6*d.* net.

THE introduction to this manual is written by Dr. A. P. Mathews. He dwells upon the rapid development of physiological chemistry, and the efforts which are being made to bring it into closer touch with the biological sciences. He therefore considers it necessary that the science should be presented in a broader way than has hitherto been the case, and implies that the present manual meets this requirement. I therefore proceeded to study the work with considerable expectations of profit, especially when I considered that it was an outcome from the laboratories of the University of Chicago, which have, in recent years, produced so much of original and valuable work in various physiological fields.

I have closed the book with a feeling of great disappointment. The ideal the authors have set before them has not been realised; in fact, it is not often I have read a book which is so full of faults. It has a few good points; every teacher can always learn something from other teachers; the idea of inserting a chapter on the general characters of the cell, taking yeast as an example, is a good one; the directions given for the examination of milk from the sanitary standpoint form a new and useful departure in such text-books. In several other particulars, a competent teacher will glean some useful hints in adding to or amending his repertory of class exercises.

It was, however, for the student that the book was originally written, and for him it is practically useless.

From some points of view the work is a pretentious one, giving information on complex subjects which indicate a desire on the part of the authors to be considered up to date; but this character is lamentably lacking on many questions where one should have expected to find recent and important work described in detail; thus there is no reference to work of Bayliss and Starling on the pancreas, no mention of the distinctions between the euglobulins and pseudoglobulins, and the description of the urinary pigments is hopelessly out of date.

The arrangement of the exercises may be logical as the preface states, but it is absolutely unpractical. For instance, the first exercises the student is set to work out are the preparation of lecithin and cholesterin from the yolk of the egg. The egg may be the starting point of life, but the complicated methods necessary for the obtaining of a complex fat like lecithin hardly

form a suitable introduction to the study of physiological chemistry, but would have come more fittingly after the student knew a little about the nature of the simpler fats. There is, moreover, little or no indication of the relative importance of the substances described; the space devoted to cystin and cerebrin, for instance, is entirely disproportionate to their importance.

The description of the analytical methods is most slipshod; they are usually given in telegraphic or notebook English; they are interlarded with questions, "why is this?" or "what does this mean?" which, in the case of the majority of students, will remain for ever unanswered, for nine out of ten will never take the trouble to "consult this or that text-book," or "ask the instructor," which is the only answer the present work affords.

The omission of small but often important points is not confined to the description of the more complicated methods of analysis, but is seen also in those which are elementary; thus in the directions given for the making of hæmin crystals, the application of heat is omitted; in the description of the Adamkiewicz test, the student is left in doubt as to whether the glyoxylic acid to which the reaction is due is contained in the substance to be tested or the reagents added. In the description of the biuret reaction, no indication is given of its value as a diagnostic test between the native proteids and the products of proteolysis; in the description of the nitric acid test for proteoses, the most characteristic portion of the test, namely, the reappearance of the precipitate on cooling, is omitted; the only experiments relating to blood-clotting are those connected with the inhibitory influence of oxalates; those who follow the directions given for the performance of Hopkins's method of uric acid estimation will fail because of the omission of small details; in Gmelin's test for bile pigments the important detail that *fuming* nitric acid must be used is left out; directions are given for testing for iron in the liver, but no directions for the preliminary removal of blood from the organ; uric acid is spoken of as the result of metabolism of the white blood corpuscles, but the essential fact is omitted that it is from their nuclei, and the nuclei of other cells also, that this substance originates. We are told that ammonium urate is apt to be mistaken for globulin in urine, but no means are furnished of distinguishing the two; and in another part the student is led to suppose that true peptones may appear in the urine. The only method given for the estimation of urea is the hypobromite process, and the apparatus recommended, that of Doremus, is one of the least satisfactory for the carrying out of this test, the importance of which is now mainly historical.

Such are a few of the faults of omission with which the pages abound. Let us next turn to instances of faults of commission, the actual mistakes with which the book bristles. The coagulating points of the muscle proteids are wrongly given, and the most important proteid of all, myosmogen, is altogether left out; histone is classified with the native albumins, and globin with the globulins; for the performance of the biuret test, heating is recommended; in the phenylhydrazine test for dextrose, it is stated that crystals only appear on cooling; indol and tryptophan are spoken of as synonymous; starch is stated to be convertible into sugar by acid in a *few* minutes; in the preparation of serum globulin, water is recommended for washing the precipitate; the sugar formed by the pancreatic juice is stated to be glucose; to obtain the iodine reaction with glycogen boiling with the reagent is the means adopted; the yellow colour of urine is ascribed to a mixture of several pigments not yet isolated, to which are added in brackets the astonishing words "called by Garrod urochrom." Albumose is stated to be a normal constituent of blood; at least that is how I read it, though I admit the passage is so obscure that it might equally well read the other way; the old misstatement that gelatin does not give Millon's reaction is perpetuated; students are led to suppose that the reaction of normal human urine is alkaline; at all events they are told to ascertain whether the alkalinity is due to fixed or volatile alkali; and as a final instance of the careless way in which the book has been prepared, the name of v. Fleischl is persistently misspelt. This does not by any means exhaust the list of glaring errors with which the book abounds, but enough has been said to show that this is an unsafe work to place in students' hands.

W. D. HALLIBURTON.

POPULAR AMERICAN ENTOMOLOGY.

The Insect Folk. By Margaret Warner Morley. Pp. vi+204; illustrated by the author. (Boston and London: Ginn and Co., 1903.) Price 2*s.*

Ways of the Six-Footed. By Anna Botsford Comstock, B.S., Lecturer in Cornell University Extension. Pp. xii+152. (Boston and London: Ginn and Co., 1903.) Price 2*s.*

THESE are two popular publications on the insects of North America, and may conveniently be noticed together, though, except that they are uniform in size and appearance, and are both by ladies, there is little resemblance between them.

The first is for young children, and seems to be intended partly as a reading book, for it is in very simple language, and is mostly in words of one or two syllables, and all long or technical words are explained in a glossary at the end of the book.

We are pleased to see that children are advised to keep insects under observation, and not to kill them, except in the case of those which are injurious.

Neuroptera, Hemiptera, and Orthoptera are the orders dealt with, and the first chapter is on dragonflies, which are more numerous and of more varied colours in America than in Europe.

We may, perhaps, quote one of the longer sentences.

"I once went up the side of a beautiful mountain in North Carolina, where was such a mighty host of cicadas in the trees that I could not hear my companion speak, and a little way off the noise sounded like a torrent of rushing water."

Notwithstanding the simple style of the book, the authoress has contrived to include in it a good deal of information that will be new to most people who are not fairly well acquainted with entomology; and part

of it relates to insects which are found in Europe as well as in America, and it appears to be accurate and trustworthy. We may, however, dispute the statement which we meet with here, not for the first time, that the small cockroach (*Blatta germanica*), called in America the croton bug, "is supposed to have been brought to England by soldiers from the Crimea," if this is supposed to imply that it was then first introduced into England, for it was well known as an inhabitant of most parts of Europe, England included, long before that time, though it may perhaps have become commoner after the Crimean War.

Frequently the information is directly addressed to the children who are supposed to be instructed, as:—

"Mollie wants to know why it would not be a good plan for people who live where there are many mosquitoes to raise dragonflies?"

"That is a very sensible idea, Mollie, and it has been tried."

Mrs. Comstock is already well known as an entomologist, especially as the illustrator of her husband's "Manual for the Study of Insects," &c. Her book consists of a series of ten popular articles on entomology, most of which have previously appeared in magazines. The subjects are "Pipers and Minnesingers" (mosquitoes, cicadas, crickets, &c.), "A Little Nomad" (*Incurvaria acerifoliella*), "A Sheep in Wolf's Clothing" (*Basilarchia archippus* mimicking *Anosia plexippus*), "The Perfect Socialism" (bees, ants, termites and wasps), "Two Mother Masons" (Pelopæus and Eumenes), "The Story we Love Best" (*Ceratina dupla*), "A Dweller in Tents" (*Pantographa limata*), "A Tactful Mother" (Chrysopa), "A Seine Maker" (Hydropsyche), and "Hermit and Troubadour" (Cicada).

The book is written in a popular and attractive, but not childish, style, and is very nicely illustrated. There are forty-seven illustrations altogether, several of which occupy a full page.

OUR BOOK SHELF.

Catalogue of Books, Manuscripts, Maps, and Drawings in the British Museum (Natural History). Vol. i., A—D. Pp. 500. (London: Printed by Order of the Trustees, 1903.)

FEW even of the *habitués* of the Natural History Museum have any adequate idea of the extent and value of the collection of books on natural history (in its widest sense) subjects contained within its walls. Nor is this difficult to account for. Owing to the exigencies of work, the collection is split up into a zoological, a geological, a mineralogical, a botanical, and a general library, the latter containing all those works which treat of subjects belonging to more than one department of the museum. But even this subdivision by no means expresses the real facts of the case, the various departmental libraries being further divided into subsections. For instance, the bird room, the spirit building, the entomological department have each libraries of their own, while even individual officers who have charge of one group of animals possess a collection of books in their own rooms.

In these circumstances there can be no question but that the director has been well advised in recommending the Trustees to sanction the publication of the "Catalogue," of which the first volume is before us, since it is certain that such a series of volumes will be of great interest and value not only to workers in the museum, but likewise to naturalists and bibliographists all over the world.

The collection had its origin in the departmental libraries of the establishment at Bloomsbury, and was largely augmented by purchase, by means of a special Parliamentary grant, at the time of, and subsequent to, the transference of the natural history collections to South Kensington. An important addition was the bequest of the Tweeddale library, some years after the transference. In spite of certain gaps, the collection is believed to be one of the finest in the world. When complete, it is estimated that the catalogue will include some 60,000 entries, the present volume containing about one-fourth of this number.

The editing has been confided to Mr. B. B. Woodward, who, in the present volume, appears to have discharged an arduous task with conspicuous success. Although the work is only an "author-catalogue," many of the entries contain information with regard to the contents of the works, their dates of publication, or other bibliographical detail. It should be added that, on account of their special interest and importance, four subject-headings, namely, atlases, dictionaries, encyclopædias, and gazetteers, have been included. R. L.

A Class Book of Botany. By G. P. Mudge and A. J. Maslen. Pp. xvi + 512. (London: Edward Arnold, n.d.) Price 7s. 6d.

THE scope of this book is somewhat ambitious, for although it is limited to the requirements of intermediate examinations, it takes up in considerable detail the four main branches of botany. Morphology and anatomy are treated in the course of a series of types; classification with special chapters on floral morphology and physiology occupy the second and third parts of the book. Judging by experience, the relegation of morphology to the amount which is distributed throughout the discussion of a series of types is injudicious, because a sound knowledge of external morphology is necessary to the elementary student, partly as a preliminary to anatomy and generally as a foundation for other branches of the subject. It should be pointed out that the authors have not tied down the types to one or two specimens, but, where necessary, additional examples are given; nevertheless, the specific training value of a morphological introduction is wanting. Further, by adopting the type system, the authors provoke comparison with the admirable book written by Dr. Scott, more especially since the cryptogamic types are practically the same in both cases, and Mr. Mudge is not endowed with the same happy power of expression, nor does he display the accuracy which distinguishes the "Structural Botany." The style is, indeed, too rigid, and this only serves to emphasise the numerous mistakes or to give rise to misconceptions. To mention a few instances we find p. 13, "a root . . . always . . . grows downward"; p. 16, "spines have become enlarged and form thorns"; p. 60, "the petiole is polystelic"; and p. 80, a samara is described as a "winged, one-seeded capsule."

Turning to the chapters dealing with classification and morphology of the flower, for which Mr. Maslen is responsible, these are much more satisfactory, and both in choice and arrangement of subject-matter the author's judgment commends itself. The physiological section might with advantage be more practical, and would be much improved by some rearrangement. It is not obvious why the consideration of the absorption of food material by the roots should

be placed after photosynthesis, and after the account of parasites and saprophytes; here it is noticeable that Lathræa is placed amongst carnivorous plants, without any mention of Groom's work. But few practical experiments are suggested, and it would be easy to improve the apparatus depicted in figs. 204, 206, 208, and 219. Finally, the last chapter, in which irritability is discussed, is headed "Movements of Plants," which quite ignores the phenomena of stimulus, and the stimulating source.

In the introduction, the authors state that they have been impressed with the need of a work which should contain all the information which is necessary for certain examinations. On the contrary, the present tendency, and there is much to be said in favour of it, is to bring out smaller books, written by specialists, which deal only with one branch of the subject.

Traité de Chimie physique, Les Principes. By Jean Perrin. Pp. xvi + 300. (Paris: Gauthier-Villars, 1903.)

THIS volume deals with the elements of dynamics, the thermodynamical potential, the phase law and other allied subjects of which a knowledge is indispensable to the modern chemist. The treatment is non-mathematical, but the author indulges in a good many discussions of a philosophical character. In defining the scope and aim of physical chemistry, he refers to the old style of thinking, according to which physics was the science of reversible phenomena, and chemistry the science of irreversible phenomena. The notion of *force* is defined by means of the extension of a stretched elastic string or wire. Why should not this treatment be adopted in books where relations involving mass and acceleration do not play a prominent part? We notice, as a useful feature, that Lord Kelvin's definition of absolute temperature is dealt with at some length. In the preface the author rightly directs attention to the desirability of abandoning such misleading notions as that of absolute in contradistinction to relative velocity, the statement that "heat cannot pass from a cold to a hot body," which is like speaking of an apple passing from one hand to the other, and the prevalent confusion of language in speaking of ideas involving force and energy.

The Arithmetic of Elementary Physics and Chemistry. By H. M. Timpany. Pp. 74. (London: Blackie and Son, Ltd., 1903.) Price 1s.

THIS collection of numerical exercises is very limited in its scope. It is composed of four sections; one includes problems on relative densities, another is devoted to examples on moments and centres of gravity, a third is concerned with the conversion of thermometric scales and with specific and latent heats, while the last deals with the calculation of the weights and volumes of the substances taking part in chemical reactions. Typical examples are worked out for the guidance of the student.

Gisements minéraux. Stratigraphie et Composition. By François Miron. Pp. 157. (Paris: Gauthier-Villars and Masson et Cie, n.d.)

M. MIRON here provides geologists and others with a compact account of numerous non-metalliferous mineral deposits which are useful in numerous branches of technology. A previous volume in the series known as the "Encyclopédie scientifique des Aide-Mémoire," to which the present book also belongs, dealt with those minerals in which the metallurgist is particularly interested, and attention is here chiefly directed to the natural sources of sulphur, nitrates, phosphates, borates, compounds of the alkali and alkaline earth metals, and other minerals.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Human Science and Education.

THERE surely never was a time when there was more need for consideration of the root-principles of higher education. It is generally allowed that we in England are behindhand in the matter, that we have allowed the Germans and Americans to have the start of us. And awaking to this conviction we have a difficulty in seeing in what direction we should move in an attempt to recover our lost ground.

I accede with pleasure to a suggestion of the Editor of NATURE that I should endeavour to lay before his readers some of my views as to the direction in which those studies which have *man* for their subject should move. At first sight it might seem that the present place is inappropriate for a paper of this kind. Yet it is among the students of nature that my contentions as to the study of man are perhaps most likely to find support.

What I plead for is that the two great branches of knowledge, the science of nature and the science of man, should be brought nearer together, that it should be recognised how much they have in common, and that the reasonable votaries of both should make common cause against the same enemies.

The enemy in higher education of the science of nature is the technical spirit, which will not take a wide outlook, which ties all investigation down to narrow points of practice, which does not see that breadth of study and imaginative insight are necessary in our schools of science if we would produce men of real efficacy for the work of the world and not mere technical experts. The enemy of the science of man is the spirit of convention, which is dominated by rhetoric and commonplace, which has no ambition to see the facts of human nature and of history as they really are, but interprets them by tradition by self-interest, by sentiment. And between these two enemies of the children of the light there springs up a natural alliance. The man who has received a narrow technical training may be a good linguist or the like, but is not likely to appreciate a wide humanistic culture. The man who has received a merely conventional literary education may master technical details, but will scarcely understand how the steady growth of science, of ordered knowledge, has changed our whole way of regarding life, religion or society. The two enemies will combine when they can to keep education at its present level, and to ridicule all attempts to provide a really scientific training in universities and schools.

It is scarcely necessary to say much in these days as to the importance of a thorough organisation of the study of nature and natural forces in our colleges. There has been in this matter extraordinary progress in the last thirty years. At any rate it would be an impertinence for me, who have never been trained in any branch of natural science, to dwell on this matter. But while natural studies have moved forward rapidly, those which concern man have in our universities scarcely moved. The course in humanity, and in modern history, is at Oxford almost exactly what it was thirty years ago. Cambridge is less averse to change than Oxford, and has been more mobile; yet it may be doubted whether human studies have imbibed much more of the modern spirit in Cambridge than at Oxford. In the new universities which are springing up on all sides, generally speaking the side of natural science is more or less well developed with teachers and apparatus, but in the matter of history, psychology, archæology and the like they are much to seek. In the case of the new University of London, one sees the germs of better things. Several of the schemes of study there arranged look well on paper. Only funds are needed to set the machine in motion. In London there are great institutions, like the Record Office and the British Museum, which are in the nature of things obliged to be scientific, and one hears great things of the London School of Economics.

I think the readers of NATURE will admit that the slow-

ness and incompleteness with which reorganisation is going on in the studies concerned with man is an undesirable, even a dangerous, fact. The disparity between the two halves of human knowledge has grown so great that there is a fear that almost all young men of original or inventive mind will turn to the study of material nature. It would be foolish to make any comparison between the importance of the knowledge of man's surroundings and the knowledge of his nature, his works, and his history. Both are beyond value. But if the two halves of the human brain, so to speak, work on different plans, what will become of the unity of man himself?

A reason why the votaries of natural science should have some sympathy with those who are endeavouring to remodel humanist studies is that it is from the natural sciences that methods and ideas have flowed into those relating to man. The ideas of continuity, of adaptation to environment, of evolution, were transplanted into historic studies from those of biology, and it was soon found that they flourished almost as well, and bore almost as much fruit, in the new field as in the old. But whereas the highly trained and scientific worker in history, psychology, archæology, and kindred studies is quite alive to the use of the new scientific methods, they have as yet only partially affected education in these subjects, even in our universities. The books used by the students are changed in character, but not the ways of working. Undergraduates are not thoroughly taught the principles of weighing evidence, they are not accustomed to work on the comparative method, they do not acquire historic imagination. They have not learned to judge by evidence rather than by authority, nor rigidly to distinguish degrees of probability.

Of course, education is not, and cannot be, only scientific. To everyone's education there should be other sides. There should be a religious side, in some ways the most important of all. There should be an artistic side. Every boy and every girl should be taught to draw or to play some instrument, and to appreciate good work done in the art which is thus practised. And every student should be taught to use the English language to some purpose, and to appreciate what has been best written in that language, and in one or two other languages. But at present I am not speaking of religious, of artistic, or of literary education, but of scientific education, of the direct training of the faculties for dealing with the facts of the world; and it is my contention that this scientific side of education has been comparatively neglected in the case of those who have not taken up some branch of physical science. In fact, so completely has the really scientific character of such studies as history and archæology and economics and the like been, at least in this country, overlooked that when we hear of a man studying science it is at once assumed that he is giving his attention to the facts of the natural rather than of the human world. But the word science has not and cannot rightly have any meaning but "ordered knowledge." Whatever can be surely known is matter of science.

But I must come to the practical question of the organisation of study, and especially of university study. Knowledge of the physical world has so greatly grown by two things, the improvement of method and the organisation of research. Improved methods of investigation in the study of man and of history have fairly come in: they are scarcely yet fully recognised in schools and universities, but the best authorities in the various branches of the subject are acquainted with them. What is most needed is a new organisation of research.

At present in our universities the spread of better methods in the human studies has principally effected this, that the student works on better text-books. This in itself is something, but not very much. Compare, for example, such a subject as geology. Would it be regarded as sufficient if the students of geology read books in which the latest and most approved views are expressed? Surely not; until the student has grubbed for himself in the chalk pit and the cliff, and learned in museums to recognise the substances belonging to various strata of the earth, he has done nothing worth doing. He must not take results ready made, but must work for himself, see for himself, learn the value of evidence and the touch of fact. I venture to think that the case is the same in human studies. Here also it is of little use to accept the best results, unless the student grasps the grounds on which they are reached. Here also he must for himself work on the data, see why one view is more probable than another, map out the exact state of the evidence.

Our remedy is to adopt in the human sciences organisation and methods of study which have triumphed in the natural sciences. In every college and university there should be, beside the laboratory of the chemist and the dissecting room of the physiologist, work-rooms for the students of man. As regards psychology and anthropology, which are two foundation stones of the arch, this is already conceded. Specimens and apparatus are there acknowledged to be necessary. The same necessity exists as regards other branches of human study. Work-rooms are needed in which the student should be, so far as possible, brought into contact with evidence. All the important books, dictionaries and the like should, of course, be there. And besides, the authorities for the books should be so far as possible put together, facsimiles of documents and of inscriptions, maps, chronicles, coins, seals, and the like. In the economic section every kind of statistics should be at hand. In the department of ancient history there should be casts of inscriptions, photographs of sites, facsimiles of manuscripts, casts of statues and of coins. Even when such objects are not direct authorities for the points of which the student is in search, they form his mind by bringing him into contact with fact and evidence, and they greatly stimulate his imagination by placing him in presence of some of the surroundings of history. The result of work of this kind would be a change of outlook and of method, the substitution of investigation for theory, of science for fancy. It would prepare the student for wider work in the actual world, for which, of course, it would be no substitute but a *propaedeutic*.

Those who teach and organise natural studies are fully alive to the great demands made by the changed state of the world, and are demanding endowment with energy and persistency. They are quite right. But the teachers of human studies are more inert and less keenly alive to the need of expansion. But science, ordered knowledge, is, in spite of all divisions, one, and it will be a great misfortune for the country if in the extension and re-endowment of our university system the necessity of thorough and elaborate investigation of man in all his aspects, his history and his works, falls into the background.

Oxford, October. P. GARDNER.

Uniformity in Scientific Literature.

IN 1894 a committee was appointed by the British Association to inquire into the question of uniformity in the size of the pages of proceedings, transactions, and scientific journals in which original papers are published. The appearance of a number of *Proceedings* of the London Mathematical Society of a different size from its predecessors, in accordance with an announcement circulated as recently as the end of August, suggests that it may be desirable to direct attention to the report of this committee (Brit. Ass. Rep., 1895, p. 77).

In this country all the more important octavo journals in question are printed on either medium or demy paper; as examples we may cite the Royal Society's *Proceedings*, the *Philosophical Magazine*, the *Proceedings* of the Physical Society, &c. A considerable number of foreign journals (*e.g.* Wiedemann's *Annalen*) are of practically the same size. The difference between medium and demy octavo is too small to cause any inconvenience either in placing the volumes together on a shelf or in binding together reprints of papers. In the case of certain American and Italian journals a somewhat larger sized page has been adopted, but the difference is entirely in the margin, the printed portion being in some cases smaller even than in our demy octavo journals. This allows of reprints being cut down for binding with others from the *Philosophical Magazine* or British Association *Report*, and still leaving plenty of margin. Where papers are too long to be published in octavo form, medium and demy quarto are the most prevalent sizes. Here again there is not much to choose between the two, and, as in the case of octavo, the committee decided to recommend the demy size as a standard. The most inconvenient pamphlets to deal with are those in which the paper is too small for binding up

with demy quarto, and the printed page is too large to allow of the paper being cut down to demy or even medium octavo size. The *Atti* of the Lincei Academy may be cited as an important example. Fortunately, however, such exceptions are comparatively few in number, and they include none of the main English journals in which original papers are published on mathematics or physics.

It is my hope that by again directing attention to this matter further uniformity may be secured in the sizes of proceedings and transactions by the gradual elimination of inconvenient sizes, and by the avoidance of further divergences. The size of the new number of London Mathematical *Proceedings* is peculiarly unfortunate, as it is not uniform even with those outstanding foreign journals which do not conform to the recommendations of the committee.

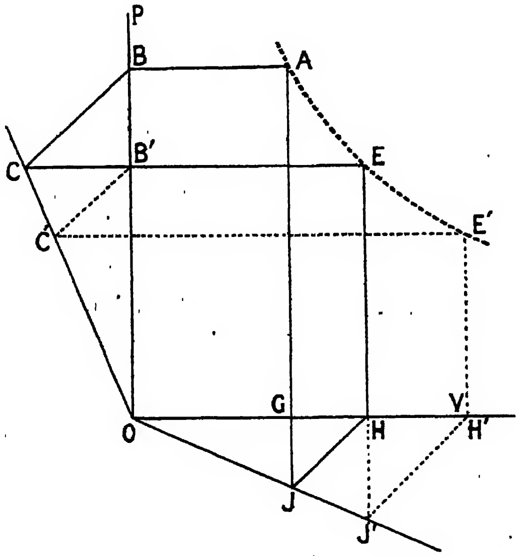
G. H. BRYAN.

Expansion Curves.

MR. STODDART's method of finding points on the curve pv^n = constant, to which Prof. Perry directed attention on October 8 (p. 548), is interesting, but it does not give a great number of convenient points on the curve. If the points A, E, . . . are called (v_1, p_1), (v_2, p_2), . . ., the values of v and p form two series of quantities in continued proportion, *i.e.* such that $v_1/v_2 = v_2/v_3 = \ldots$, and $p_1/p_2 = p_2/p_3 = \ldots$

A modification of the method, bringing out more clearly its essential simplicity, and, moreover, far easier in practice, would be to calculate the positions of *two* points A, E instead of finding A and the specially related angles α, β.

It will then be seen from the diagram, by drawing the lines needful to find a third point (say for definiteness in



the direction of increasing v and decreasing p), that the method advocated is only that of finding the above two series of continued proportionals, and that *any* angles would serve the purpose, all that is necessary being that all the construction lines like JH must be parallel to each other, and similarly all the lines like BC parallel to each other. But no modification of the method will give more than the points I have indicated.

By drawing the tangents at the points so found, the accurate construction of the curve would evidently be facilitated. This can be neatly done by taking care in the choice of the first two points; for in these curves the gradient is $-p \div v/n$, so that the tangent at the point (v,p) cuts the axis of x at the point the abscissa of which is $v(1+1/n)$. Hence if we choose the first two points (v_1, p_1) and (v_2, p_2) so that $v_2 = v_1(1+1/n)$, the tangent at the first point will pass through the foot of the second ordinate, and similarly the tangent at the second point will pass through the foot of the third ordinate, and so on.

Or, if we take $v_2 = v_1\sqrt{(1+1/n)}$, so that $v_3 = v_1(1+1/n)$, the first tangent will pass through the foot of the third ordinate, and so on.

This happens to be approximately the case in Prof. Perry's diagram, which for convenience has been reproduced here with a set of additional construction lines.

Coopers Hill. ALFRED LODGE.

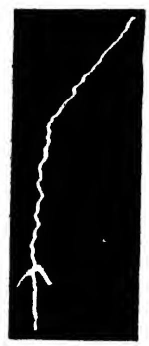
Rocket Lightning.

A PECULIAR species of lightning, bearing a strong resemblance to ascending rockets, was witnessed on the evening of July 22 by two of the professors in Sibpur Engineering College, Howrah, near Calcutta, one of whom wrote me the following careful account in a letter dated the next day. I wrote back suggesting local inquiry in the direction in which the phenomenon appeared, and sending some extracts from Hann's "Lehrbuch der Meteorologie" bearing on the subject. The reply, dated September 1, shows that the suggested inquiry is impracticable.

11 Leopold Road, Ealing, W. J. D. EVERETT.

WE saw some strange lightning yesterday evening at about 9 p.m. It was a clear, moonless night, with just a bank of cloud very low in the S.S.W., with a well-marked edge, height say from horizon (flat) to 5° up. There was a misty cloud above this. These clouds we could only see properly when the flashes came. Stars were visible at about 10° above the horizon at this point, and the sky was quite clear all over elsewhere. Now and then flashes showed from behind the lower cloud (the flashes themselves were mostly hidden, and thunder was not audible). The flashes were not so frequent as usual, say one per minute or so. Generally here they are almost incessant during thunderstorms.

At intervals of three minutes or so, immediately after a flash—which, as common here, was mostly multiple, lasting a second or so altogether—a luminous trail shot straight up to 15° or so, about as fast as, or rather faster than, a rocket, and of very similar appearance, but with minute waves, like ribbon lightning. It was hardly as bright as most lightning. S. and I saw it repeated seven times, and Prof. Brühl (physics) three or four times after we directed his attention to it. He was equally surprised at the novelty, and he has been out here some eighteen years. One of the trails turned off, as shown; the others were about vertical as seen from here. Each grew up steadily from below, and then disappeared at once. The upper end was definite, and did not branch or spread.



In each case it followed immediately on a vivid flash or set of flashes. It was certainly not fireworks of any kind. It terminated in apparently clear sky. Its appearance as a uniformly and very bright ribbon was different from any fireworks. It was somewhat yellowish, not purple as lightning often is. It was much too far off for fireworks to be so high and bright. No thunder was audible.

July 23. W. H. EVERETT.

THANKS for trouble of making extracts from Hann *re* lightning, which, as you say, describe phenomena different from what we saw.

Peake is in charge of the Meteorological Office for India, and did not hear about it, nor did I see anything in the Calcutta newspapers.

There would be practically no Europeans or any competent observers nearer the lightning than we were; as it must have occurred at a spot above the Sunderabunds, a wilderness of waterways and jungle. And there are probably not a score of men in all Bengal who would take serious interest in such lightning if they did happen to see it. I was lucky to have Brühl as a witness, he being an old resident, and one who keeps his eyes open.

It was not like a string of fireballs, for it was of uniform width. But it had, as Hann says of globular lightning, doubtless some connection with the breaking down of the air by the volleys of discharges. W. H. E.

September 1.

Our Winters in Relation to Brückner's Cycle.

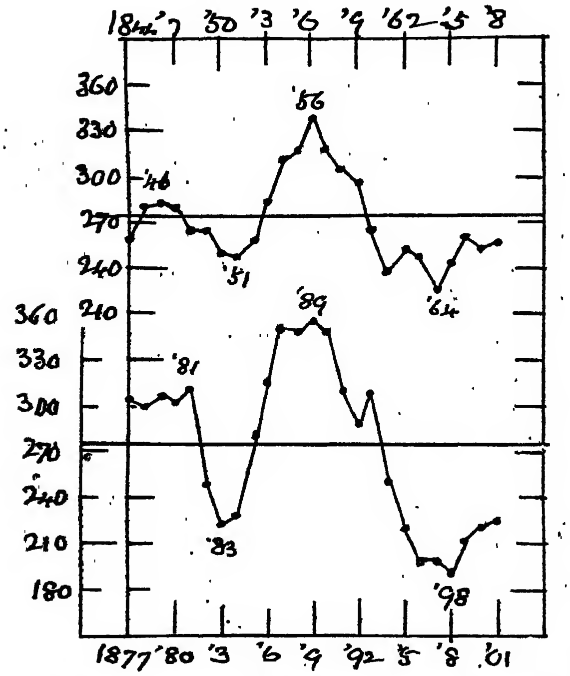
IT was said in Bacon's time that every thirty-five years "the same kind of suite of years and weathers comes about again" (see his essay "Of Vicissitude of Things"), and the important researches of Brückner on this subject are now receiving considerable attention.

The value, 35 years, as used by Brückner, is, of course, an average. The interval from centre to centre of his cold and wet periods (or the opposite) is sometimes as much as 40, sometimes as little as 30. It has been noted, further, that 35 is very nearly three times the sun-spot cycle of 11·1 years.

Now if we look into the variation of certain weather-elements at Greenwich since 1841, it may, I think, be truly said to-day that the same kind of weather has come round again after about 33 years. Let us take *e.g.* our winter seasons as measured by the total number of frost days from September to May.

In the upper curve of the diagram herewith, each year point represents the sum of frost days in five winters so understood; the first (1844) for winters ending 1842–46, the second, winters ending 1843–47, and so on.

Similarly, in the lower curve, each point represents a five-winter group, but thirty-three years later, commencing



Curve showing the variation of frost days from five-year sums for the period 1842—1902.

with 1877, and ending with 1901 (which includes last winter).

There is obviously a general correspondence between these curves; high values in one matched with high values in the other, and low with low. Twenty-five pairs of values being thus compared, there are only four in which the members of the pair are on opposite sides of the average line (273).

Again, we have, in general,

Diminishing cold	1846–51 (5 years)
	1879–83 (4 ,,)
Increasing cold	1851–56 (5 ,,)
	1883–89 (6 ,,)
Diminishing cold	1856–64 (8 ,,)
	1889–98 (9 ,,)

From these last dates there is a rise.

The earlier curve might thus be considered a kind of programme for the series of winters commencing 33 years after the first. It will be interesting, I think, to see how far it continues to be so in the future.

The winters about 1856 and 1889 appear to have been conspicuously cold times. We might, perhaps, anticipate another such time in the early 'twenties, the curve not rising so high between, though, of course, individual winters might be very severe. This seems to be suggested by the course of the curve after 1868, but the correspondence may perhaps fail.

Other examples of such recurrence, corresponding more or less closely, might be given. The long record of Rothesay rainfall (from 1800) will be found worth treatment in this way; conspicuously dry times occur about 1822, 1855, and 1887, and the smoothed curve from 1835 to date may be said to repeat in its main features that from 1802 to 1867.

ALEX. B. MACDOWALL.

An Ant Robbed by a Lizard.

THE following account of the robbery from an ant by a lizard may interest some of your readers.

While walking along the main road on the outskirts of Bordighera yesterday morning, I noticed a strange-looking insect moving across it in a peculiar way. On getting nearer, I saw that what had attracted my notice was a black ant—about an inch long with brown wings—dragging a cricket bigger than itself. It held the cricket by the head, and as the ant moved backwards it drew the cricket towards it. While doing so it entered the shadow cast by my umbrella, and instantly released its hold and got out of the shadow, but finding there was no danger it returned and seized its prey again by the head, and recommenced its backward movement. A low wall ran alongside the road, and when the ant got within six feet of it a common brown lizard appeared on the top of the wall and evidently soon caught sight of the ant, for it ran quickly down the wall and to within two feet of it, when it crouched for a second or two like a cat ready to spring, and then charged the ant, apparently butting the cricket free with its head. Before the ant could regain its hold the lizard seized the cricket in its mouth, and darted up the wall in the direction from which it originally appeared on the scene, leaving the ant running round and round, moving its wings in an agitated manner, vainly searching for its lost prey.

J. W. STACK.

Villa Mona, Bordighera, September 1.

A NEW MECHANICAL THEORY OF THE ÆTHER.[1]

THIS memoir was communicated to the Royal Society in February, 1902, and has now been issued in the dual form of a contribution to the *Philosophical Transactions* and a volume of Prof. Osborne Reynolds's collected papers.

It may safely be described as one of the most remarkable attempts that have been made of recent years to formulate a dynamical system capable of accounting for all physical phenomena at present known. A theory such as is here set forth may not improbably play the same part in modern science that was assumed by the atomic theory and the kinetic theory of gases in the science of the time when these theories were propounded.

If we suppose the ultimate particles—Prof. Reynolds calls them "grains"—constituting the material universe to be either spheres, or what comes to the same thing, point atoms behaving in the same manner as uniform smooth spheres, then it is impossible to assume these grains to be of equal size and distributed at random through space without assuming them (as in the kinetic theory of gases) to be in motion among themselves. On the other hand, a medium in which the motion of the different grains among themselves partakes of the nature of diffusion does not lend

[1] "The Sub-Mechanics of the Universe." By Osborne Reynolds, M.A., F.R.S., LL.D., M.Inst.C.E. Pp. xvii + 256. (Cambridge University Press: Published for the Royal Society of London, 1903.) Price 10s. 6d. net.

itself kindly to the explanation of such phenomena as the propagation of transverse waves. The medium considered in the present investigation is assumed to consist of uniform spherical grains which are so close together as to prevent diffusion, and when in a state of "normal piling" the centre of each grain is supposed to be equidistant from those of twelve neighbouring grains, this being the distribution corresponding to minimum volume, and the system "constituting to a first approximation an elastic medium with six axes of elasticity symmetrically placed." [It may be pointed out before proceeding further that there is more than one way of piling balls so that each ball is in contact with twelve neighbouring ones and the total volume is a minimum.]

The grains are supposed to be capable of limited relative motion, and local inequalities may exist due to the presence or absence of a number of grains above or below that necessary for normal piling. In such cases singular surfaces are formed between the grains in unstrained and those in strained piling. The author finds that the local negative inequalities produced by the absence of grains present the ordinary properties of matter. They are free to move through the medium without resistance, the grains streaming freely through their singular surfaces, and they attract one another according to the law of the inverse square. The density of matter is thus negative, taking that of the medium to be positive, and if the density of water be taken as -1, the author finds that of the medium to be 10^4. The diameter of the grains in C.G.S. units is 5.534×10^{-18}, their mean path is 8.612×10^{-28}, their mean relative velocity is 6.777×10, the mean pressure is 1.172×10^{14}, the rate of propagation of the transverse wave is 3.004×10^{10}, and the rate of degradation of the transverse wave is such that it would require 56 million years to reduce the total energy in the ratio of 1 to e^2. The absorption thus produced is of such a magnitude as to account for the blackness of the sky on a clear night compatibly with the absence of any measurable absorption of light by the ether. On the other hand, the absence of any evidence of normal waves until quite recently is accounted for by the conclusion that the rate of degradation of the normal wave would reduce its energy to about one-eighth in 3.923×10^{-6} of a second, or before it had traversed 2200 metres. In addition to positive and negative inequalities of which the latter correspond to matter, the existence is assumed of "complex inequalities" due to the displacement of grains from one position to another, and a comparison of the attractions of such inequalities with those due to the inequalities representing matter is in complete accordance with the known smallness of gravitative as compared with electric action.

The theory accounts for the refraction, dispersion, polarisation by reflection, metallic reflection and aberration of light.

The analytical investigation is based on the general equations of motion and conservation of any entity (Section ii.), these equations being generalisations of the well-known equations of continuity of hydrodynamical and allied systems; the formation of the equations of motion in a purely mechanical medium (Section iii.), the separation of the motion into its components of "mean" and relative motion (Sections iv.–vii.), the extension of the kinetic theory to granular media (Sections viii.–x.), and an elaborate analysis of the changes taking place in the angular inequalities, the momentum and energy, the mean and relative systems, and the mean inequalities and their motions (Sections xi.–xiv.). It should be observed that the present theory involves the assumption that positively electrified bodies do not repel each other, and for this the author gives arguments in § 226. In the final section (xv.) the numerical values of the quantities which define the condition of the granular medium, as stated above, are deduced from the results of physical experience.

The mathematical reasoning is very difficult, in some places almost impossible, to follow, owing to the large number of doubtful points or inaccuracies in the equations. Even if the fundamental conclusions should prove to be correct, there are many points in the argument which are at present obscure, and require to be cleared up. To take a few examples, in equation (4), p. 10, a new symbol r is introduced without any explanation, and the dual use of δ is very confusing. Having used δS to denote a volume element, and δs a surface element on this page, the author suddenly changes from δS to δs in the first of equations (20) on p 16, and to ds in the second and third, although he refers to equation (2) of p. 10, which involves δS. On p. 13 in equation (13), the differential is omitted after the treble sign of integration; also in (16) one of the expressions under the sign of summation is multiplied by the differential element dS, while the other is not; in the former equation the reader will naturally supply the missing $dx\, dy\, dz$, but the meaning of the latter equation is obscure. Again, turning to p. 105, we find that § 116 refers to "The mean velocities of pairs having relative velocities $\sqrt{2}V_1'$ and $V_1'/\sqrt{2}$," while in § 120 we read, "Since the mean velocities of pairs of grains having relative velocity $\sqrt{2}V_1'$ is $V_1'/\sqrt{2}$ . . . ." In § 117, "All directions of mean velocity of a pair are equally probable whatever the direction of the mean velocity." On p. 120, equation (181), it is not easy to see how, if N be equal to the number of grains in unit volume, the square root of N should be equal to N $dx\, dy\, dz$ multiplied by a certain function of the coordinates, nor how by integrating the equation with respect to y and z the square root of N now becomes equal to N multiplied by another function multiplied by the linear differential dx. In ordinary circumstances there is no useful purpose served in filling a review with a list of *errata* which any reader could easily correct for himself. But the present investigation would be difficult to follow even under the most favourable conditions, and the presence of so many formulæ and statements which cannot possibly be correct as they stand renders the task well nigh hopeless.

An objection of an entirely different character applies to the sections in which Maxwell's law of distribution of velocity components and partition of energy is extended to a medium of closely packed spheres such as that considered by Prof. Reynolds. A great deal has been written as to the validity of Maxwell's law, and of the fundamental assumptions involved in the proofs of it. The general opinion on which all mathematical physicists are pretty well agreed is that the law holds good to a first approximation in gaseous media the molecules of which are not too closely crowded together; but one method of proof after another has on closer examination been found to involve some assumption or other which usually breaks down in the case even of a dense gas. Moreover, Mr. Burbury has gone so far as to establish a different formula for the law of distribution in dense gases. To assume the law to hold good in the extreme case of a medium the ultimate particles of which are permanently interlocked must be regarded, failing other evidence than that given by Maxwell, as a very doubtful step.

A number of interesting questions suggest themselves for the consideration of physicists, such as the ultimate distribution of energy between the grains and molecules, the determination of the temperature of cosmic space as defined by the mean kinetic energy of the grains, the influence of the absorption of the medium, however small, on the progress of cosmic

events, the existence of directional properties of the ether determined by the regular arrangement of the grains, and the finity or infinity of extent of the medium. It may be confidently anticipated that Prof. Osborne Reynolds's granular medium will play an important part in the physics of the future. It is, however, to be hoped that the subject will receive careful and critical study in the hands of numerous mathematical physicists, and that it will not be left for the experimenter and philosopher blindly to accept Prof. Reynolds's doctrines as the basis of speculations about things which they do not understand. The practice of assuming statements to be true because Maxwell made them has been too prevalent in the past, and there is not very much difference between those who adopt this attitude and writers who publish papers at their own expense to show that the earth is not round or that gravitation does not exist. The dogmatic statements of the former class of philosopher often afford plenty of material for the abusive attacks of the latter.

G. H. BRYAN.

THE EFFECT OF EDUCATION AND LEGISLATION ON TRADE.

IN his second presidential address to the Society of Chemical Industry at its annual meeting held in Bradford, Mr. Levinstein again addressed himself to the subject of education. He thinks that almost too much importance has been attached to education as being the *only* factor which has caused the industrial progress and superiority, in certain classes of merchandise, of Germany in comparison with this country. Attention is therefore directed to other considerations which he considers have also to be taken into account, such as the unification of the various German States after the Franco-German war, which, of course, gave an internal free trade to the German nation, the nationalisation of the railways and canals, and the protective patent laws.

He then refers to America, which he does not consider to be a better educated country than our own. Naturally the new Education Act of 1902 comes under review. Mr. Levinstein is doubtful, as are many others, if the Bill will advance secondary education, because the number of persons appointed to the councils who represent secondary education is exceedingly small. No remark is made upon another aspect of the case, namely, that a great many of those appointed know practically nothing about primary, and still less about secondary education. In some cases which have come before our notice, persons of little education (beyond their own inflated opinion of themselves), but desirous of local fame, and having plenty of "push," have brought themselves forward and been elected, while those who really are educated, and know what education means, have been passed by.

The raising of secondary education to a really high and uniform standard will be extremely costly. But the expenditure on primary education, according to the provisions of the new Act, will absorb such a large amount of the ratepayers' money that they will be disinclined to incur further expenditure in order to make it really efficient. No student can enter a German technical college without passing an extremely searching and thorough examination. In Great Britain the total number of students, from fifteen years and upwards, taking complete day technological courses is 3873; probably not more than 10 per cent. could pass the entrance examination of Charlottenburg.

As an illustration of what Manchester is doing in the way of technical training, Mr. Levinstein gives an account of "the department for preparing, bleaching, dyeing, printing, mercerising and finishing textiles, together with the manufacture of paper." There is no dabbling here with manufacture in a test tube, such as we see in some of our educational institutes. The department is lodged in a separate building, apart from the school of technology. It is fitted with the latest and most up-to-date machinery, taken from this country and abroad. As all the machinery is driven by separate motors, there will be no difficulty in replacing it, as it becomes out of date and obsolete, by means of newer and more modern machinery.

In this country we excel in the production of first-class yarn and cloth, made from first-class raw material. These goods will always fetch a good price. But within the last quarter of a century a demand has sprung up for cheap imitations, made from inferior materials, but which must have the external appearance of the first-class article. It is in the weighting of silk, the intermixing of fibres and the manufacture of imitation velvets that the foreigner excels. But the demand is enormous, and if we would hold our own in the markets of the world, we must learn how to manufacture these cheap goods. The British manufacturer must learn to adapt himself to the times and to the tastes and wishes of the consumer.

Manufacturers have often refused to employ chemists, except as "testing machines," because the chemist is so often only a theorist, sometimes not even that, and understands absolutely nothing about machinery. This excuse will, however, soon be no longer tenable. Students who have passed through the department just mentioned at the Manchester Technical School should be fully qualified to take a position not only in dye, bleach, print, mercerising, or finishing works, but also in paper mills. They will have not only a knowledge of chemistry, but also of machinery. It is a pity that technical institutes do not make it compulsory for those who intend to become works chemists to include in the syllabus a course in engineering, both practical and theoretical.

Referring to the "Patent Law Amendment Act," Mr. Levinstein has great hopes that satisfactory results will accrue to our manufacturers. The chief clause in the Act, and one for which British manufacturers have been agitating for many years, is that which deals with the granting of licences. Hitherto the foreigner could patent anything he chose, manufacture it abroad, and "dump" it down here, without his being under any obligation to manufacture it on British soil. And it was a matter of great difficulty to compel him to grant a licence to a British firm to manufacture the goods. Under the new Act, if he does not manufacture in this country, he can be compelled to grant a licence for the manufacture of the product, or failing this his patent may be declared void.

It is only after more than twenty years of agitation that this Act has been passed. Mr. Levinstein reviews the pioneering work which had to be done before the inertia of the Board of Trade was overcome.

Finally, the difficult and vexed question of foreign tariffs is dealt with. Mr. Levinstein considers that the reasons we have not made greater headway, so far as our export trade is concerned, are:—our education has been at fault; our patent laws were bad, and foreign tariffs have often been prohibitive; and we would add the want of adaptability of some of our manufacturers. The Government is also exceedingly slack in making known to our traders, at the earliest moment possible, changes in foreign tariffs. Interested Continental traders learn at once, through their Minister of Commerce, not only changes which have taken place, but changes which are contemplated. But the wheels of our Government, in respect to information which may

be of vital importance to the traders, move so exceedingly slow. The fact is, we require a Minister of Commerce with a competent staff, and the sooner the Government awakes to the fact the better for the country.

F. MOLLWO PERKIN.

NOTES.

IT is probably known to some that a project has been started, and is already well advanced, to found a prize for physics at St. Peter's College, Cambridge, as a tribute to the memory of the late Prof. Tait, of Edinburgh, honorary fellow of the college. Besides members of the college who have heartily taken part in the enterprise, many friends of Prof. Tait, both in Belfast and Edinburgh, have recorded their appreciation of him and of his great services to the advancement of science by joining in this memorial of him at the college of which he was so brilliant a member; and it is believed that others, if they were made aware of the proposal, would desire, for a like reason, to be associated with it. Mr. I. D. H. Dickson, St. Peter's College, Cambridge, will reply to any inquiries, and until more formal thanks are made by the college, will gratefully receive and acknowledge any donations that may be sent to him for the purpose of the memorial.

IT is expected that a monument to the electrician, Zenobe Gramme, will shortly be raised in Brussels. Owing to the efforts of M. Léon Janssen, the general manager of the tramways of Brussels, a committee has been appointed to accomplish this purpose.

WE learn from the *British Medical Journal* that the proposal of the German committee of the Virchow memorial to erect a statue of Virchow in one of the public streets of Berlin, near the place where his scientific work was conducted, will be carried out. Contributions towards this memorial should be sent to the Bankhaus Mendelssohn und Cie, Berlin, W., Jägerstr. 49, 50. An obelisk of unpolished grey granite has been placed over Virchow's grave in the old Matthäikirchof, Berlin. It bears on one side a black marble tablet, on which is inscribed "Rudolph Virchow," and the date of his birth and death.

WE regret to see the announcement of the death, in his seventy-first year, of Prof. Rudolf Lipschitz, the professor of mathematics at the University of Bonn.

THE death is announced of Prof. Alexander Rollet, of Graz, in his seventieth year. He was educated at Vienna, but was deeply influenced by Ludwig, and devoted himself especially to the physiology of the blood and muscles. He was called to Graz in 1863, and was four times rector of that university.

A MESSAGE from Rome, through Laffan's Agency, dated October 20, states that Mount Vesuvius is again active, enormous globes of steam being emitted from the principal crater, accompanied by incessant subterranean rumblings and explosions. A stream of lava is flowing down one side of the volcano.

THE Odontological Society of Great Britain announces that it is prepared to receive applications for grants in aid of the furtherance of scientific research in connection with dentistry. For particulars and forms of application inquiry should be made of the honorary secretary, Scientific Research Committee, Odontological Society, 20 Hanover Square, London, W.

THE new college farm established at Madryn, midway between Aber and Llanfairfechan, in connection with the Agricultural Department of the University College of North Wales, was formally opened on October 17 by the Earl of Onslow, President of the Board of Agriculture. In the course of his inaugural address, Lord Onslow advocated the desirability of giving greater attention to forestry in this country.

FOR a long time plague has been endemic in Hong Kong, the disease reappearing after a period of intermission in an inexplicable manner. Prof. Simpson has lately pointed out in a report to the Colonial Office that domestic animals and poultry may contract plague in a latent form from feeding upon plague-infected material, and has suggested that infected food may be a potent source in disseminating the disease. According to the *Times* (October 17) Sir Henry Blake, the Governor, has recently instituted an investigation of the inhabitants and vermin of a large native quarter in the colony certified to be free from plague. This has revealed that a considerable number of the bugs, fleas, spiders and cockroaches contain plague bacilli. Samples of blood from supposed healthy natives upon examination showed the presence of plague bacilli in 5 per cent. of the specimens. Under favourable conditions such infected persons and vermin become possible sources of danger, and sporadic outbreaks must be expected while they are present. It is difficult also to see what measures can be taken to eradicate the disease in these circumstances.

IN the course of the Harveian oration delivered before the Royal College of Physicians on Monday, Dr. W. H. Allchin referred to recent work on radio-activity and the constitution of matter, and its bearing on biological processes. He remarked that as the atomic and molecular theory was utilised to furnish an explanation of that flux of chemical activity which is denominated bioplasm, so have speculations on ionic action been pressed into the same service, and with some promise, wholly hypothetical as they may be. Nerve action is simply electrical action, negative ions being released where nerve blends with muscle or where systems of concatenated neurons come into connection. Ion after ion is precipitated, and thus neural conduction takes place. This play of ions is excited or inhibited by the character of the fluids with which the protoplasm is bathed—by the nature, that is, of the ions which these fluids contain. Most effective in stimulating protoplasmic action are such substances as sodium salts, as those of lime restrain it, and since such inorganic bodies are among the products of tissue waste, it may be that in the ions of metabolism are to be found the causes of that rhythmic tendency to activity which nerve cell and muscle fibre alike exhibit. If normal neuro-muscular action may be thus induced, the theory offers a clue to the comprehension of some of the most obscure morbid manifestations of these tissues. In many departments of physiology, notably in that concerned with nerve and muscle and with secretion, a large mass of information has been acquired as the result of experiments, whilst but little has been done towards ascertaining the ultimate structure of the tissues concerned —little, that is, beyond what was known a score of years ago or more. In respect to such tissues as these, microscopic examination would seem almost to have reached its limits; and for the complete comprehension of the physico-

chemical phenomena, more recently ascertained, the problem of the chemical and electrical constitution of the muscle or nerve fibre and of the gland cell awaits solution.

A REPORT on the photogrammetric measurement of the height of clouds at Simla during the twenty months June, 1900, to January, 1902, by Mr. W. L. Dallas, is published in the *Indian Meteorological Memoirs*, vol. xv. part ii. Only forty-seven good observations were secured, as it frequently happens that the lower clouds are ordinarily thick and below the level of the observatory (7224 feet). These observations give the mean height of cirrus 30,440 feet above Simla, and the maximum height 38,440 feet; of cumulus the mean and maximum heights are 7304 feet and 14,318 feet respectively.

WE have received from Mr. W. G. Davis a work on the climate of the Argentine Republic, compiled from observations made to the end of the year 1900. All the meteorological elements have been submitted to a careful and elaborate discussion, and the work is a most valuable contribution to the climatology of the South American Continent. In a general outline of the treatise, Mr. Davis points out that, in a country which embraces 33° of latitude, and the surface of which slopes from the Atlantic to the snow-clad Andes, great differences must prevail in the atmospheric conditions. In the narrow zone lying to the north of the Tropic of Capricorn, the mean annual temperature varies from 23° C. on the coast to less than 14° at the western limits, while the rainfall decreases from 1600 mm. to less than 50 mm. At 8° or 9° farther south, we find, in the Pampas, a mean temperature of 19°, which rapidly decreases towards the slopes of the Cordilleras; in the eastern part of Entre Rios the rainfall is 1000 to 1200 mm., and diminishes to less than 100 mm. in the province of San Juan. At 10° further south there is little difference in the isotherms (13° or 14°) between the Atlantic and the Andes, while the rainfall (200 to 400 mm.) is practically the same. At the extreme south of the Republic the climate is rigorous; in Tierra del Fuego the summer mean temperature is 8° to 9°, and the winter 2° to 3°. Rains are frequent, and no month is free from snow. At Staten Island the mean annual precipitation is 1400 mm., while in Tierra del Fuego less than half this quantity falls.

MR. R. W. PAUL has sent us his new catalogue of electrical testing instruments. The list, in addition to the usual resistance boxes, bridges, galvanometers, and other familiar testing instruments, includes several new pieces of apparatus and new patterns. Amongst these may be noticed the new pattern of Kelvin double bridge for the measurement of low resistances; there is also a new model Ayrton-Mather narrow-coil galvanometer having conveniently interchangeable coils. A new set of standard wattmeters, designed by Messrs. Duddell and Mather, is included in the list; these are constructed as much as possible from insulating materials, and range from 0·01 watt to 200 kilowatts. We hope to have an opportunity of describing them more in detail later. An interesting type of resistance has been designed for use with these wattmeters; it is made of silk-covered manganin wire, which is woven into a fabric with silk threads, thus giving a high resistance free from errors due to capacity or self-induction.

WE have received from Mr. C. E. Kelway a description of his system for warning ships at sea of approaching danger by equipping lighthouses with Hertzian signalling apparatus. The ships themselves would be fitted with a receiving apparatus which would respond when they came within the range of the wireless signals sent out from the lighthouse; these are to be sent out at regular intervals at the same times as the sound warnings. A ship, by observing the time that passes between receiving the wireless signal and the sound warning, is enabled at once to calculate its distance from the lighthouse; if it now continues on its course for a few miles and then makes a second observation, all the necessary data for ascertaining, trigonometrically, the exact position of the lighthouse are obtained. A special stop-watch reading directly in distances and a special position finder have been devised by Mr. Kelway for use with his system. The system was, we understand, submitted to the consideration of the recent Berlin Wireless Telegraphy Conference; it illustrates one of the many ways in which wireless telegraphy may be made of service to ships.

FROM the *Bulletin* of the Cracow Academy we have received reprints of several papers by Profs. Ladislaus Natanson and St. Zaremba dealing with certain points in the dynamical theory of viscosity.

MESSRS. TEUBNER, of Leipzig, announce the forthcoming publication of a new work entitled "Encyklopädie der Elementar-Mathematik," under the joint authorship of Profs. H. Weber (Strassburg) and J. Wellstein (Giessen). It is specially written for teachers, and will consist of three volumes dealing respectively with elementary algebra and analysis, elementary geometry, and applications of elementary mathematics.

THE *Proceedings* of the Edinburgh Mathematical Society for 1902–3 contain the reprint of some correspondence between Robert Simson (1687–1768, professor of mathematics at Glasgow, 1711–1761), Matthew Stewart (1717–1785, professor of mathematics at Edinburgh 1747–1772), and James Stirling, F.R.S. (1692–1770, author of works on Newton's cubic curves and on the calculus). The correspondence in question was bought at the Gibson Craig sale of manuscripts by Mr. J. S. Mackay in 1887.

THE *Bulletin* of the American Mathematical Society for October contains an English translation of Poincaré's review of Hilbert's "Foundations of Geometry." Hilbert's monograph is undoubtedly a classic, and Poincaré's comments upon it, as might be expected, are full of interest. One passage may be quoted as dealing with a misunderstanding which is too common. "Some people have gone so far as to . . . ask whether real space is plane, as Euclid assumed, or whether it may not present a slight *curvature*. They even supposed that experiment could give them an answer to this question. Needless to add that this was a total misconception of the nature of geometry, which is not an experimental science."

IN the *American Naturalist* for August, Dr. E. W. Doran emphasises the importance of the use of vernacular names for animals, and urges that, when these are of a composite nature, a uniform method in regard to the use of hyphens should be adopted in zoological literature. The rules he proposes with a view of attaining this desirable end will, we think, meet with the general approval of English writers.

MR. C. R. EASTMAN, on morphological grounds, expresses, in the *American Naturalist*, his disbelief in Dr. Patten's assertion that Cephalaspis was provided with a fringe of jointed and movable appendages along the ventral margin of the trunk. No such appendages exist in the allied Pterichthys, and it seems incredible that a vertebrate can possess more than two pairs of limbs. In these respects the writer has the support of Dr. Gaskell.

AT the conclusion of a paper on reptiles and amphibians from Arkansas and Texas, published in the *Proceedings* of the Philadelphia Academy for August, Mr. W. Stone discusses their bearing on previous views as to the zoogeographical zones of this part of the United States. He concludes that the boundary between the Austro-riparian and Sonoran areas, so far as reptiles are concerned, lies between the 96th and 98th meridians of longitude, that the Texan district of Prof. Cope should be referred to the Austro-riparian instead of to the Sonoran province, and that transcontinental zones of distribution are not indicated by reptilian evidence. The marked faunal division between the 96th and 98th meridians is due to this line marking the limits of the heavy rainfall of the Gulf coast.

A CURIOUS problem is presented by the hermit-crab. As is well known, these crustaceans present a marked asymmetry, which nearly always takes the form of a dextral spiral—in correlation with the circumstance that they generally inhabit dextral molluscan shells. Is, then, this asymmetry due to this habit, or was it pre-existent? In discussing this question in a paper on the metamorphoses of the hermit-crab, published in the *Proceedings* of the Boston (U.S.) Natural History Society, Mr. M. T. Thompson concludes that it cannot at present be definitely answered, owing to our imperfect knowledge of the relationships of the different generic representatives of the group. Nevertheless, the asymmetry is structurally adapted to the conditions imposed by the mode of life in question, and the presumption is accordingly very strong that it was from the first the result of a sojourn in dextrally spiral shells.

MR. M. J. NICOLL, who in 1902–3 accompanied the Earl of Crawford in his yacht, the *Valhalla*, round the world as naturalist, and made good collections in several branches of natural history, will again join the *Valhalla*, in the same capacity, next month for a winter tour in the West Indies. Mr. Nicoll's specimens collected during the last voyage are being examined and arranged at the British Museum, to which Lord Crawford has presented them. Mr. Nicoll's ornithological notes made during the voyage will be published in the next number of the *Ibis*.

IT has always seemed strange that so large and strongly marked an animal as the okapi (*Okapia johnstoni*) should have remained unknown to Europeans until its recent discovery on the Semliki by Sir Harry Johnston. But it would now appear, as is suggested by Herr Hesse, that a prior well-known African traveller, Wilhelm Junker, had obtained an imperfect skin of this animal at Zemio, in the Welle-basin, twenty years ago, although he did not recognise the nature of it, and was inclined to refer it to the water-chevrotain (*Hyomoschus aquaticus*). But as the animal was called by the natives "makapi," and was "of the size of a dwarf antelope," it seems more probable that the skin in question was that of a young okapi (see *Journ.* R.G.S., vol. xxii. p. 459).

IN the October number of *Climate* Dr. Louis Sambon continues his series of articles on the chief disease scourges of the tropics, dealing with malaria, yellow fever, cholera, plague and sleeping sickness. Another article of interest discusses the results obtained by the campaign against mosquitoes in various parts of the world.

THE Corporation of London has approved and adopted a series of regulations drafted by its Public Health Department for the sanitary control of the milk supply of the City. Some of these deal with the registration of the premises and their sanitary condition, contamination of milk, milk from diseased cows, &c. Others seek to secure the cleanliness of milk-shops and vessels, and the safeguarding of the milk-supply against infection from without.

THE health of the great armies of Europe is discussed by Dr. V. Lowenthal in an interesting statistical article in the *Revue générale des Sciences* (September 30). Of the armies of the six great Powers, France, Germany, Austria, Russia, Italy, and England, France heads the list both in the total mortality rate and in the attack rate. On the whole the German Army is the most healthy, then comes the Italian, and then the British. But for the enormous incidence of venereal affections, the latter, however, would in all probability appear as the most healthy.

"THE GEOLOGY OF THE COUNTRY AROUND TORQUAY" is the title of a memoir by Mr. W. A. E. Ussher that has just been issued by the Geological Survey. The author has for many years been engaged in a detailed examination of the Devonian rocks, and he gives full particulars of the complex structure of the area and of the several subdivisions of the strata, with lists of fossils. Useful tables are given showing the Continental equivalents. The terra-cotta clays of Watcombe, and the red sandstones and conglomerates that form portions of the picturesque cliffs, are grouped as Permian. Cavern-deposits, Raised Beaches, and other superficial deposits are described, and there is a short chapter on economics.

MESSRS. DAWBARN AND WARD, LTD., are publishing a series of penny pamphlets dealing with various subjects of interest to practical photographers. The first number in the series discusses the prevention and cure of halation, and the fourth number the camera and its movements.

THE ninth annual volume—that for the present year—of the *Reliquary and Illustrated Archaeologist* has been issued by Messrs. Bemrose and Sons, Ltd. The volume contains the four quarterly issues of the magazine which have been published this year, and most of the articles are excellently and profusely illustrated. The publication appeals preeminently to antiquarians, ethnologists and archæologists.

MR. JOHN MURRAY has published a cheap edition—five shillings net—of Nasmyth and Carpenter's classical work on "The Moon." The original work was published thirty years ago, and was reviewed in these columns on March 12, 1874 (vol. ix. p. 358). Three editions of the book were issued, but they have been out of print for several years, and the publication of the work in a popular and compact form will be welcomed by many students of astronomy.

A FIFTH edition of the "Manual of Pathology" by the late Prof. Joseph Coats has been published by Messrs. Longmans, Green and Co. The new edition has been revised throughout by Prof. L. R. Sutherland, and considerable alterations have been made without interfering materially with the original plan of the book. The chapter on bacteriology has been omitted, and the illustrations have been increased in number from 490 to 729. Two new coloured plates have also been added.

THE fourth revised edition of Prof. Max Verworn's "Allgemeine Physiologie" has been published by Mr. Gustav Fischer, Jena. The first edition of this well-known work was reviewed in NATURE in 1895 (vol. li. p. 529). A translation of the second edition, by Dr. F. S. Lee, was published in 1899, and was also noticed at length in these columns (vol. lx. p. 565). Since the third German edition was published in 1901, progress has been made in the

knowledge of the physiology of the cell, and the sections devoted to this subject have been carefully revised for the new edition now available.

WITH the advance of scientific education in this country scientific instrument makers are continuously bringing out improved forms of apparatus. We have recently received from Messrs. Brewster, Smith and Co. an improved form of a "double surface condenser." This is one of the most compact and efficient condensers which has come before our notice. We have tested it for condensing such volatile substances as ether, carbon disulphide, and acetone, and have found that even with rapid distillation the condensation is very complete. Generally speaking, in order to condense these substances satisfactorily, it is necessary to employ a very long condenser; of course, this means using a great amount of bench space. As the new condensers are used in a perpendicular position, the saving in space is very great.

MESSRS. BREWSTER, SMITH AND CO. have also sent us a "new Bunsen burner and midget furnace." It can hardly be said that the Bunsen burner is new, but the combination of furnace and burner is very convenient. The makers claim that marble is reduced to quicklime in ten minutes. This will, of course, to a large extent depend upon the quantity of marble taken in the first place—we find that from one to one and a half grms. is readily reduced to quicklime in twenty minutes. These little furnaces are not only useful for reducing calcium carbonate to lime, but also work very well in fusion experiments.

THE measurements by Biltz and Preuner of the density under different pressures of sulphur-vapour at 448° have usually been regarded as indicating that the vapour is composed of S_8 and S_2 molecules, and that the molecule S_6 does not exist. The application to the isothermal of the law of mass-action, discussed by Preuner in the *Zeitschrift fur physikalische Chemie*, shows that this theory is inadequate, and that the vapour must contain molecules intermediate in complexity between S_8 and S_2. The proportions by volume of the constituents are calculated to be, under 104 mm. pressure, 29.2 per cent. S_8, 19.0 S_6, 19.7 S_4 and 32.1 S_2, and under 453.4 mm. pressure, 77.8 S_8, 15.1 S_6, 4.7 S_4 and 2.4 S_2.

SINCE Beckmann showed that iodine in all solvents has the molecular weight I_2, it has been suspected that the formation of violet or brown solutions is dependent upon the extent to which the iodine combines with the solvent. By means of comparative experiments on the solubility of iodine and the periodide $N(CH_3)_4I_9$, described in a recent number of the *Zeitschrift fur physikalische Chemie*, Strömholm has obtained evidence that iodine actually combines with water, alcohol and ether, forming brown solutions, whilst the violet solutions in carbon disulphide, benzene and chloroform contain uncombined iodine; similarly it is shown that iodine has little tendency to combine with methyl iodide when dissolved in ether, or with sulphur dissolved in carbon disulphide.

THE additions to the Zoological Society's Gardens during the past week include a Black Lemur and young (*Lemur macaco*) from Madagascar, a Brazilian Hare (*Lepus brasiliensis*) from Brazil, eight Hamsters (*Cricetus frumentarius*), a Snow Bunting (*Plectrophenax nivalis*), four Lacertine Snakes (*Coelopeltis monspessulana*), two Dark-green Snakes (*Zamenis gemonensis*), a Vivacious Snake (*Tarbophis fallax*), European; three Cuban Snakes (*Liocephalus andreae*) from Cuba, two Garter Snakes (*Tropidonotus ordinatus*), a Prickly Trionyx (*Trionyx spinifer*) from North America, a South Albemarle Tortoise (*Testudo vicina*) from Galapagos, a Wrinkled Terrapin (*Chrysemys scripta rugosa*) from the West Indies, two Amboina Box Tortoises (*Cyclemys amboinensis*) from the East Indies, two Annulated Terrapins (*Nicoria annulata*) from Western South America, a Horned Lizard (*Phrynosoma cornutum*) from Mexico, a Carinated Lizard (*Liocephalus carinatus*) from the West Indies, two Hispid Lizards (*Agama hispida*) from South Africa, two Scoresby's Gulls (*Leucophoeus scorebii*) from Chili, deposited; a Tasmanian Devil (*Sarcophilus ursinus*) from Tasmania, received in exchange.

OUR ASTRONOMICAL COLUMN.

SEARCH-EPHEMERIS FOR COMET 1896 V.—A further portion of the search-ephemeris for Giacobini's comet (1896 v.), published by Herr M. Ebell in No. 3898 of the *Astronomische Nachrichten*, is given below. As will be seen from this ephemeris the computed brightness is now decreasing, although the comet should be in a favourable position for observers in the northern hemisphere:—

12*h*. *M.T. Berlin*.

1903	α h. m. s.	δ ° ′	log *r*	log Δ	Brightness.

A NOVEL FEATURE FOR GEODETICAL INSTRUMENTS.—In a paper contributed to No. 26, vol. iii., of the *British Optical Journal*, Sir Howard Grubb describes a novel feature in geodetical instruments which replaces the half-silvered, half-plain piece of glass generally used in such instruments by a piece of glass having a thin film of lead sulphide deposited on its surface. This film both reflects and transmits the incident light, and by varying its thickness the proportion of transmitted to reflected light may be varied.

Taking the case of the prismatic compass as an illustration, the rays of light from the object the position of which is to be determined are transmitted by the film of lead sulphide, and, at the same time, the previously collimated rays from the compass card are reflected by it. As both sets of rays are parallel, and the reflection of the card is superimposed on the image of the distant object, parallax does not interfere in the observations, and the position of the eye may therefore be changed without introducing any error into the reading, thereby rendering it possible to make the readings much more quickly and accurately than when using the older forms of reflecting-transmitting apparatus.

THE PATH OF COMET 1894 I. (DENNING).—No. 2 of the *Mitteilungen* of the Heidelberg Observatory contains a paper by Dr. P. Gast on the observations and calculations of the path of comet 1894 I.

The first part is devoted to a series of new observations of the comparison stars made during the year 1902, and is followed by a collection of the observations of the comet which were made at various observatories, then the various observations are compared among themselves and with the computed elements of this comet. The paper concludes with a discussion of the perturbations produced by Jupiter and the finally deduced elements. In a supplementary list the positions of eighty-eight reference stars for the year 1900 are given, the value of the precessional constant, the secular variation, and the star's proper motion being stated in each case.

OBSERVATIONS OF MARS.—In the October number of the *Bulletin* de la Société astronomique de France, MM. Flammarion and Benoit publish the results of their observations of Mars made at Juvisy during the last opposition of that planet. Although the planet was nearer to the earth during this opposition than it was in 1901, the unfavourable meteorological conditions prevented the making

of a complete record, but the set of fourteen drawings of the polar cap which accompany the paper show very clearly the diminution of the cap from October 15, 1902, to March 15, 1903, and its augmentation from then until July 1, the minimum apparently taking place at an earlier date than usual.

In addition to detailed descriptions of the most interesting observations, the paper contains reproductions of ten excellent drawings showing various features on the planet's surface.

NATAL GOVERNMENT OBSERVATORY.—The report of the Government Astronomer for Natal, Mr. E. Nevill, for 1902 is chiefly devoted to the various meteorological records of the colony, and forms a valuable addition to the meteorology of last year.

After giving brief descriptions of the staff, the instruments, the management of the time signals, the magnetic observations, and the tide records, the report gives a number of tables containing very complete records of the meteorological results obtained at the Durban Observatory and twenty-two inland stations, and the less complete records of twenty-six subsidiary stations which are scattered throughout the colony.

In dealing with this section of the report Mr. Nevill directs special attention to the importance of obtaining the fullest possible records of the meteorological conditions in Natal, because, in addition to their local importance, it has been shown that there is a very close connection between them and the conditions obtaining in Australia and India. In the latter case there are trustworthy indications that the meteorological conditions of Natal are those which are likely to prevail in India during the following season; this is especially marked in the case of the rainfall.

INHERITANCE OF PSYCHICAL AND PHYSICAL CHARACTERS IN MAN.[1]

THERE are probably few persons who would now deny the immense importance of ancestry in the case of any domestic animal. A majority of the community would probably admit also that the physical characters in man are inherited with practically the same intensity as the like characters in cattle and horses.

But the preeminence of man in the animal kingdom is justly attributed, not to his physical, but to his psychical character. The latter is seen developing apparently under the influences of home and of school, and we conclude, perhaps too rashly, that home and school are the chief sources of the psychical qualities. We are too apt to overlook the possibility that the home standard is itself a product of stock, and that the relative gain from education depends in a surprising degree on the raw material presented to the educator.

It is possible to hold this view and yet believe that moral and mental characters are inherited in either a qualitatively or a quantitatively different manner from the physical characters. Both may be influenced by environment, but one in a far more marked way than the other.

Some six or seven years ago, then, I set myself the following problem: What is the quantitative measure of the inheritance of the moral and mental characters in man, and how is it related to the corresponding measure of the inheritance of the physical characters?

The problem really resolved itself into three separate investigations:—

(a) A sufficiently wide inquiry into the actual values of inheritance of the physical characters in man.

For this investigation upwards of 1000 families were measured, giving ample means of determining the quantitative measure of resemblance for both parental and fraternal relationships.

(b) A comparison of the inheritance of the physical characters in man with those in other forms of life.

No substantial difference in this inheritance has been discovered.

(c) An inquiry into the inheritance of moral and mental characters in man.

Owing to the great difficulty of comparing the moral characters of a child with those of its adult parents, I confined my attention to *fraternal* resemblance, for if fraternal resemblance for moral and mental characters is less than, equal to, or greater than its value for physical characters, the same must be true for parental inheritance.

In the next place it seemed impossible to obtain moderately impartial estimates of the psychical characters of *adults*. The inquiry, therefore, was limited to *children*, so that the partial parent or relative could be replaced by the fairly impartial school teacher.

After much consideration and some experimenting, schedules were prepared in which teachers could briefly note the chief characteristics of the children under their charge. These schedules were white for a pair of brothers, pink for a pair of sisters, and blue for a brother and sister. With the schedules specially devised headspanners were distributed, directions for the use of the headspanner, and general directions as to the estimation of the physical and mental characters.

The material took upwards of five years to collect. Appeal was made through the columns of the educational journals to teachers of all kinds, and the observations were made not only in the great boys' public schools and the grammar schools of the country, but in modern mixed schools, in national and elementary schools of all kinds, in board schools, and private schools throughout the kingdom. Some 6000 schedules were distributed, and between 3000 and 4000 returned with more or less ample data. I have most heartily to thank the masters and mistresses of some 200 schools in which observations have been made for me. In the midst of arduous professional claims on their time and energy, they have, in many cases at considerable personal inconvenience, recorded and measured the children in their charge for a purpose only dimly foreshadowed for them.

Much of what I have to say upon the nature of the theory applied will not be new to those who have examined recent biometric work, and some of it will not be intelligible except to the trained mathematician. Still we must strive in broad lines to see how the work has been done, and, above all, to justify our treatment of the psychical character.

[To illustrate the method the lecturer examined the degree of resemblance between the cephalic indices of brothers, the cephalic index of a person being 100 × the ratio of breadth to length of head. This scarcely changes with growth after the first two years of life. A table was exhibited showing the cephalic index for 1982 pairs of brothers.]

Taking the boys, for example, with cephalic indices between 74 and 75, these boys had seventy-eight brothers who were distributed according to the column headed 74 to 75. Brothers are not alike in cephalic index, but distributed with a considerable range of variation. The arithmetic mean of the cephalic indices of this array of brothers is 77·45. Thus the average brother of a boy with cephalic index 74·5 has a cephalic index =77·45. This is the phenomenon of regression towards the general population mean (78·9) discovered by Francis Galton.

We now find by taking all the arrays that whatever the cephalic index of first brother be, cephalic index of mean second brother

$$= (1-\alpha)\{\text{mean cephalic index of whole population}\} + \alpha\,\{\text{cephalic index of first brother}\}$$

and that in the case of cephalic indices for two brothers the quantity α, defined as the "resemblance," has the value 0·5.

Now from this result we have learnt two great features about inheritance in man. Firstly, that part of the cephalic index of the second brother depends in the above linear manner on that of the mean of the whole population and part on that of the first brother; and, secondly, that these parts are about equal. Are these true for other characters than the cephalic index? Undoubtedly, for all physical characters. And further, the fraction α, which we have called the resemblance, is, for brethren, in all cases about 0·5.

This surprising uniformity in the inheritance of the measurable physical characters can be extended to physical characters not capable of accurate measurement, and to psychical characters provided we assume a certain distribution of frequency for such characters in human popu-

[1] Abstract of the Huxley Memorial Lecture for 1903. Delivered before the Anthropological Institute on October 16, by Prof. Karl Pearson, F.R.S.

lations. Suppose, then, we assume that the moral and mental qualities in man, like the physical, follow a normal law of distribution. What results shall we obtain by thus assuming perfect continuity between the physical and psychical? I cannot free myself from the conception that underlying every psychical state there is a physical state. Hence I put to myself the problem as follows:—

Assume the fundamental laws of distribution which we know hold for the physical characters in man, and see whither they lead us when applied to the psychical characters. They must (*a*) give us totally discordant results. If so, we shall conclude that they have no application to the mental and moral attributes. Or (*b*) they must give us accordant results. If so, we may go a stage further, and ask how these results compare with those for the inheritance of the physical characters; are they more or less or equally subject to the influence of environment? Here are the questions before us. Let us examine how they are to be answered. Taking as an example *ability in girls*, we find that the resemblance between sisters is 0.47. There can, I think, be no doubt that *intelligence* or *ability* follows precisely the same laws of inheritance as cephalic index or any other physical character.

I ask you to admit that I came to this inquiry without prejudice. I expected *a priori* to find that the home environment largely affected the resemblance in moral qualities of brothers and sisters. Putting any thought of prejudice on one side, accept for a moment the methods adopted, and look at the broad results of the inquiry. You have in the first table the mean resemblance of the physical characters of brothers and sisters from my records of family measurements. You have in the second table the mean of the physical measurements of our school records. These two series absolutely confirm each other, and give a mean resemblance of 0.5 nearly between children of the same parents for all physical characters. How much of that physical resemblance is due to home environment? You might at once assert that size of head and size of body are influenced by food and exercise. It is quite true. But can any possible home influence affect cephalic index or eye colour? I fancy not; and yet these characters are within broad lines inherited exactly like the qualities directly capable of being influenced by nurture and exercise. I am compelled to conclude that the environment influence on physical characters is to the first approximation not a great disturbing factor when we consider degrees of fraternal resemblance in man.

Now turn to the list of the degrees of resemblance in the mental and moral characters. We find, perhaps, slightly more irregularity than in the case of the physical characters. The judgment required is much finer, the classification much rougher, but the obvious conclusion is still that the values of the coefficient a giving the resemblance again cluster round 0.5.

We are forced, I think literally forced, to the general conclusion that the physical and psychical characters in man are inherited within broad lines in the same manner and with the same intensity.

This *sameness* surely involves something additional. *It involves a like heritage from parents.* So we inherit our parents' tempers, our parents' conscientiousness, shyness and ability, even as we inherit their stature, forearm and span.

At what rate is that? [A table was shown which represents our present knowledge of parental inheritance in man and in the lower forms of life, the resemblance of parent and offspring being again roughly 0.5.] So the psychical characters are not features which differentiate man from the lower types of life.

If the conclusion we have reached to-night be substantially a true one, and for my part I cannot for a moment doubt that it is so, then what is its lesson for us as a community? Why, simply that geniality and probity and ability, though they may be fostered by home environment and good schools, are nevertheless bred and not created. The education is of small value unless it be applied to an intelligent race of men.

Our traders tell us we are no match for the Germans or Americans. Our politicians catch the general apprehension and rush to heroic remedies. Looking round impassionately from the calm atmosphere of anthropology, I fear there really does exist a lack of leaders of the highest intelligence, in science, in the arts, in trade, even in politics. I do seem to see a want of intelligence in the British professional man and in the British workman. But I do not think the remedy lies in adopting foreign methods of instruction or in the spread of technical education. I believe we have a paucity just now of the better intelligences to guide us, and of the moderate intelligences to be guided. The only account we can give of this on the basis of the result we have reached to-night is that we are ceasing as a nation to breed intelligence as we did fifty to a hundred years ago. The only remedy, if one be possible at all, is to alter the relative fertility of the good and bad stocks in the community. We stand, I venture to think, at the commencement of an epoch which will be marked by a great dearth of ability. We have failed to realise that the psychical characters which are in the modern struggle of nations the backbone of a State are not manufactured by home and school and college; they are bred in the bone; and for the last forty years the intellectual classes of the nation, enervated by wealth or by love of pleasure, or following an erroneous standard of life, have ceased to give us the men we want to carry on the ever-growing work of our Empire, to battle in the fore rank of the ever-intensified struggle of nations.

The remedy lies in first getting the intellectual section of our nation to realise that intelligence can be aided and be trained, but no training or education can create it. You must breed it; that is the broad result for statecraft which flows from the equality in inheritance of the psychical and the physical characters.

THE APPLICATION OF LOW TEMPERATURES TO THE STUDY OF BIOLOGICAL PROBLEMS.[1]

THE cellular doctrine lies at the basis of modern biological research. Living matter in its simple and complex conditions consists essentially of protoplasm with a contained body or nucleus. The two elements plasma and nucleus constitute the elementary organism—the cell. The lowest individual forms of life are represented by a single cell, and such unicellular organisms may be either of a vegetable or animal type. The cells in each instance exist as free living and independent organisms. The higher forms of life are built up of parts in which the structural unit remains the cell, despite the modifications the cell necessarily undergoes as a fixed element in the various tissues and organs. All phases of animal and plant life are demonstrably of cellular origin and organisation, and their vital manifestations represent the summed up activities of cells. Every vital problem, therefore, is ultimately a cellular problem, and a direct study of the cell, in so far as may be possible, is the keynote of biological research. The methods to be adopted will depend upon the problem it is desired to investigate. A histological technique, aided by the microscope, will naturally be employed where it is desired to study the relations of parts and the structural organisation of the tissues and their cellular elements. The soluble products of the living cell spontaneously present themselves for examination by chemical and other means. It is otherwise with regard to the agencies acting and the processes occurring within the confines of the cell. These are naturally beyond the range of the ordinary methods of observation. The essential processes of life are intracellular and intimately bound up with the living substance of the cell, and of these but few data are possessed. The importance of the problems involved is as great as their investigation is difficult. The cell exercises its vital functions in virtue of a specific physical and chemical organisation of its molecular constituents. The ordinary methods of biological and chemical research modify or destroy this organisation, and do not admit of an intimate study of the normal cell constituents. For this purpose it is essential to eliminate or to reduce to a minimum the influence of external modifying agents on the cell or its immediate products. An intracellular physiology can only be based on a direct study of intracellular constituents apart from their secretions and products. This, in ordinary circumstances, is impossible with

[1] By Dr. Allan Macfadyen. Communicated to Section B of the British Association at Southport, by Prof. J. Dewar, F.R.S.

respect to actively functionating and intact cells. It is obvious, therefore, that the first desideratum is a suitable method of obtaining the cell plasma for experimental purposes, and it is only recently that this has been successfully accomplished. The most feasible means of procedure appeared to be the use of *mechanical* agents which, whilst bringing the cell substance within the field of observation, would, at the same time, be least likely to affect its character and constitution. The method consists in a mechanical rupture of the cells and the release of their contents under conditions favouring the conservation of their properties. The first successful application of this description of method was made by Buchner in the particular instance of the yeast cell, and with brilliant results. The researches of Buchner were of wide biological significance, and were suggestive of much more than a cell-free alcoholic fermentation of sugars. They demonstrated the possibilities of the new methods with regard to more general vital problems. The Buchner process consisted in a mechanical trituration of the yeast cell with the aid of sand and a subsequent filtration of the resultant mass under pressure through Kieselguhr. The filtrate contained the expressed constituents of the yeast cell which were capable of passing through Kieselguhr, and the product, in virtue of its fermentative properties, was termed "zymase."

The author and his colleagues have, during the past four years, been engaged in investigating the application of cognate methods to biological research. The advice and help generously afforded by Prof. James Dewar materially forwarded the progress of the research.

It was considered that, by the employment of low temperatures, a disintegration of living cells might possibly be accomplished, and a wide field of inquiry opened to investigation in the biological laboratory. For this purpose the methods of mechanical trituration required refinement in several directions.

The conditions it was desired to fulfil were, a rapid disintegration of the fresh tissues and cells, an avoidance of heat and other modifying agents during the process, and an immediate manipulation of the cellular juices obtained.

It had likewise been noted that ordinary filter pressing through Kieselguhr removed physiologically active substances from the cell juices. Liquid air appeared to be the most convenient means of obtaining the necessary cold, and it presented the advantage of a fluid freezing medium in which the material to be manipulated could be directly immersed. The temperature of this reagent (about $-190°$ C.) would, in addition, prevent heat and chemical changes, whilst reducing the cells to a condition of brittleness favourable to their trituration without the addition of such substances as sand and Kieselguhr, which might modify the composition of the resultant product.

The method, if successful, would meet the conditions desired for the subsequent study of the intracellular juices. It may be briefly and generally stated that, by the application of low temperatures, a mechanical trituration of every variety of cell *per se* has been accomplished, and the fresh cell plasma obtained for the purpose of experiment. A number of control experiments have demonstrated that immersion in liquid air is not necessarily injurious to life—bacteria, for example, having survived a continuous exposure for six months to its influence. The actual trituration of the material is accomplished in a specially devised apparatus, which is kept immersed during the operation in liquid air.

The normal and diseased animal tissues have been treated in this manner, and their intracellular constituents obtained, *e.g.* epithelium, cancer tissues, &c.

Moulds, yeasts and bacteria have been rapidly triturated under the same conditions, and the respective cell juices submitted to examination.

The severest test of the capabilities of the method was furnished by the bacteria, an order of cells for which the standard of measurement is the *mikron*. The experiments proved successful in every instance tested. The typhoid bacillus, for example, is triturated in the short space of two to three hours, and the demonstration has been furnished that the typhoid organism contains within itself a toxin. From these and other researches it has become evident that there exists a distinct class of toxins and ferments which are contained and operate within the cell or bacterium, in contradistinction to the now well-known class of toxins which are extracellular, *i.e.* extruded during life from the cell into the surrounding medium. To this latter class belongs the diphtheria toxin, which has been so successfully used in the preparation of diphtheria antitoxin. A number of infective organisms do not produce appreciable extracellular toxins, and the search must therefore be made within the specific cells for the missing toxins to which the intoxication of the body in the course of the disease in question is probably due. The practical utility of investigating these intracellular toxins has already become evident in the preparation from the intracellular toxin of the typhoid bacillus of a serum having antitoxic value as regards this toxin.

The experiments made with the pus organisms have already shown that intracellular toxins exist in this important order of disease germs.

The cell juices of other types of pathogenic bacteria, such as the tubercle and diphtheria bacillus, present characteristics of equal interest.

The application of low temperatures has aided the investigation of certain other biological problems.

The photogenic bacteria preserve their normal luminous properties after exposure to the temperature of liquid air. The effect, however, of a trituration at the same temperature is to abolish the luminosity of the cells in question. This points to the luminosity being essentially a function of the living cell, and dependent for its production on the intact organisation of the cell.

The rabies virus has not yet been detected or isolated, although regarded as an organised entity. The seat of the unknown rabies virus is the nervous system. If the brain substance of a rabid animal be triturated for a given length of time at the temperature of liquid air, its infective properties as regards rabies are abolished. This result appears to be a further indication of the existence in rabies of an organised virus.

The method described admits of a fresh study of the question of immunity from an intracellular standpoint.

The intracellular juices of the white blood cells have been obtained, and tested with regard to bacteriolytic properties and the natural protection that may thus be afforded to the body against the invasions of microparasites.

The application of low temperatures to the study of biological problems has furnished a new and fruitful method of inquiry.

PHYSICS AT THE BRITISH ASSOCIATION.

THE meeting of the International Meteorological Committee at Southport during the week of the meeting of the Association resulted in an unusually large proportion of the papers presented to Section A dealing with cosmical problems, and these were taken in the department of the section devoted to astronomy and meteorology. Of the matters brought before the department devoted to physics, there seems little doubt that the most important were those involved in the discussions on the introduction of vectorial methods into physics, on the treatment of irreversible processes in thermodynamics, and on the nature of the emanations from radio-active substances respectively, and of these a short account follows.

In opening the discussion on the introduction of vectorial methods into physics, Prof. Henrici pointed out that, although vectors were invented for use in dynamics, the ideas involved were fully introduced into physics by Faraday's representation of the stresses in a medium by lines of force. Maxwell was aware of this, and devoted some sections of the opening chapter of his "Electricity and Magnetism" to an exposition of the properties of vectors, and expressed many of his later equations in vectorial form.

So long as we have to deal with quantities which involve magnitude and direction, but which are not specified as starting from a definite point, *i.e.* with non-localised vectors, a very simple algebra is all that is necessary, and when at any time it is required to extend our methods to localised vectors the methods of Grassmann's "Ausdehnungslehre" are available. The algebras which have been proposed for dealing with the simpler case agree in making addition follow the parallelogram law for compounding two forces, but they differ in the meanings they

attach to multiplication. In Prof. Henrici's algebra the products of two vectors α, β are:—$(\alpha\beta)$ a non-directional or "scalar," in magnitude equal to the product of one vector into the component of the other along the first, and $[\alpha\beta]$ a vector perpendicular to the plane drawn through α and β, and in magnitude equal to the area of the parallelogram of which α and β are concurrent sides. This algebra is evidently identical with those of Heaviside and Gibbs, and, like them, open to the objection that it does not discriminate between "polar" vectors, *e.g.* forces and "axial" vectors, *e.g.* couples. Its relation to that of quaternions is expressed by the equation $\alpha\beta = -(\alpha\beta)+[\alpha\beta]$, where $\alpha\beta$ is the quaternion product of α and β. If, now, u be a scalar function of the vector ρ of a point P, and P be displaced through a distance $d\rho$, the change du in the value of u will be proportional to $d\rho$, and may be denoted by $d\rho\,.\,\nabla u$, where ∇u is a vector such that for a given magnitude of $d\rho$, du is a maximum when $d\rho$ is parallel to ∇u. Hence the direction of ∇u is that of the greatest rate of change of u, and its magnitude that rate of change. Similarly for a vector function η of ρ $d_\rho\eta = (d\rho\nabla.)\eta$, and ∇ follows quite generally the laws of combination of vectors. Thus we have $(\nabla\eta)$ the "divergence" of η and $[\nabla\eta]$ the "curl" of η, with their numerous applications. By the use of this operator ∇, theorems like those of Green and Stokes can be proved in a generalised form with great ease and elegance, and the equations for the electromagnetic field follow in a couple of lines of work.

With so powerful a calculus as this at command, Prof. Henrici considers it the height of folly, after using vectorial methods in those elementary parts of physics which deal with addition of forces or velocities, to drop them for Cartesian coordinates and direction cosines at the next step forward. He advocates the use of vectors throughout, and, like Heaviside, would make trigonometry follow and depend on vectors by the definitions $x=r \cos \theta$, $y=r \sin \theta$. Vectors would thus be introduced into school curricula previous to or along with the use of squared paper and the idea of coordinates.

In the discussion which followed, Sir Oliver Lodge, Dr. Sumpner and others spoke as to the usefulness of vectorial methods in physical work. Prof. Larmor said there could be no doubt as to the extreme elegance of vectorial methods, and attributed the slow progress they had made to the want of uniformity in definitions and notation, which rendered it necessary for each writer who used vectors to describe his notation and methods before his work could be understood by his readers. Mr. Swinburne also referred to this difficulty. Prof. Boltzmann pointed out that this confusion would have been avoided if Hamilton had accepted Grassmann's methods and notation. The writer suggested that the question of the possibility of introducing greater uniformity into the notation and methods of vector algebra was a suitable one to be considered by a committee of the British Association. Prof. Henrici thought there would be little difficulty in coming to some agreement between the advocates of the various systems now in existence. His communication was ordered to be printed *in extenso* in the reports, so that those interested in the subject might be able to consider the suggestions made in detail.

Mr. Swinburne opened the discussion on the treatment of irreversible processes in thermodynamics by pointing out that so much attention was devoted in books on thermodynamics to the consideration of the changes involved in reversible processes, and so little to irreversible ones, that there was a danger of the latter being overlooked, although they are the only ones which really occur in nature. His object was to bring them more prominently forward, and to suggest a method of introducing the subject which would not involve alteration or extension of fundamental ideas on passing from reversible to irreversible changes. The sketch of the method he proposed was necessarily brief, and it was not easy at the time to see to what the proposals made would eventually lead. This probably accounts for the unsatisfactory nature of the discussion, which consisted to a great extent of statements by the speakers that they had been unable to understand what was proposed, or of condemnation of any attempt to alter the definition of entropy. Fortunately, copies of Mr. Swinburne's communication were available, and a quiet perusal of his suggestions shows that they are by no means so drastic as was supposed.

He points out that, while the first law of thermodynamics asserts that heat is a form of energy, the second states that only a portion of a given supply of heat is available for conversion into work, although energy of other forms is wholly convertible. That part of a supply of heat which cannot be converted into work during a cyclic change of state of the body containing the heat he proposes to call the "waste heat." It depends on the temperature of the coldest available reservoir of heat of large capacity, say that of the sea. Any process which goes on in an isolated system involves in general an increase of this "waste," and the quotient of this increase by the temperature of the coldest available reservoir of heat Mr. Swinburne defines as the increase of entropy of the system during the process.

A part of the system may decrease in entropy, but the rest must increase by at least an equal amount. If the increase is equal to the decrease the increase is said to be "compensated," if it exceeds the decrease the excess is the "uncompensated" increase of entropy. A reversible change in an isolated system involves no increase of entropy of the system, and any change in the entropy of any part of the system must therefore be "compensated." When irreversible changes occur there is an increase of entropy of the system, and an uncompensated increase of entropy of some part of it. So far as reversible changes are concerned, it is evident that Mr. Swinburne's definition of entropy leads to the same result as the one commonly used, *i.e.* $\int \frac{dH}{\theta} = d\phi$. For if in a Carnot cycle heat H_1 is taken in by the working substance at a temperature θ_1, the increase of entropy of the substance $=H_1/\theta_1$, and if at the temperature of the coldest available reservoir θ_0, H_0 is given up by the substance, H_0 is Mr. Swinburne's waste heat, and H_0/θ_0, according to his definition, the increase of entropy of the substance when it took in H_1 from the reservoir θ_1. As temperatures are measured on the absolute scale, the two quantities are identical.

From this point onwards Mr. Swinburne's treatment of the equilibrium of isolated systems is much like those in use at present, except that he objects to the use of some of the names, *e.g.* "thermodynamic potential," now commonly used.

Prof. Perry, in the discussion which followed, stated that engineers, while using the definition of entropy which connected it with reversible changes, were quite aware that most of the processes with which they had to deal were irreversible, and that their theory was an approximation only.

Prof. Larmor thought Mr. Swinburne's method was a praiseworthy attempt to introduce simplification and precision into a part of the subject which had received little attention, and was still somewhat obscure, and Mr. Boys added that the ideas brought forward were well worthy of careful consideration.

Before stating his views as to the nature of the emanations from radio-active substances, Prof. Rutherford gave a short *résumé* of the known facts about radio-activity. Substances which possess the property throw off material which carries with it a positive electric charge. This charged material can penetrate to some extent through solids, is deviated in electric and magnetic fields, and appears to consist of particles of matter of about twice the weight of a hydrogen atom, moving with a velocity about one-tenth that of light. This is known as the α radiation, and accounts for about 99 per cent. of the energy sent out by a radio-active substance. Another kind of radiation, known as the β or kathode ray, is also emitted. It is negatively charged, more penetrative and more easily deviated than the α radiation, and appears to consist of particles of about one-thousandth the mass of the hydrogen atom. A third kind of radiation, known as the γ, is more penetrative still, but up to the present has not been sufficiently studied to enable its properties to be definitely stated. The matter which remains after the α radiation has been thrown off behaves in the case of thorium and radium like a gas of large molecular weight, diffuses, condenses at low temperatures, may deposit itself on bodies with which it comes into contact, and may again divide into a posi-

tively charged α radiation and a second emanation, and so on until the changes cease to produce the usual effect on an electrometer. Whatever the nature of the radio-active material, the amount of radiation it emits in unit time is equal to λ times the amount of radio-active element present, where λ is a constant for each type of matter, and is unaffected by chemical and physical agencies.

Prof. Rutherford regards the process which goes on in radio-active substances as a gradual breaking up of the atoms of the substance, and this gradual disintegration as the cause of the radio-active properties. The electrically neutral atom of a radio-active substance throws off a positively charged body which constitutes the α radiation; what remains of the atom constitutes the emanation. This again throws off a positively charged body, and the process repeats itself until the positively charged bodies are exhausted, and the substance no longer possesses radio-active properties.

This disintegration theory fits all the known facts, but it involves the existence in the atom of a radio-active substance of a store of energy hitherto unsuspected, amounting in the case of radium to at least 10^{16} ergs per gram. This energy exists, according to Prof. Rutherford, as kinetic energy of motion of the atoms in closed paths with velocities comparable with that of light, and disintegration is the moving off at a tangent of one or more of the particles of an atom. If this is the case it seems probable that the atomic energy of elements not yet found to be non-radio-active is of the same order of magnitude, and may be set free by methods of which we are not yet cognisant.

In the discussion which followed Sir Oliver Lodge said the theory put forward by Rutherford seemed to him to be a valuable working hypothesis, very near, if not absolutely, the truth. It was supported by Larmor's electrical theory, according to which the atoms of matter should be unstable.

Lord Kelvin, in a letter communicated to the section, put forward another theory as to the nature of the processes going on in radio-active materials. According to it each atom of matter has positive electricity distributed uniformly through its mass, and concentrated at one or more points, in general within it, atomic quantities of negative electricity, to which Lord Kelvin gives the name "electrions." A normal atom has the necessary number of electrions to neutralise the positive electricity associated with its matter. The α radiation consists of atoms of matter which have less than the normal number of electrions. When they move into matter they quickly pick up the negative charges necessary to render them neutral, and cease to be detected. The β radiation consists of electrions thrown off during violent oscillations of the atoms of matter, and are readily absorbed by matter. The γ radiation consists of vapour of the radio-active matter, *e.g.* radium, which would possess the penetrative power it is found to have if the Boscovichian forces between the atoms of radio-active matter and ordinary matter were small. The large amount of energy radiated is, according to this view, derived from without the atoms, where it exists in a form which we have not yet found a means of detecting.

Prof. Armstrong pointed out that, as the experiments of Rutherford and Soddy had been made on what was supposed to be radium bromide, the dissociation which they believed to be taking place might be of the compound and not of the element. He was disposed to regard Lord Kelvin's theory with favour.

Mr. Soddy thought ordinary chemical changes were excluded by the fact that the rate of production of the radiations was unaffected by chemical and physical conditions which greatly affected the former. The view Prof. Rutherford and he put forward was that at each stage of the process a new element was formed.

Prof. Dewar gave an account of the experiments on the effects of low temperature on the properties and spectrum of radium carried out partly in conjunction with Sir W. Crookes and recently communicated to the Royal Society.

Prof. Schuster thought the internal energy more probable than the absorption theory, and questioned whether the instability of the atoms predicted by electrical theory would account for the high velocities of the emanations. He was disposed to regard these high velocities as probably due to some cause not yet known.

Prof. Larmor agreed with Prof. Rutherford's theory, and pointed out that, just as atoms of matter must have size, or a half-size atom would still be an atom, so it may be that the atoms of electricity have size and configuration, and thus account for the complicated structure of the radium atom.

Mr. Whetham directed attention to the still unexplained fact that the negatively charged emanation seemed to deposit more readily on negatively than on positively charged bodies, and Dr. Lowry, after recounting some experiments on the flash of light seen when certain substances are crushed, suggested that the emanation might be a modification of a constituent of the atmosphere, *e.g.* helium.

C. H. LEES.

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE Southport meeting of Section B proved to be one of the most successful held during recent years; the meetings were largely attended, and a keen interest was exhibited in the proceedings of the section. After the reading of the presidential address (NATURE, p. 472), Prof. J. Campbell Brown described an apparatus for determining latent heats of evaporation, in which a known quantity of heat, generated electrically in a platinum wire, is absorbed in converting a liquid at its boiling point into vapour at the same temperature; very concordant results are obtained.

In a paper on some derivatives of fluorene, Miss Ida Smedley showed that whilst fluorenone $\begin{matrix} C_6H_4 \\ | \\ C_6H_4 \end{matrix} \!\!> C{=}O$, is orange-red in colour, the corresponding sulphur derivative, thiofluorenone, is intensely red; the radicle $>CS$ has thus a greater tendency to produce colour than the carbonyl group. In a paper on the action of diastase on the starch granules of raw and malted barley, Mr. A. R. Ling showed that the starch derived from both raw and malted barley is dissolved and hydrolysed by diastase at a temperature below its gelatinising point, and that the optical and reduction constants differ according to the sample of grain from which the starch is derived. Evidence was adduced in two other papers on the action of malt diastase on potato starch paste, one by Mr. A. R. Ling and the other by Mr. A. R. Ling and Mr. B. F. Davis, that when diastase is heated in aqueous solution at 60°–70° for a short time, the molecule of the enzyme becomes so changed that it no longer yields the same products when it acts on potato starch paste.

Dr. H. C. White described the chemical and physical characteristics of the so-called mad-stone, which, in accordance with a superstition current in the southern States of America, is used to detect and cure the bites of venomous snakes or rabid animals; the mad-stone is found to be a concretionary calculus from the gullet of the male deer, and is devoid of discriminative or curative powers.

Prof. E. A. Letts, Mr. R. F. Blake, and Mr. J. S. Totton read a paper on the reduction of nitrates by sewage, in which it was shown that, when potassium nitrate is added to the effluent from a septic tank, practically all the nitrogen is evolved in the free state or as nitric oxide; the oxygen of the nitrate is evolved as carbon dioxide.

A method for the separation of cobalt from nickel and for the volumetric determination of cobalt was described by Mr. R. L. Taylor; it is based on the fact that cobalt is precipitated quantitatively as a black oxide from neutral solutions by barium or calcium carbonate in presence of bromine water. The black oxide has the composition Co_8O_{14} or Co_7O_{11}.

Prof. J. Dewar, F.R.S., contributed a description of the more recent results obtained from his investigations at low temperatures; he described the methods by which he has succeeded in determining the densities of solid hydrogen, nitrogen, and oxygen, the methods of producing solid hydrogen and nitrogen, and the methods by which he has been able to determine the latent heats, specific heats, and the coefficient of expansion of liquid hydrogen.

A paper on the application of low temperatures to the study of biological problems, by Dr. Allan Macfadyen, is printed in another part of the present issue (p. 608).

Mr. J. Hübner and Prof. W. J. Pope, F.R.S., gave a paper on the cause of the lustre produced on mercerising

cotton under tension, which was illustrated by photographs in natural colours; the lustre of mercerised cotton is proved to be due to a corkscrew-like structure of the mercerised fibre brought about by a simultaneous swelling, shrinking and untwisting which attends the immersion in caustic soda.

Sir H. Roscoe, F.R.S., in presenting the report of the committee on duty-free alcohol, explained the conditions under which the Board of Inland Revenue are now prepared to allow the use of duty-free alcohol for the purposes of research work.

Prof. G. von Georgievics, in a paper on the theory of dyeing, argued strongly in favour of the mechanical as opposed to the chemical theory of dyeing, and claimed that the experimental work upon which the chemical theory is based is erroneous.

In opening a discussion on the general subject of combustion by a paper on the slow combustion of methane and ethane, Dr. W. A. Bone pointed out that his own experimental work showed that, in the combustion of methane, a primary oxidation to formaldehyde and steam occurs, followed by rapid oxidation of the formaldehyde to carbon monoxide, carbon dioxide and steam; in the burning of ethane both acetaldehyde and formaldehyde are formed as intermediate products.

In a preliminary note on some electric furnace reactions under high gaseous pressures, Messrs. J. E. Petavel and R. S. Hutton gave an account of work carried out in an enclosed electric furnace constructed to work with gaseous pressures up to 200 atmospheres. The reactions at present under investigation include the direct reduction of alumina by carbon, the formation of calcium carbide and of graphite, and the production of nitric acid and of cyanogen compounds.

In a paper on the atomic latent heats of fusion of the metals considered from the kinetic standpoint, Mr. H. Crompton showed that, if in the solidification of a liquid energy is lost solely in bringing moving monatomic molecules to rest, a constant can be deduced in a very simple manner from the latent heat of fusion; approximately the theoretical value is obtained for this constant with many of the metals, but not with gallium and bismuth.

Dr. E. P. Perman brought forward a number of results which he has obtained concerning the influence of small quantities of water in bringing about chemical reaction between salts; he investigated more particularly the action of potassium iodide upon salts of lead and mercury. In a paper on the constitution of disaccharides, Prof. Purdie, F.R.S., and Dr. J. C. Irvine described the methylation of cane-sugar and maltose; from experiments on the hydrolysis of the products of methylation they deduced evidence substantiating the constitutions attributed by Fischer to these two disaccharides.

Amongst other papers read in the section may be noted the following:—Stead's recent experiments on the causes and prevention of brittleness in steel, by Prof. T. Turner; the colour of iodides, by Mr. W. Ackroyd; on essential oils, by Dr. O. Silberrad; the cholesterol group, by Dr. R. H. Pickard; on acridines, by Prof. A. Senier; sur le spectre de self-induction du silicium et ses comparaisons astronomiques, by M. le Comte A. de Gramont; fluorescence as related to the constitution of organic substances, by Dr. J. T. Hewitt; freezing point curves of binary mixtures, by Dr. J. C. Philip; mutarotation in relation to the lactonic structure of glucose, by Dr. E. F. Armstrong; the synthesis of glucosides, the preparation of oximido-compounds and the action of oxides of nitrogen on oximido-compounds, by Mr. W. S. Mills; further investigations of the approximate estimation of minute quantities of arsenic in food, by Mr. W. Thomson.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE programme of the geological section of the British Association is usually more or less affected by the geological character of the country around the place of meeting, and this was the case in the present year, though the geology of Southport cannot compare in interest with that of Belfast, Glasgow, or other recent meeting places.

Mr. J. Lomas (Geology of the country around Southport) explained that the solid rock, Keuper and Bunter, is for the most part below sea-level, and only reaches the surface in a few places where it projects through the thick covering of Drift. The Drift is mainly Boulder-clay with an undulating surface, on which are found a number of lake-deposits, left by lakes or meres now partially or wholly drained.

One of these, Martin Mere, was visited by most of the geologists present, and was the subject of a paper by Mr. Harold Brodrick. Upon the Boulder-clay there is a bed of grey clay, which may be of either lacustrine or estuarine origin, and on it grew a forest of oak and Scotch fir. Numbers of trunks of the trees still remain, and Mr. Brodrick remarked that they have usually fallen in a north-east direction. These tree trunks are buried in a bed of peat, which is in places as much as 19 feet thick, and many dug-out canoes have been found in this peat.

The "submerged forest" at Leasowe, in Cheshire, is the remains of a similar mere which has been cut through by the sea, and the peat and tree trunks are now found on the coast below the level of high water. The question whether this points to a depression of the surface of the land was discussed, but the speakers hesitated to give any definite opinion.

Mr. Whitaker read the report of a committee appointed by the council of the Association to record observations on changes in the sea coast of the United Kingdom, and though there was no reference to Southport in the report, its reading was followed by considerable discussion. At Southport itself the land is gaining on the sea, and Mr. Lomas considers this to be due to the large amount of material brought down by the River Ribble. The sand dunes on the coast are, he believes, also due to material brought down by the river, which, drying at low water, is blown inland by the prevailing south-west wind. He remarked that sand dunes are usually found at and near the mouth of a fairly large river.

The question of coast changes was also discussed in a paper on a raised beach in County Cork by Messrs. Muff and Wright, of the Geological Survey. The beach deposits rest upon a platform of solid rock which is some 7 to 12 feet above the corresponding part of the present shore, and the beach deposits are covered by a thick bed of Boulder-clay, showing that they are of early Glacial, if not of pre-Glacial, age. This is almost an exact counterpart of the raised beach in Gower, South Wales, which was described by Mr. R. H. Tiddeman in a paper read before Section C of the British Association at Bradford in 1900.

Mr. Lamplugh (Land shells in the infra-Glacial chalk-rubble at Sewerby, near Bridlington) directed attention to the similarity of these raised beaches to that at Sewerby in Yorkshire. There we find (1) a beach deposit, a few feet above the present high-water mark, banked against an old chalk cliff; (2) a bed of land wash; (3) a bed of blown sand; and upon it (4) a bed of chalk-rubble, in which Mr. Lamplugh has found many specimens of *Pupa muscorum*, a land shell. Consequently the bed is a land wash corresponding to the "Head" of Cork and Gower. The author found this bed on the foreshore at Sewerby, showing that when it was formed the sea stood at a lower level than at the time of the beach deposits. This land wash is underneath all the Glacial Drifts of the Yorkshire coast.

In the discussion which followed the reading of these papers, it was suggested that the raised beaches may be due to an alteration in the level of the sea rather than to earth-movement. Mr. Clement Reid, however, remarked that, though the old sea beaches in Cork, Gower, and Yorkshire are about the same height above the present sea-level, there is at Penzance a well-marked notch in the rock at 65 feet above the sea, and in Sussex there is evidence of a sea-surface not only a few feet above the sea at Selsea, but also as much as 135 feet above the sea in Goodwood Park.

The relations of an estuarine deposit at Kirmington, in Lincolnshire, to the Glacial Drift was the subject of the report of a committee appointed at Belfast last year. The Kirmington Drift deposits are known to rest upon chalk, though the chalk has not yet been reached. A silty sand and chalk-rubble (1) is the lowest bed at present examined; upon it rests (2) a purple clay, no doubt a Boulder-clay, 12 feet thick; and above that (3) sand and chalky gravel 12 feet. Upon this (4) a thin fresh-water bed has now been found; and (5) a clay with estuarine shells, the whole being under (6) a second bed of Boulder-clay. The estuarine bed

with a fresh-water layer at its base is thus shown to be between two Boulder-clays, and the committee hopes to carry operations down to the Chalk before the meeting of the Association next year.

The report of the committee on Irish caves described explorations in some caves at Edenvale, near Ennis. Remains of man, associated with those of the bear, reindeer, &c., were recorded.

Implements, mainly Palæolithic, from the district between Reading and Maidenhead were dealt with in a paper by Mr. Llewellyn Treacher. He has obtained them in considerable numbers from gravels at levels of from 60 to 120 feet above the river Thames. The implements are usually of flint, but two examples of implements made from quartzite pebbles were described. The geological history of these pebbles is well known; they are from the Triassic pebble beds of the Birmingham district, and were brought into the Reading country by the River Thames in an early part of its history, when it drained an extensive tract now within the drainage area of the River Severn. Such pebbles are abundant in the old Thames Gravel, which caps much of the high ground north and north-west of Reading up to a level of about 500 feet above the sea, and no doubt the makers of the implements obtained the pebbles from the old Gravel.

The Swiss geologist, M. André Delebecque, read a short but very interesting paper on the lakes of the Upper Engadine. The lake of St. Moritz is, he said, obviously a rock basin, whilst the lakes of Sils, Silva Plana, and Campfer were, he believed, once a single lake also filling a rock basin. The torrents descending from side-valleys have now partially filled up this basin and divided it into the three lakes.

This paper led to a discussion on the origin of rock-basins. The author thought that, though Glacial erosion could hardly take place in very compact rocks, yet in many places even granite and gneiss become much decomposed, and glaciers may have swept away the decomposed rock and thus have produced hollows. Mr. Marr considered that every region containing rock-basins must be studied by itself, and that they are probably the result of many different causes.

Mr. Lamplugh said that, in regions of extreme Glacial erosion, we find true rock-basins near the gathering ground of ice, but as we approach the margin of the glaciated area we find lakes due to terminal moraines, kettle holes, &c.; thus in the marginal areas the lakes are not the result of direct ice-erosion, but are due to secondary causes.

Mr. Clement Reid said it was unfortunate that in north Europe the ice had so completely cleared away the soft deposits of the late pre-Glacial age that we have very little evidence as to the age of the lake or rock-basins.

In south Europe such evidence is often to be found, and he mentioned a case in Italy, near Florence, where there have been three lakes; the lowest, now silted up, is of about the age of our Cromer Forest Bed, the second, also filled up, is a Pleistocene lake, whilst the third, and highest, still exists as a lake. The speaker suggested that these lakes were due to earth-movements in a direction at right angles to the valley.

Passing to petrography, Mr. Teall contributed a most interesting paper on dedolomitisation. Taking a cherty dolomite, such as that of Durness, he showed that it has been dedolomitised by the formation of magnesian silicates, whereas in the case of the marbles formed of calcite and brucite it may be inferred that, under the conditions which prevailed during the intrusion of the plutonic rocks, the carbonic acid freed itself more readily from the magnesia than from the lime, thus in the absence of silica giving rise to the formation of periclase and converting the original dolomite into an aggregate of calcite and periclase, the periclase having been subsequently changed to brucite. The author instanced the predazzite of the Tyrol as a rock probably formed in this latter way. The history of the rock would then be as follows:—(1) formation of the limestone; (2) dolomitisation; (3) intrusion of igneous rock and dedolomitisation in consequence of the development of silicate or periclase; (4) hydration.

Mr. G. W. Lamplugh, whose name is well known in connection with the study of crush-breccias and conglomerates, read a paper on the disturbances of junction-beds from differential shrinkage and similar local causes during consolidation. He thought that in many cases rock was indurated before it became covered up by the succeeding strata, and that many of the curious structures we see in calcareous rocks may have been due to hardening before anything was laid on top of them. He instanced structures common in the Chalk and Lower Cretaceous rocks. He suggested that shrinkage during consolidation may account for the peculiar appearances which we sometimes see where a thin clay or shale is interbedded with thick sands, such as in the Hastings Sands, or at a junction such as that of the sand of the Lower Greensand with an underlying clay.

Mr. J. Lomas referred to a similar problem in a paper on Polyzoa as rock-cementing organisms.

The difficult question of the distinction between intrusive and contemporaneous igneous rocks was raised in papers by Mr. W. S. Boulton and by Messrs. T. H. Cope and J. Lomas, and was discussed at some length.

Mr. Boulton dealt with the basaltic rock associated with the Carboniferous Limestone at Spring Cove, Weston-super-Mare. The igneous rock shows a marked pillow-structure, contains tuff and agglomerate, and includes lumps and masses of the limestone.

The tuff within the sheet behaves like a lava showing flow structure, and is clearly not the result of sedimentation. The author believes the included limestone-fragments were derived from the underlying calcareous floor when it was a sea-bottom, the masses having been rolled and picked up by the lava, and thus become intercalated between its spheroidal masses. He thought the igneous rock was a submarine flow of lava. Messrs. Cope and Lomas dealt with the igneous rocks of the Berwyns. The district has a dome-like structure, shales and limestones of Llandeilo age being exposed on the top of the dome, whilst the newer Bala beds form a ring around. There are four thick sheets of rock which have hitherto been regarded as contemporaneous volcanic ashes. The authors, however, believe them to be intrusive igneous rocks.

Mr. J. G. Goodchild (Some facts bearing on the origin of eruptive rocks) contended that intrusive masses, as a rule, replace their own volume of the rocks which they invade, and do not cause displacement to any important extent. This paper gave rise to some discussion, for there were present many believers in the existence of laccolites. One speaker suggested that the presence of flow structure along the margins of intrusive igneous rocks was scarcely in harmony with the author's views. It was, however, admitted that there were difficulties when a dyke ends upwards or laterally against strata.

The palæontological papers were of considerable interest. Mr. A. C. Seward, president of the botanical section, read a paper before Section C on the fossil floras of South Africa. He considers that the plants from the Uitenhage series of Cape Colony are of Wealden age, and assigns those from the Stormberg Series to the Rhætic period. With regard to the Vereeniging plants, he describes them as belonging to a flora which flourished in South Africa, India, South America, and Australia during some portion of the Permo-Carboniferous epoch, perhaps that part nearly corresponding to the Upper Carboniferous of Europe. We have, he said, in South Africa as in South America, evidence of an overlapping or commingling of the northern and southern botanical provinces.

The Carboniferous flora of the Ardwick series of Manchester was the subject of a paper by Mr. Newell Arber, and some additional details as to the Carboniferous Mollusca were furnished in the report of the committee on life-zones in the rocks of that period.

Dr. Smith Woodward described an Acanthodian fish, Gyracanthides, from the Carboniferous of Victoria, Australia, and in illustration of another paper he exhibited some fragments of bone from Brazil. They were from a Red Sandstone formation, probably of Triassic age, and it had been suggested that they belong to an Anomodont reptile.

Mr. W. G. Fearnsides (on the Lower Ordovician rocks in the neighbourhood of Snowdon and Llanberis) gave an account of his discovery of fossils round the south-west and north-west flanks of Snowdon, from Criccieth to Llanberis. They are in beds corresponding to the well-known South Wales Llanvirn series, and are the first fossils recorded from beds on Snowdon older than the fossiliferous Bala ash of the summit.

Finally, the committee appointed last year to investigate the fauna and flora of the Trias of the British Isles made its first report. It was written by Mr. H. C. Beasley, and deals with cheirotheroid foot-prints. The attendance at the meetings of the section was good, and on several occasions the papers led to animated and interesting discussions.

H. W. M.

ZOOLOGY AT THE BRITISH ASSOCIATION.

THE president's address—which was postponed until Friday, September 11, in order to avoid the hours fixed for the opening addresses in the other biological sections—dealt first with the inadequacy of the public provision made for the advancement of zoology and its applications in this country, and secondly with some considerations bearing on the problems of variation and heredity, more especially as seen in the Cœlenterata. In fact, influenced no doubt by the personal work of the president, a considerable number of the communications brought before the section this year dealt with the Cœlenterata, especially with corals and coral reefs.

Thursday, September 10.—The forenoon was given up to coral papers, and the afternoon mainly to reports of committees. Dr. J. E. Duerden (from the United States) gave two papers, "Septal Sequence in the Coral Siderastræa" and "Morphology and Development of Recent and Fossil Corals"—these being some of the results of the author's studies of living West Indian corals while he served as curator of the museum at Jamaica. He directed attention to the general occurrence of boring filamentous Algæ, and to the fact that the colours of West Indian corals are mainly due to the presence of symbiotic yellow cells (zooxanthellæ) in the endoderm. Mr. C. Crossland had a paper describing the coral formations he met with on the east coast of Africa, near Zanzibar, and Mr. Stanley Gardiner gave a general account of the coral reefs of the Indian Ocean. In connection with this, Prof. Herdman directed attention to the fact that, in the Gulf of Manaar, calcareous masses ("calcretes") of great extent are formed *in situ* on the sea-bottom by the cementing of sand and other loose material by calcareous incrusting Polyzoa. Miss Edith Pratt had a paper on the assimilation and distribution of nutriment in *Alcyonium digitatum*. The polypes exercise choice, and feed mainly on small Crustacea. Miss Pratt regards the so-called nerve-plexus as part of a system of amœboid endoderm cells conveying nutriment throughout the colony. Prof. Hickson described a case of polymorphism in a *Pennatula murrayi* from eastern seas. Dr. J. Cameron gave a lantern demonstration on the origin of the epiphysis in Amphibia as a bilateral structure.

The reports of committees were as follows:—(1) On bird migration in Great Britain and Ireland. This is the final report, and consists chiefly of Mr. Eagle Clarke's observations on the starling and the rook. (2) Naples Zoological Station. This includes a detailed account, by Mr. W. Wallace, of his investigations on the oocyte of Tomopteris. (3) "Index Animalium." The first volume, dealing with the period 1758–1800, has been issued, and the indexing of 1801–1900 is now being continued by Mr. Sherborn. (4) Zoology of the Sandwich Islands. This is the thirteenth report, and the work is still in progress. (5) Coral reefs of the Indian region. (6) Plymouth Marine Laboratory. (7) Millport Marine Laboratory. As on this occasion the physiological section did not meet separately, the physiological papers were taken in Section D. These included two reports:—(1) The microchemistry of cells. This dealt chiefly with the localisation of potassium in the living cell, and was drawn up by Prof. A. B. Macallum. (2) The state of solution of proteids.

Friday, September 11.—After the presidential address came a paper by Dr. Gamble and Mr. Keeble on the bionomics of *Convoluta roscoffensis*, with special reference to its green cells. This was followed by three short notes by Prof. R. J. Anderson—the skull of *Ursus ornatus*, the skull of *Grampus griseus*, and the peritoneum in *Meles taxus*. The section did not meet on Saturday.

Monday, September 14.—The morning was devoted to a joint discussion with botanists on fertilisation, in which the president, Prof. Hartog, Prof. Bretland Farmer, Mr. W. Bateson, Mr. M. D. Hill, and Mr. Jenkinson took part. The following papers were then read:—M. D. Hill, on nuclear changes in the egg of Alcyonium; Prof. Hartog, on the function of chromatin in cell division, and on the tentacles of Suctoria; Prof. Hickson, on conjugation in Dendrocometes (demonstrated with slides); J. W. Jenkinson, on some experiments on the development of the frog; Dr. Leighton, on British reptiles; N. Annandale, on the coloration of Malayan reptiles; H. C. Robinson, on the walking fish of the Malay Peninsula, and also an exhibition of convergent series of Malayan butterflies.

Tuesday, September 15.—Prof. Herdman gave a short account of a remarkable phosphorescence phenomenon observed in the Indian Ocean, which led to descriptions of other similar occurrences by the president, Mr. Stanley Gardiner, Mr. Bateson, and others. Prof. Herdman then read a joint note by Mr. James Hornell and himself on pearl-formation in the Ceylon pearl oyster, giving a biological classification of pearls into (1) ampullary, (2) muscle pearls, and (3) cyst pearls. The remaining papers were mainly physiological in their bearing, viz. Captain Barrett-Hamilton, on a physiological theory of the winter whitening of animals; Prof. B. Moore, on a new form of osmometer for direct determinations of osmotic pressure of colloids, and also experiments on the permeability of lipoid membranes; Prof. Sherrington and Dr. Grünbaum, on the cerebrum of apes; Mr. J. Barcroft, on the origin of water in saliva; Dr. Greaves, demonstration of visual combination of complementary colours; Mr. C. V. Hughes, note on two rare birds; Dr. Rennie, on epithelial islets in the pancreas of Teleosteans; Mr. D. C. McIntosh, on variation in *Ophiocoma nigra*; and Prof. W. C. M'Intosh, on the eggs of the shanny. Dr. Rennie suggests that his epithelial islets are blood-glands which have entered into a secondary relation to the pancreas, and that they maintain their primitive function of producing an internal secretion.

The section did not meet on Wednesday, but on Thursday, September 17, there was a dredging expedition, in which the president and a number of the members of Section D took part. The expedition was in the Lancashire Sea-Fisheries steamer, *John Fell*, kindly lent for the purpose by the committee, and was under the leadership of Mr. Dawson (Superintendent of Fisheries), Mr. Isaac Thompson (of the Liverpool Marine Biology Committee), and Prof. Herdman. The first hauls of the fish and shrimp trawls were taken in the shallow waters off Southport and the estuary of the Mersey, in order to show the fauna of the characteristic Lancashire small-fish "nurseries"; a visit was paid to the local shrimping fleet, a fishing boat was overhauled and boarded and its nets examined, and the other routine operations of the fisheries steamer in policing and inspecting the district were fully explained to the party. The processes of taking the physical observations, and of examining, counting, and recording a haul of the trawl were also gone through. Later in the day dredging and tow-netting took place further out to sea on harder ground with a more varied fauna. Although not strictly part of the work of the section, this dredging expedition made an interesting and appropriate finish to a very successful zoological meeting.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. SYDNEY YOUNG, F.R.S., professor of chemistry in University College, Bristol, has been appointed to the chair of chemistry in Trinity College, Dublin, vacant by the resignation of Prof. Emerson Reynolds.

ONE of the two open entrance scholarships which were recently founded at the Victoria University of Manchester, each of the value of 100*l*., has been awarded to Mr. W. C. Denniston.

DR. JOHN WHITE, of the University of Nebraska, has been appointed head of the department of chemistry at the Rose Polytechnic Institute, succeeding Prof. W. A. Noyes, who was recently appointed chief chemist of the American National Bureau of Standards.

THE course of Saturday morning lectures on the teaching of mathematics, which the London Technical Education

Board announced would be commenced by Prof. Hudson at King's College, Strand, on October 17, has been postponed until next term, and will begin on January 23, 1904.

AT a special convocation of the University of Toronto on October 2, the following honorary degrees were conferred, in connection with the opening ceremonies of the new physiological and medical laboratories:—LL.D. (*honoris causa*), Prof. W. W. Keen, Jefferson Medical College, Philadelphia; Prof. W. H. Welch, Johns Hopkins University; Prof. William Osler, F.R.S., Johns Hopkins University; Prof. R. H. Chittenden, Yale University; Prof. Charles S. Sherrington, F.R.S., University of Liverpool. *In absentia*, Prof. H. P. Bowditch, Harvard University. The inaugural address at the opening of the laboratories was delivered by Prof. Sherrington.

THE new buildings of the Essex County Technical Laboratories, Chelmsford, will be opened by the Earl of Onslow, President of the Board of Agriculture, on Friday afternoon, October 30. The buildings, which have just been completed at a cost of nearly 12,000*l.*, comprise chemical, physical and biological laboratories and class-rooms, together with agricultural and horticultural museums and libraries, and provide facilities for systematic instruction in agriculture and horticulture, as well as in pure science. The laboratories are intended to be a centre for agricultural and horticultural information for the whole county, and they include rooms for the analysis of soils, manures, foods, seeds, &c., and for other scientific work carried on in the interest of these industries.

IN reply to a memorial to the Board of Agriculture, asking that ordnance maps might be sold at reduced prices for teaching purposes, the Geographical Association has been informed that the Board is prepared to authorise the Ordnance Survey Department to produce and supply to educational authorities a special edition of the outline 1-inch maps, printed on cheap but reasonably strong paper, at the following prices:—200 copies, 1*l.* 5*s.*; 500 copies, 2*l.*; 1000 copies, 3*l.*; 5000 copies, 12*l.* For larger numbers the estimated price would be 2*l.* per 1000 copies. The Board has stipulated that any maps thus supplied should not be sold, and a heading is to be printed on the maps to this effect. Referring to the educational advantages of the Board's decision, Dr. Herbertson, secretary of the Geographical Association, remarks:—"It is universally agreed that all sound geographical teaching must begin in a study of the home region, and it is therefore to be hoped that most teachers will avail themselves of the facilities so generously granted, either individually or by making application through the local education authority."

MUCH of the success of the Glasgow and West of Scotland Technical College could probably be traced to the wide-spread interest in its work shown by the Corporation of Glasgow, by Scottish manufacturers and merchants, and by the associations both of professional men and of artisans. The most recent annual report of the governors of the college provides many indications of the belief in the value of higher technical education by the inhabitants of Glasgow and its neighbourhood. The Corporation of Glasgow has made a grant of 5000*l.*, of which 4500*l.* was towards working expenses and 500*l.* towards the building fund; many manufacturers and others have given facilities for visits to their works by parties of students, and many merchants have made additions to the college equipment or have supplied laboratory material. It is of interest to note that the total expenditure involved by the erection of the new buildings, the foundation stone of which was laid last May by the King, exclusive of equipment, will be not less than 210,000*l.* Of this sum the governors are able to announce promises of donations and grants amounting to 182,382*l.*

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 7.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. G. C. **Champion** exhibited on behalf of Prof. Hudson **Beare** some specimens of a Ptinus new to the British list, captured in a granary at Strood on May 11, 1901.—Mr. C. O. **Waterhouse** exhibited on behalf of Mr. Charles **Pool** specimens of a beetle of the genus Niphus, closely resembling *N. crenatus*, but with distinct shoulders, and more parallel elytra which are less strongly striated. They were found in large numbers in a corn chandler's at Edmonton.—Mr. H. St. J. **Donisthorpe** exhibited specimens of *Aphanisticus emarginatus* from the Isle of Wight, a beetle new to the British list, and a Scymnus, new to science, from the same locality.—Mr. M. **Burr** exhibited a living adult male earwig, *Labidura riparia*, Pall., captured near Boscombe at the end of August. He said that the very noticeable pale coloration becomes darker after death, sometimes nearly black, which might account for some of the numerous "colour-varieties."—Dr. Norman **Joy** exhibited a specimen of *Argynnis selene*, taken last year in Berkshire, showing a remarkable tendency to melanism, and rare Coleoptera taken in the same county during 1903.—Sir George **Hampson** exhibited a collection of Norwegian butterflies made by him on the Dorsefjeld, on the Alten fiord, at Bossekop, and other localities this year, including series of *Colias hecla*, Lef., *Chrysophanus hippothöe*, and var. *stieberi*, Gerh., *Œneis norna*, Thnb., *Melitaea*, var. *Norvegica*, Auriv., the Norwegian form of *M. aurelia*, *Argynnis freiga*, and *A. frigga*, a Labrador, Arctic, and North American species, now found further south, at Kongsvold, for the first time.—Mr. A. H. **Jones** exhibited examples of *Erebia christi*, taken this summer in the Laquinthal, and of the species of Erebia, to which it is allied; a local form of *Satyrus actaea*, var. *cordula*, from Sierre; and a short series of *Chrysophanus dorilis* (type) and *C.* var. *subalpina* from the Laquinthal, with *P. hippothöe*, var. *eurybia*, showing the strong resemblance on the upper surface which the ♀ of this latter species bears to the ♀ *subalpina*.—Mr. A. J. **Chitty** exhibited specimens of *Procto trupid*, which he said approached *Poncra constricta* in appearance, but might be an Isobrachium. If so, it was new to the British list.—Mr. H. Willoughby **Ellis** exhibited *Criocephalus polonicus*, Motsch, a longicorn beetle new to Great Britain, from the New Forest, and also specimens of all stages, from the egg to the imago, to illustrate the life-history of the species. He also exhibited specimens of *Asemum striatum*, L., with larva and pupa, accounted heretofore rare in the New Forest, but this year occurring in abundance.—Mr. Ambrose **Quail** exhibited cases showing the life-history of some Australian Hepialidæ.—Dr. D. **Sharp,** F.R.S., exhibited specimens illustrative of the egg-cases and life-histories of eight species of South African Cassididæ, as described in a paper by Mr. F. Muir and himself.—Mr. W. L. **Distant** also showed the pupa cases of some African species of Aspidomorpha, with the cast heads of the larvæ.—Mr. Roland **Trimen,** F.R.S., exhibited some cases of mimicry between butterflies inhabiting the Kavirondo-Nandi district of the Uganda British Protectorate, particularly that in which *Planema poggei*, Dewitz, is imitated by an apparent variety of *Pseudacraea künowii*, Dewitz, and also by a hitherto undescribed form of the polymorphic ♀ *Papilio merope*, Cram. He mentioned that both *Planema poggei* and *Pseudacraea künowii* were described and figured by Dewitz in 1879 from single specimens taken by Dr. Pogge in Angola, and added the interesting fact that the only other example of the undescribed mimicking form of the ♀ *Papilio merope* known to him—in the Hope Department of the Oxford University Museum—is ticketed "Angola; Rogers, 1873." The president referred to the special interest attaching to an interpretation of this remarkable form of the female *merope*; at the same time he pointed out that the interpretation so convincingly illustrated that evening had been made out last spring by Mr. S. A. Neave, who exhibited this form of the female *merope*, together with *Planema poggei* as its model, at both *soirées* of the Royal Society in May and June, a time when Mr. Trimen's absence from England unfortunately prevented him from seeing them.—Dr. T. A. **Chapman** exhibited *Coenonympha oedipus*, *Satyrus dryas*, and *Heteropterus morpheus*, taken last summer near Biarritz, and *Erebia crias* and *E. stygne*, from the Logroño Sierra, Spain. These he suggested were probably examples of homœochromatism. Little attention has been directed to homœochromatism in European butterflies, and these were certainly not examples of the detailed mimetism we are now familiar with in Müllerian groups from the African

and neotropical regions.—Dr. **Chapman** also exhibited living imagines of *Crinopteryx familiella*. These had just emerged at Reigate, where they and their parents, descended from pupæ brought from Cannes in March, 1901, had lived out of doors during their active existence, being brought into the house only during their pupal æstivation. This seemed noteworthy in so southern (Mediterranean) a species. The experiment seemed quite likely to continue successful for the next generation.—Mr. Ambrose **Quail** read papers on the antennæ of the Hepialidæ and on *Epalxiphora axenana*, Theyr.—Mr. Gilbert J. **Arrow** read a paper on the laparostict lamelicorn Coleoptera of Grenada and St. Vincent, West Indies.—Mr. T. H. **Taylor** communicated notes on the habits of *Chironomus* (*orthocladius*) *sordidellus*.—Mr. F. Du Cane **Godman**, F.R.S., communicated descriptions of some new species of Erycinidæ.—Mr. W. L. **Distant** communicated additions to the rhynchotal fauna of Central America.—Dr. D. **Sharp**, F.R.S., read a paper on the egg-cases and early stages of some Cassididæ.

PARIS.

Academy of Sciences, October 12.—M. Albert Gaudry in the chair.—The perpetual secretary announced to the Academy the death of Prof. Rudolf Lipschitz, correspondant for the section of geometry.—On the relations between the theory of double integrals of the second species and that of the integrals of total differentials, by M. Émile **Picard**.—On the temperature of inflammation and on the slow combustion of sulphur in oxygen and in air, by M. Henri **Moissan**. The temperature of inflammation of sulphur is 282° C. in oxygen and 363° in air, at atmospheric pressure. Sulphur dioxide can be detected after twelve hours at 100° C., giving a distinct quantity of solid at −186°.—Palæontological observations in Alaska, by M. Albert **Gaudry**. The abundance of mammoth remains near Yukon leads to the conclusion that at a far distant epoch the climate was far less severe than at present.—On the new function $E_a(x)$, by M. G. **Mittag-Leffler**.—The detection and estimation of urea in the tissues and in the blood of vertebrate animals, by M. Nestor **Gréhant**. The alcohol extract is evaporated at 50° C., the residue treated with nitrous acid, and the gases pumped out, the carbon dioxide being measured. Both the blood and muscles of mammals were found to contain urea, of birds, none.—On linear equations of finite differences, by M. Alf. **Guldberg**.—On the working of coherers, by M. Albert **Turpain**.—Contact electrification and the theory of colloid solutions, by M. Jean **Perrin**. If a substance in contact with water takes a strong electrification and small surface tension, the stable state of the system will be realised by an emulsion of granules of fixed diameter, dispersed in the water.—The action of carbonic acid under pressure on metallic phosphates, by M. A. **Barillé**.—On a series of bismuth compounds, by MM. G. **Urbain** and H. **Lacombe**. From an examination of the double nitrates, the author concludes that bismuth stands in the same relation to the rare earths as zinc does to magnesium.—On the estimation of vanadium in metallurgical products, by M. Em. **Campagne**. The metal is converted into chloride, the bulk of the ferric chloride removed by ether, and the vanadium converted into $VOCl_2$ by evaporation with hydrochloric acid. This is converted into sulphate, and titrated with permanganate.—On the nitric esters of the alcohol-acids, by M. H. **Duval**. The preparation and properties of the nitrates of glycollic, malic, and glyceric acids are described.—The abnormal fixation of trioxymethylene on certain organo-magnesium derivatives, by MM. M. **Tiffenau** and R. **Delange**. The compound obtained by the action of magnesium upon benzyl chloride behaves abnormally with trioxymethylene, giving orthotolyl alcohol, $CH_3.C_6H_4.CH_2OH$, instead of the phenyl-ethyl alcohol, $C_6H_5.CH_2.CH_2OH$, which might have been expected. The magnesium compound, however, possesses the normal constitution, $C_6H_5.CH_2.Mg.Cl$, as is shown by the production of phenylacetic acid by the action of carbon dioxide.—The action of mixed organo-magnesium compounds upon amides: a new method for the preparation of ketones, by M. Constantin **Béis**. When an amide is heated on the water bath with an excess of an organo-magnesium compound, and the product treated with water, ketones are produced. Methyl-ethyl-ketone, diethyl-ketone, methyl-propyl-ketone, isobutyl-ethyl-ketone, acetophenone, and phenyl-ethyl-ketone have been prepared by this method, which appears to be of general application.—On the oscillatory movements of *Convoluta roscoffensis*, by M. Georges **Bohn**.—On the vegetative apparatus of the yellow rust of cereals, by M. Jakob **Eriksson**.—The necessity of a microbial symbiosis for obtaining a culture of the Myxomycetes, by M. **Pinoy**.—On a new mineral species, by M. A. **Lacroix**. The mineral, which is named grandidierite, has the composition

$$7SiO_2.11(Al,Fe)_2O_3.7(Mg,Fe,Ca)O.2(Na,K,H)_2O,$$

and is one of the most basic silicates known. It was found in South Madagascar.—On the Turonian of Abou Roach (Egypt), by M. R. **Fourtau**.

VECTORS AND ROTORS.

Vectors and Rotors, with Applications. By O. Henrici, Ph.D., LL.D., F.R.S., and G. C. Turner, B.Sc. Pp. xv + 204. (London: Edward Arnold, n.d.) Price 4s. 6d.

PROF. HENRICI can always be depended upon to embellish any mathematical subject which he touches, because, with the skill of the analyst, he combines the keen perception of the geometer, which ever seeks to render the results of analysis in some way visible by spatial representation—or, perhaps, to reach the results directly (and often more simply) without any aid from analysis at all. To a mathematician of this kind the subject of vector analysis is peculiarly appropriate. We are therefore indebted to Mr. Turner for putting into systematic form the lectures delivered by Prof. Henrici at the City and Guilds Technical College, and producing a very simple and elementary work the methods and ideas of which should find a very early introduction into our ordinary mathematical teaching.

The system here put forth is non-Hamiltonian. A vector is throughout a mere "carrier." With Hamilton it was this and more; every unit vector, when employed as a factor, said Hamilton, is to be regarded as a quadrantal versor the plane of which is perpendicular to the vector. In the non-Hamiltonian system the vector is not in any way associated with the notion of rotation. Some vectors are, except as regards *direction* and *sense*, absolutely unrestricted in space; others (such as forces acting on a body) are restricted to definite right lines and are called *localised vectors*. For these latter the special name of "rotors" has been invented, and Prof. Henrici must excuse an adherent of the Hamiltonian system for saying that this name seems to be wholly unjustified in a system which refuses to associate the notion of a rotational operation with any vector. Assuming that a "rotor" means, perchance, a "rotator," how comes it that such a name is applied to a mere "carrier"? There is another term also adopted by Prof. Henrici the justification of which is at least difficult, viz. the term "ort." A vector of unit length is called an "ort," which is explained to be "short for orientation," and "orientation" makes a dangerous suggestion of rotation. The "ort" is, of course, Hamilton's *unit vector*. The "rotor" and the "ort" should be regarded by anti-Hamiltonians as the trail of the serpent.[1]

The contrast between the two systems is well illustrated by the discussion of the product, $\alpha\beta$, of two vectors, α and β, which forms the subject of chapter iii. of Prof. Henrici's book. With Hamilton the nature of the expression follows simply and naturally; $\alpha\beta$ means α/β^{-1}, an operation implying rotation—the conversion of the vector β^{-1} into the vector α. It can therefore be taken as either a combined tensor and versor operation, or a combined scalar and vector operation. This at once gives us the complete specification of the vector of $\alpha\beta$, and also that of the scalar of $\alpha\beta$, making the latter equal to $-ab\cos\theta$, where a and b are the tensors of α and β, and θ the angle between them.

Prof. Henrici, by a very simple and consistent rule, specifies the vector part and makes it identical with Hamilton's specification, but he makes the scalar $+ab\cos\theta$, by what, after all, amounts to a perfectly arbitrary and dogmatic definition (p. 95), its systematic connection with the mode of defining $V\alpha\beta$ being somewhat strained and unconvincing.

This, however, is a matter of no consequence, since he is quite at liberty to lay down his own definitions, inasmuch as he is not hampered by the Hamiltonian notion of rotation as associated with a vector.

As regards notation in this part of the subject, it may be pointed out that Prof. Henrici uses $[\alpha\beta]$ for the Hamiltonian $V\alpha\beta$, and (α,β) instead of $S\alpha\beta$, which certainly does not seem to be an improvement, especially when we have to write down a long vector or scalar equation—such, for example, as (iii.), p. 199. Again, the notation $[\alpha|\beta+\gamma]$, instead of $V\alpha(\beta+\gamma)$, is scarcely pleasing to the eye, even if it is not calculated to lead to slips in working.

The only indication that Prof. Henrici gives of his view of the quaternion system is found in p. 104, where he dispenses with the operation of division by vectors. "This operation is complicated and will not be considered at all. It leads to the much more complicated Theory of Quaternions." It is, however, quite open to a Hamiltonian to say nothing about division of vectors; he can treat his vectors as mere "carriers," and claim all the results of a non-Hamiltonian theory as his own; for a non-Hamiltonian is not necessarily an anti-Hamiltonian theory. It remains, of course, quite true that with Hamilton division is the primary notion, and multiplication the secondary.

The subjects selected by Prof. Henrici for vector treatment are geometrical and statical. Almost all the prominent results of elementary geometry are shortly and neatly obtained, and among the illustrations of this subject are the Peaucellier and Hart mechanisms for the description of a right line. There is a very full discussion of centres of mass, and a planimetric method of finding the centre of mass of any area, which method is not so well known as it ought to be. The determination of the centre of parallel forces by the use of link (or funicular) polygons is fully explained, while—to the great advantage of the student—Prof. Henrici is very lavish of his figures.

So very few elegances escape the watchful eye of Prof. Henrici that one feels a pleasure in pointing out something that he might have included in his discussion of force systems. The centre of a parallel system of forces is known to everyone, but the *astatic centre* of a system of coplanar forces has received little attention. Yet it is a striking entity, and one which is closely allied to the other centre. Its definition is fairly well known; perhaps the best specification of it treats it as the point of intersection of the line of no moment with the line of no virial.

The portion of the book dealing with statics treats largely of the stresses in frameworks, shearing forces, bending moments, &c., the treatment being, of course,

[1] Prof. A. Lodge suggests the term "locor" for rotor.

all vectorial, that is, geometrical, and marked by great clearness of exposition. Such a treatment of statics forms a most needful corrective of the methods of a purely "analytical statics," which has a strong tendency to keep the subject aloof from reality, and to obscure its physical nature. "One does not find figures in this book," boasted Lagrange in his "Mécanique Analytique," but the absence of geometrical methods and conceptions is not to the advantage of the subject.

In the penultimate chapter Prof. Henrici gives a short, very useful, and well explained account of the reciprocal figures of graphic statics, and the last chapter is a very short one on the deduction of the elementary trigonometrical formulæ from vector methods. With all deference to the author, however, it is to be feared that pupils will not, within time at the earth's disposal, be so much accustomed to think in vectors as to deduce their notions of a sine and a cosine otherwise than by the old method.

Next to the systematic teaching of the solution of all kinds of equations by graphic constructions, the wider employment of geometrical methods in dynamics is our greatest desideratum, and for this reason we have to thank Prof. Henrici for this elegant little treatise.

GEORGE M. MINCHIN.

THREE PROTOZOAN ARTICLES.

A Treatise on Zoology. Edited by E. Ray Lankester, LL.D., F.R.S., &c. Part i. Introduction and Protozoa. Second Fascicle. Pp. vi+451. (London: A. and C. Black, 1903.) Price 15s. net.

THE erratic order in which the various volumes of Prof. Lankester's treatise are appearing is, from the nature of their subject, a matter of very little consequence, and we are glad to welcome now this instalment of the protozoan chapter. It is the second fascicle of part i., of which the first fascicle, containing the introduction and the groups not here included, has still to appear. The inconvenience of the intended arrangement of parts is clearly demonstrated, and it is very fortunate that it has not resulted in the detention at the press of the valuable essays which make up this volume. A large part of the editor's difficulties have resulted, it is clear, from his adherence to the plan of producing bound volumes of nearly uniform size—in following, that is to say, the mode of publication of the recent "Cambridge Natural History" and of other similar works of collaboration. We believe it would prove to be in the interest of authors and readers alike if no attempt were made by the editors of series of this kind to produce periodically completed volumes, and if the separate articles were issued uniformly, but unbound, in the style of German monographs. The total expense to the purchaser of the whole series could remain the same by an obvious arrangement, while the gain to many specialists would be immense. We have a case in point in the present volume. Prof. Minchin's valuable monograph on the Sporozoa occupies about one-half of the whole volume, and might, we gather, have been already for some time in our hands if it had appeared separately in paper covers. Its subject is precisely one in which publication might well have been both early and individual in the interests of the medical profession, for which it has, perhaps, its chief importance at the present time. The deliberate manufacture of volumes, as such, while we can see nothing at all to recommend it, is exposed at the same time to the serious objection of stimulating over-production. The publication of a complete "Cambridge Natural History," and now of what is virtually an Oxford treatise, suggests inevitably that among the whole body of English zoologists a good deal of research has been recently sacrificed to text-book writing, of which a large part, however conscientious, has been redundant.

We can say this now with the greater assurance, because it cannot be taken as applying to the excellent articles on the Foraminifera, the Sporozoa, the Ciliata, and the Acinetaria in the present volume. The section dealing with the Sporozoa, by Prof. Minchin, takes its place as an admirable systematic account of the group, prefaced by a general sketch of their characters and of the typical life-history. The recent developments of our knowledge of sporozoan parasites in connection with malarial disease give a special importance, as we have said, to this monograph. Prof. Minchin provides in his description of the Hæmosporidia exactly what is now becoming essential knowledge for the student of disease, and it is highly desirable, we think, that medical men should approach the study of this group from a more general point of view than that permitted in the restricted accounts of the malaria parasite written specially for their use. In the interests of further developments of curative and preventive treatment in new directions, it is of the first importance that the morphology and life-cycles of the members of this group should be completely determined, although, as the author claims, "the life-cycle of the malarial parasite is now thoroughly known in all its features." The recent work of Schaudinn, who has explained the occurrence of relapse in malaria without fresh infection as due to a kind of parthenogenetic reproduction by resistant and long-lived macrogametocytes, is an example of the value in these inquiries of a zoological outlook, and it is to be remembered that the "black spores" of Ross have not yet been assigned with certainty to their place in a life-cycle. With regard to the voluminously alleged connection between the Sporozoa and cancer, Prof. Minchin is content to express the hostility of most zoologists, but he gives all the necessary material for following the discussion elsewhere. In summing up the affinities of the whole group he decides against the theory of Euglenoid ancestry which Bütschli advanced, and argues in favour of a descent from the Rhizopoda, quoting the interesting example of parasitism which Schewiakoff has found in simple amœboid forms. He concludes his article with a valuable compilation of sporozoan hosts, including Labbé's list with modern additions, and an abundant bibliography is appended, brought up to the beginning of the present year. It would be difficult to suggest any improvement in the author's selection of illustrations or in their execution.

Prof. Hickson, who has undertaken the Infusoria, does not include the Flagellata, but deals only with the Ciliata and Acinetaria, grouped as the Corticata Heterokaryota. Here again we can have nothing but praise for his admirably illustrated account of these

classes, and can only regret that it has been necessarily rather compressed. The limits of space have forced the author to deal briefly with the physiological inquiries for which the Ciliata have provided such a wonderfully fertile field. The work of Verworn and others upon the nuclear functions by means of "protozoan vivisection," and the studies of Miss Greenwood in intracellular digestion, are very shortly dealt with, while the classical accounts by Maupas of the processes of reproduction among the Ciliata deserve more expansive treatment than they receive in Prof. Hickson's excellent summary. Enough is given, however, of these biological studies to illustrate the author's discussion of the significance of the heterokaryote body, the individuality of the Infusoria after conjugation, and the incidence of somatic death among them, with which he prefaces his descriptive classification of the whole group.

The Foraminifera are dealt with in an article of the highest distinction by Mr. Lister, whose powers of lucid description, together with many original drawings and photographs of first-class merit, allow the reader to follow, perhaps for the first time with ease, the intricacies of skeletal structure and life-history found in this group. A unique value is given to this section by the inclusion within it of Mr. Lister's own researches into the remarkable phenomena of dimorphism in the Foraminifera, which he illustrates by a complete account of the alternation of the microspheric and megalospheric generations in the life-cycle of Polystomella. This dimorphism, with other characters, is followed through the various groups of Foraminifera so far as our present knowledge allows, and the facts are summed in a concluding survey, to which is appended a systematic classification and bibliography. Mr. Lister lays stress on the importance of life-history as evidence in the determination of phylogeny in this group, and this is becoming more and more evident in the case of other groups also of Protozoa. As an example of the questions of fundamental importance which are likely to arise in the further study of these life-histories may be noted the occurrence of the multiform condition especially in the microspheric generation, which Mr. Lister has ingeniously compared with the repetition of ancestral form seen in the sexually produced larva of the Cladoceran Leptodora, but not in its parthenogenetically developed young. This section marks a brilliant advance in description of the Foraminifera, and Mr. Lister is to be heartily congratulated upon it.

The earlier pages of the volume are given to an article by Prof. Farmer on the structure of animal and vegetable cells, of which, short as it is, nearly one-half is devoted to the discussion of reducing divisions and to some other physiological points. The problem of the structure of protoplasm and of the resting nucleus is dealt with, on the whole, perfunctorily, and is nowhere illuminated by reference to the results of Fischer and others in connection with the action of fixatives—results notably confirmed and extended in this country by Hardy—which already promise to remove these questions from the dust of a microscopists' quarrel and place it on the stage of exact physical inquiry.

PRACTICAL PHOTOGRAPHY.

Carbon Photography made Easy. By Thos. Illingworth. Pp. 150. (London: Iliffe and Sons, Ltd., 1903.) Price 1s. net.

Portraiture for Amateurs without a Studio. By Rev. F. C. Lambert, M.A. Part i. (Technical) and Part ii. (Pictorial). Pp. iv+176. (London: Hazell, Watson and Viney, Ltd., 1903.) Price, each part, 1s. net.

The Elementary Chemistry of Photographic Chemicals. By C. Sordes Ellis, F.I.C., F.C.S. Pp. 120. (London: Hazell, Watson and Viney, Ltd., 1903.) Price 1s. net.

Photography by Rule. By J. Sterry. Pp. 124. (London: Iliffe and Sons, Ltd., 1903.) Price 1s. net.

PHOTOGRAPHY as now practised may be regarded from so many points of view, and pursued for so many different purposes, that it is desirable to have treatises on special branches of it, such as those now under notice. A considerable advantage of this method of setting forth the facts and methods of photography is that each section may be dealt with by one who has paid special attention to it, and is able to speak upon it with authority.

Mr. Illingworth, for example, is a man whose business very largely consists in the making of carbon prints. His practical directions are, therefore, beyond criticism, and we put up with, without a murmur, his reference to "chloride, bromide, platinum, or other commoner printing processes" because of the frank and full way in which he describes the process in which he is a specialist. His book would have been better without the chapter devoted to the "Chemistry of the Carbon Process," for here he has gone outside his experience and his knowledge, and what he has set down tends to error and confusion. The discriminating student will discover this for himself, but beginners cannot always separate the wheat from the chaff, and it is for beginners that the book appears to be chiefly intended.

In a volume on the chemistry of photographic chemicals one looks for a special knowledge of the chemicals used in photography, but in the book before us there is not much evidence of this. The author appears to go out of his way to say that a "chemical change theory" of the developable image "is the one generally accepted at the present day." We very much doubt it. But in the matter that deals with the subject as set forth by the title, there are many statements that need modification, if not correction. Silver nitrate is doubtless the most important of all "photographic chemicals," but only little more than a dozen lines are devoted to its consideration. We are told that when prepared by dissolving silver in nitric acid hydrogen is evolved, and that when obtained in the solid form, preferably by fusion, it is not likely to be alkaline. Now fused silver nitrate often is alkaline, and as to the equation showing hydrogen liberated from nitric acid by the metal, the less said the better. We are told that the oxidation of sodium sulphite to sulphate by exposure to the air "is easily detected by the crystals becoming powdery and opaque,"

and that ammonia, when used as a follower to mercuric chloride in intensification, dissolves the silver chloride and forms ammonium dimercurous chloride, while sodium sulphite precipitates the mercury in the metallic form. The word "sensitisers" is applied to substances not usually so called, such as potassium bichromate. We are told that "when toning takes place with gold chloride, chlorine is given off." Of course it is not "given off" as that expression is commonly understood. Many other matters that need correction might be noted. Generally, methods of preparation are given, rather than the properties of the things as the photographer gets them. The latter is what is chiefly wanted, as photographers do not make their own chemicals, nor, indeed, are the instructions herein given generally a sufficient guide to enable them to do so.

Mr. Lambert, in his two small volumes on portraiture, writes from first to last from his own experience, and not only so, but in the greater number of cases demonstrates by examples the effects that he states result from certain procedures. The advantage of colour sensitised plates can be seen at a glance in the representation of the clothes, the hair, and the face or complexion of the sitter by inspecting the comparative examples given. The effects of different lenses, different positions of the camera, different methods of lighting, variations in exposure, different methods of dressing the hair and of posing the model, are all demonstrated. Indeed, it is hardly possible to think of any matter that bears upon the subject that is not dealt with and illustrated. The volumes are very suggestive to anyone interested in portraiture, and will be specially useful to the amateur who has no studio at his disposal.

Mr. Sterry has been a student of photography for a great many years, and has carefully followed, and often contributed to, the progress of the science that has taken place during the last decade or two. He is therefore specially fitted to treat of those methods of photography in which reasonable methods take the place of mere empiricism, and he has set down in a clear manner a summary of recent work so far as it affects the making of negatives and prints on bromide papers, including enlargements.

It seems to be necessary to make every book on photography a kind of manual for the beginner, and we suppose that Mr. Sterry has merely given way to the exigencies of the case when he explains what an "equivalent focus" is, and what is the size of a quarter plate. However, there are not many pages devoted to this sort of thing, and we judge that Mr. Sterry was heartily glad when he had done with them. Whatever beginners ought to do, they will not begin by photographing "by rule," and we doubt whether they can advantageously do so any more than they can well perform a quantitative exercise of any kind before they have got an idea as to how the action goes in a merely qualitative way. We intend it as a compliment to the volume and its author when we say that this book is not likely to appeal to the beginner.

We commend the courage of the author, and thoroughly agree with him when he says that hydroquinone and ferrous oxalate are the "least desirable" developers for general use. He admits, too, that different results may be obtained with the same exposures, by variations in development. Indeed, Mr. Sterry treats the subject in a fair manner, and cannot be accused of belonging to any particular "school." We cannot endorse his statement that the light intensities "between deep shadow and bright sky in an ordinary landscape have been conclusively shown to be less than 1 to 32," and his reference to the proof appears to be in error. The statement that the principal reason why negatives for enlargement should be thinner than for contact printing is the reflection of light from the surface of the paper and back to the paper from the surface of the negative in the latter case, is, we think, founded on a mistaken supposition. The difference appears to be due to the loss of the scattered light when the sensitive surface is not in direct contact with the negative. The author is mistaken in saying that the different methods of intensification give results that are "practically proportional throughout the scale." But remembering that the book is among the very first attempts that have been made systematically to describe the new methods of photography, it must be considered as notably successful, though we wish it had been rather more extended. "Rules" that have puzzled students for years are clearly explained, and effects that appeared to be erratic are shown to be the necessary results of the procedure.

OUR BOOK SHELF.

L'Evolution comparée des Sables. By Jules Girard, Membre de la Société de Géographie. Pp. iv+124. (Paris: Librairie scientifique et littéraire, F. R. de Rudeval, 1903.) Price 5 francs.

It is not clear whether this handsomely printed volume is addressed to the geological student or to the engineer. We presume, indeed, that its production has been a labour of love on the part of its author, who has brought together in a continuous form a number of facts recorded in French, German, and English publications. Here and there an original observation is introduced, like that on the deposit of angular blocks at Vauville (p. 8), which appears to present a problem akin to that of our Permian "breccias" on the coast of Devonshire. The photographs of types of sand-grains on pp. 10–13 have distinct value; in Fig. 8, however, radiolarians, though mentioned, are, to say the least, inconspicuous.

The erosion of the earth's surface by various agents is discussed, as explaining the origin of ordinary sands, and stress is properly laid on the atmospheric currents as agents of transport and accumulation of the fine material produced. Pp. 46–81 are, in fact, occupied by the subject of blown sands and dunes, and the various ways of arresting the invasion of fertile areas. The horse-shoe dunes figured on p. 70 are surely not so localised as the author suggests. They have been well discussed by Sokolów in a work translated into German in 1894, and appear, if we mistake not, in the memorable pages of Sven Hedin's "Across Asia."

The description of the changes undergone by coast-lines, especially in historic times, contains many interesting details. We miss, however, a comprehensive summary, such as would be useful to the geographer, showing how geological conditions and movements of the land have affected deposition along

the coasts. In this matter, modern American authors might have been called on. As it is, some such generalisation is promised on p. 112, but the volume ends abruptly nine pages later in the midst of local details of the Netherlands. M. Girard has certainly not allowed his subject to lead him into realms of speculation; on the other hand, his book lacks the system and arrangement which so often make a French work, even when its information is incomplete, seem like a well grouped picture in absolute harmony with its frame.

There are too many misprints in personal names throughout the book, the worst of which is "le baron de Reichtofen" on p. 55. "Scottisch" on p. 53 has also a quaint aspect. G. A. J. C.

Radium and other Radio-active Substances, with a Consideration of Phosphorescent and Fluorescent Substances. The Properties and Applications of Selenium and the Treatment of Disease by the Ultra-violet Light. By William J. Hammer. Pp. viii+72. (London: Sampson Low, Marston and Co., Ltd., 1903.) Price 5*s.* net.

MANY will probably be attracted by the first word of the title of this book, and buy it in the hope of obtaining light and leading on the new discoveries. Such, we fear, are likely to be sadly disappointed. The book is an apparently verbatim report of a lecture delivered at a meeting of the American Electrochemical Society and the Institute of Electrical Engineers. It is difficult to understand why it was reprinted in its present form, for most of the interest seems to have centred in the experiments and exhibits that accompanied the lecture. For example, we read, "Here are a couple of postal cards which I secured in Europe showing the Blue Grotto at Capri. They are printed with phosphorescent paints, and on exposing them to the light you will see that they are very pretty." Reproductions are provided of an elaborate "stage setting" to the lecture, of various tubes with the word radium written beneath, but which, so far as the reader is concerned, might as well have contained sugar, and of some photographs taken with the aid of radium. The latter, although of more general interest, are sometimes misleading. Thus Fig. 7 is a radiograph of glass lenses, and is used to throw doubt on the generally accepted fact that the radium rays cannot be reflected, refracted, or polarised, whereas it is obvious that the photograph is taken with ordinary light, either the phosphorescent light of the radium itself not being eliminated, or else by simple "fogging." With regard to the text, the part dealing with radium consists of the collection of a large number of facts collected together without discrimination or arrangement. Thus two pages are spent on Heydweiller's experiment on the loss of weight of radium, the opinions of various eminent authorities with regard to this experiment are quoted as obtained by the author, and at the end we learn that the observation in question has been admitted by the observer to have been the result of an accident. Snippets of information are provided from most of the important researches which would be quite unintelligible to those not intimately acquainted with the subject and superfluous to those who are.

The Experiment Station Record. Vol. xiv. Nos. 5–9. (Washington: the United States Department of Agriculture, 1903.)

THE "Experiment Station Record" consists in chief of a series of abstracts of papers dealing with agricultural science all the world over, together with occasional general reviews and summaries. Abstracts are very rarely wholly satisfactory to the scientific worker, but there are few subjects more in need of work of this kind than is agriculture. The recognised organs of agricultural science are numerous enough, but much valuable work escapes their notice and appears in the irregularly issued reports and bulletins of some State or institution or society, or, again, is published in a journal devoted to one of the many pure sciences on which agriculture touches. Hence the value of the "Experiment Station Record"; so thorough is the organisation of the United States Department that very little escapes its net, and the student with an intelligent capacity for reading between the lines will by its help be generally put on the track of anything which concerns him specially. Particularly he will be saved the trouble of looking through the very numerous annual reports and bulletins issued by the separate States in America, for they are fully reported in the "Record," and almost wholly neglected by the German abstractors. We believe our own Board of Agriculture is about to undertake a somewhat similar work for the many scattered publications of county councils and colleges which have been doing agricultural experiments in this country during the last ten years or so. We doubt if the "Experiment Station Record" is as well known as it deserves to be; at any rate, several of our best specialist libraries in London possess it very partially, if at all, useful as it is even to men engaged in pure science. Meantime, it has become indispensable to all workers in agricultural science, and they owe a debt of gratitude to the United States Department of Agriculture both for its publication and for the liberality with which it is distributed.

A. D. H.

Jahrbuch der Chemie. Twelfth Year, 1902. Edited by R. Meyer. Pp. xii+544; and General Register to same, i.–x., 1891–1900. (Brunswick: Vieweg und Sohn, 1903.) Price 15*s.* and 11*s.*

MEYER'S "Jahrbuch" is too well known among chemists to require description. It aims at giving a summary or review of the chief chemical contributions of the year. When one considers that in this comparatively short period upwards of 6000 researches (the number is taken from the *Centralblatt*, and does not include patent literature) find their way into print, the process of selection becomes a very arduous one, requiring on the part of the different collaborators—experts in their several provinces—not only much reading, but careful discrimination.

This large mass of material seems on the whole to be well sifted, but the condensed form in which it is presented robs the book of any literary merit, and gives it the indigestible and fragmentary character of a dictionary. English chemical literature scarcely receives full justice, not that the proportion of references is small (out of 160 papers published by the Chemical Society 28 are referred to), but these, it will be generally admitted, do not in all cases represent the most valuable English researches of the year.

The general index for the first decade is published with the "Jahrbuch," and as a book of reference should be useful. J. B. C.

Flowering Plants: their Structure and Habitat. By Charlotte L. Laurie. Pp. x + 157; with illustrations by W. L. Boys-Smith. (London: Allman and Son, Ltd., n.d.) Price 2*s.* 6*d.*

THIS little book is intended for students who have already studied the elementary principles of botanical science. It is divided into three parts, dealing with respectively, the most general conclusions of ecology relating to the habitat of plants, the minute structure of the plant and its adaptations to its habitat, and certain natural orders, regarded more particularly from the point of view of their ecological characteristics. The treatment is simple, though brief, and the illustrations are unusually good.

LETTERS TO THE EDITOR.

Heating Effect of the Radium Emanation.

IN connection with the discovery of P. Curie and Laborde that radium continuously emits heat at a rapid rate, an interesting question arises as to whether the heat emission is directly connected with the radio-activity of that element or is independent of it.

To settle this point we have performed the following experiments. The heating effect of 30 milligrammes of pure radium bromide was first measured in a differential air calorimeter. The radium bromide was then heated to a sufficient temperature to drive off the emanation, and the latter was condensed by passing through a short glass tube immersed in liquid air, and then the tubes were sealed off. On testing the de-emanated radium, the heating effect diminished rapidly during the first few hours, and fell to a minimum corresponding to about 30 per cent. of the original value and then slowly increased again. On substituting the emanation tube in the calorimeter, the heating effect at first increased for a few hours to a maximum corresponding to about 70 per cent. of the original heat emission of the radium and then slowly decayed with the time.

At any time after removal of the emanation, the sum of the heating effect of the de-emanated radium and of the emanation was found to be the same as that of the original radium. Experiments are still in progress to determine the rate of recovery and loss of heating power of the de-emanated radium and the separated emanation respectively, but so far as the observations have gone, the curves of decay and recovery are the same as those for the corresponding α radiation.

It has been shown (Rutherford and Soddy, *Phil. Mag.*, May) that, if the emanation is removed from radium, the activity of the radium decays in the course of a few hours to about 25 per cent. of its original value. This residual activity consists *entirely* of α rays. The solid radium compound regains its original activity after the lapse of about one month. Immediately after the separation of the emanation the activity (tested in a sealed vessel) rises to about twice its original value, due to the production of excited activity on the walls of the vessel, and then slowly decays with the time, falling to half value in about four days. At any time after removal of the emanation the sum total of the activity of the radium and the emanation has a value equal to that of the original radium.

There is thus an exact parallel between the variation in radiating power (measured by the α rays) and the heating effect. In order to be sure how much of the emanation was removed by heating, control experiments were made on the γ rays from the radium and the separated emanation. This was tested by observing the rate of discharge of an electroscope after the rays had passed through 5 cm. of lead. In some preliminary experiments by one of us last year it was found that the γ rays from radium appeared at the same time as β rays, and were always proportional to them. From these results it was deduced that all but 6 per cent. of the emanation was removed by the heating.

It is thus seen that the heating effect of radium *directly accompanies* the α radiation from it, and is always proportional to it, and that more than two-thirds of the heating effect is not due to the radium at all, but to the radio-active emanation which it produces from itself. This result accounts for the variation of heat emission with age observed by the Curies, an account of which was given by Prof. Dewar at the British Association.

The amount of emanation from 30 milligrammes of radium bromide, when collected in the tube, was sufficient to cause a bright phosphorescence in the tube, but it was too small either to measure or weigh. The amount of heat emitted from the radium emanation is thus enormous compared with the amount of matter involved. It seems probable that the greater part of the heating effect of radium is a direct consequence of the expulsion of α rays. It still remains to be shown in what proportion the radiated energy is distributed between the projected α particles and the systems from which they are expelled.

The results given here are at once explained on the disintegration hypothesis (Rutherford and Soddy, *Phil. Mag.*, May), in which the heat is considered to be derived from the internal energy of the atom. On the view held by some that radium gains its heat from an external source, it would be necessary to suppose that less than a third of the heat is due to the radium itself, and that the other two-thirds are due to the radium emanation which is being continuously produced, and the power of which of absorbing energy from an external source decays with the time.

McGill University, Montreal, October 16.

Papers and Procedure at the British Association.

AT the recent meeting of the British Association at Southport I heard numerous complaints (repetitions of those I have heard at not a few previous meetings) by the general public, members of the Association, on the too technical character of the papers read before it. These complaints referred to all the sections except, perhaps, those of anthropology, geography, and educational science. One overheard too often to be pleasant such remarks as "I am interested in zoology, but what is the good of coming to listen to such a paper as this? I have no idea what the speaker is talking about"—the paper, in one specific instance, was cytological, and of great value undoubtedly; and, "I have not gained much by becoming a member of the Association; the papers are all over my head." These complaints are being made by well educated men and women interested in science, but not versed in its technicalities.

Believing that this feeling in reference to the subjects brought before the various sections is growing, and is, moreover, not ill-founded, I venture, as a member of twenty years' standing, to direct serious attention through your columns to its existence, and to advocate some change in the character of the papers accepted for reading before the Association, so that the objects for which this great society was founded may be more fully attained as regards the general public of the town visited, on the support of which the Association is so largely dependent.

Purely technical papers which appeal only to the specialist in chemistry, biology, engineering, or physics, are out of place before an audience the majority of whom are not specialists, but who have become members for the occasion in the hope of listening to an understandable exposition of the subject by the men who have contributed to making that section of science. Such purely technical papers should be reserved for the societies which exist for the cultivation of that particular subject. The British Association should either become a purely scientific society or become more what it was established for, an association for the advancement of science among the people, at which the *results* of the investigations of the year are, as it were, summed up and presented to the members, both specialists and those of the general public interested in science, in language which the whole audience can understand. An author, instead of going into the details of the various intricate investigations and experiments he has made—which can often enough be followed fully only by his fellow-workers in that particular section of his subject—should far more than heretofore deal broadly with the results obtained, indicating their value to the particular subject, and their bearing on his own or other departments of knowledge. The general public have really some cause for complaint that their subscription has been obtained from them on a misunderstanding. If the Association is to become more and more a purely scientific society, then the fact should be made more widely known, so that disappointment may not be needlessly caused to those who join it. In that case, moreover, there would be no need of the publicity with which the Association meets at the various towns it visits. It might quietly assemble at the chosen town in rooms hired or lent for the purpose, and associate itself only with the specialists of the place.

Liverpool, October 20. HENRY O. FORBES.

A Little-known Peculiarity of the Hamadryad Snake.

A STRUCTURAL peculiarity of the "king cobra" which I have recently ascertained while studying the anatomy of the Ophidia seems to me to be so remarkable that it must have been noticed in such comprehensive works as Bronn's "Thierreich" and Dr. Gadow's account of serpents in the "Cambridge Natural History" were it known. I venture, therefore, to give a short account of the matter without professing to have made an exhaustive survey of the literature of the group. The windpipe of this snake opens, as usual, not far from the heart into the lung, which presents no remarkable divergencies from the lungs of other snakes; it is in the same way functional as a lung for the first half, and becomes a mere thin-walled air bag posteriorly. Before opening into the lung, however, the trachea is connected with a long series of approximately equi-sized air sacs in the neck, which follow close upon each other, and entirely occupy the neck down to the region where the heart lies. These sacs are so closely adpressed that the appearance given is that of a series of septa, dividing the space surrounding the windpipe and gullet into metamerically arranged compartments. I thought at first, in fact, that I had been able to observe a segmentation of the cœlom in this region quite analogous to that of an annelid. Each cavity, however, is continuous with the interior of the windpipe by an oval and clearly defined orifice on its lower surface. These apertures are regular and of fairly equal size, and give to the windpipe quite the appearance of a flute. There are a large number of them, thirty to forty. There is no question here of pathological conditions or of accidental cuts. The regularly disposed series of sacs into which they open negatives anything of the kind. They are, I suppose, an extreme modification of what the late Prof. Cope termed the "tracheal lung" in Chersydrus and other snakes. The most obviously comparable structure that I can think of for the moment is the ventral slit in the windpipe of the emu, which similarly opens into a thin-walled sac. This is believed to be connected with the singular "drumming" sound emitted by that bird. Perhaps some of your readers who are acquainted with the Hamadryad can inform me as to a possible "voice," or whether it can produce a varied or especially prolonged hiss. I propose to offer a more detailed account of the structure of the windpipe and other organs of this snake to the Zoological Society as soon as possible. FRANK E. BEDDARD.

The New Bishop's Ring.

REGARDING M. Forel's suggestion (see NATURE, p. 396) that persons ascending to considerable altitudes should observe whether the ring around the sun, which was so noticeable a phenomenon after the diffusion of the volcanic dust from the Krakatoa eruption in 1883, is again visible, I beg to say that, before reading his letter in *La Gazette de Lausanne*, I had noted the ring on August 20 from the Montanvert, near Chamonix, at an altitude of 6300 feet. The day was exceptionally clear, and when a peak hid the sun itself, the whitish glare fringed with reddish brown that surrounded it attracted my attention. Being upon the summit of Mont Blanc (15,780 feet) on September 1, in clear weather, I again observed the ring, which, however, was no better defined than lower down on the mountain, notwithstanding the circumstance that the dark blue sky furnished an excellent background. Angular measurements there showed that the radius of the visible outer limit of the reddish ring was between 20° and 25°.

While the phenomenon was not again seen by me last summer in Europe, it has often been observed during the past year here at my observatory, elevated only 640 feet above the sea, and an article in *Science* of January 23 by my assistant, Mr. Clayton, describes the reappearance of this second "Bishop's ring" and the accompanying brilliant sunsets during the early part of last winter. Subsequently, the ring was observed in January and February, and also in May, June, and July, when highly coloured and prolonged afterglows followed the sunsets towards the close of the latter month. During the first part of August the ring was seen on clear days, and during September the vivid yellow colour of the western sky, persisting sometimes more than an hour after sunset, was frequently recorded. To-day (October 14), after a period of rainy weather, the ring is distinct, and measurements made here some time ago gave 26° as the radius of the whitish haze and 5° more for the reddish border, indicating that its visible extension was greater even than on Mont Blanc.

M. Forel states that he has seen a coloured circle surrounding the sun since the first of last August. The fact of it not having attracted notice previously in Europe would seem to show either that the clearer atmosphere of the United States favours its perception, or that the microscopic dust in the upper air, which is supposed to produce the diffraction phenomenon, preponderates above this country. The last hypothesis is supported by the fact that, from the proximity of the West Indian volcanoes, the fine dust ejected by them during the eruptions that year may have drifted northward, before making a circuit of the globe, and a larger quantity may still remain suspended in the rarefied atmosphere above the eastern United States than exists over Europe. A. LAWRENCE ROTCH.

Blue Hill Meteorological Observatory, Massachusetts, U.S.A., October 14.

The Nervous System of Anodonta cygnea.

THE supra-œsophageal ganglion of Anodonta is usually regarded as representing both the cerebral and pleural ganglia, and is commonly spoken of as the "cerebro-pleural." Prof. Howes mentions in his "Atlas" that Prof. M. Hartog has occasionally observed a ganglionic swelling on one or both of the cerebro-visceral connectives in front of the pericardium, but that he himself has failed to find any such enlargement. In view of the doubt that exists, it seems to be worth recording that yesterday one of my pupils, A. C. Roxburgh, while dissecting an Anodonta in the Charterhouse laboratory, exposed a well-developed ganglion of the usual orange colour, upon the left connective in the exact position mentioned by Prof. Hartog. Microscopical examination removed all doubt as to the nature of the swelling. for numerous ganglion-cells were easily recognised in the teased preparation. It is thus probably more correct to term the anterior ganglion "cerebral" rather than cerebro-pleural. Perhaps some of those who are better equipped for research than is possible or advisable for those engaged in elementary laboratories might find it worth while to examine series of sections of the connective at this region. It is possible that the pleural ganglion may in most cases be represented by but a few ganglion cells the presence of which is not discernible to the unaided eye.

May I, as I am writing about this animal, direct attention to an error that is universal in text-books? The muscles always spoken of as retractors and protractor of the *foot* have not the function that their titles imply. The protrusion of the foot is due to vascular turgescence, and its withdrawal to relief of the turgid condition and contraction of the intrinsic pedal muscle fibres. *The muscles in question move the shell, the foot being the fixed point.* Thus the so-called anterior and posterior retractors of the foot should be styled the *protractors of the shell*, and the protractor of the foot the *retractor of the shell*. I may mention that I have often seen Anodonta go backwards when its deliberate movements have led it into a *cul-de-sac* in the aquarium. OSWALD H. LATTER.

Charterhouse, Godalming, October 24.

LORD KELVIN AND HIS FIRST TEACHER IN NATURAL PHILOSOPHY.

SOME interesting early recollections were related by Lord Kelvin on October 17, on the occasion of the unveiling of a stained glass window, by Henry Holiday, in the Bute Hall of the University of Glasgow in memory of John Pringle Nichol, LL.D., professor of astronomy, 1836–1859, and his son and daughter, John Nichol, LL.D., professor of English language and literature, 1862–1889, and Mrs. Jack, who was born in 1837, in the University, and died there in 1901. Prof. J. P. Nichol was the author of numerous valuable works, including the famous book on the "Architecture of the Heavens." The account which Lord Kelvin gave of his own young days at

Glasgow College is full of interest, and his testimony to the impulse he received from his early teacher will be an enduring tribute to Nichol's memory.

In the course of his remarks, Lord Kelvin said:—Principal Story, You recall to my mind the happy days of long past years, 1836, when John Pringle Nichol came to be professor of astronomy in the University of Glasgow. From the time he first came among us—I say among us, because I, as a child, was not then a member of the university, but an inhabitant of the university—when Dr. Nichol, as we then called him, came among us, he became a friend of my father, and that friendship lasted to the end of my father's life. I may also claim that I became a student of Dr. Nichol's from the time he first came to Glasgow. Year after year passed, and I still remember his inspiring influence. The work on which I am engaged at this day is work to which I was initiated in the years 1837, 1838, and 1839, when I was a child. The summer of 1840 is for me a memorable summer, a year of brightness in my memory. I had been for one session a student in the natural philosophy class of the university conducted by Dr. Nichol. From beginning to end, with the exception of a few days, when my predecessor, Dr. Meikleham, began the course which he could not continue on account of his health, the class of natural philosophy, in the session 1839–40, was taught by Dr. Nichol. He came on short notice to occupy the post, and he did it in a most admirable manner. I lately had the opportunity allowed me by my friend and colleague, Prof. Jack, to see a manuscript book of John Pringle Nichol's, a book of exercises and preparations for the natural philosophy class. I was greatly struck with it, and much interested to see in black and white the preparations he made for the splendid course of natural philosophy that he put us through during the session 1839–40. In his lectures the creative imagination of the poet impressed youthful minds in a way that no amount of learning, no amount of mathematical skill alone, no amount of knowledge in science, could possibly have produced. For, many years afterwards, one of the most important affairs I have ever had to do with began with what I learned in the natural philosophy class in that session. I remember the enthusiastic and glowing terms in which our professor and teacher spoke of Fourier, the great French creative mathematician who founded the mathematical theory of the conduction of heat. I was perfectly astonished. I remember how my youthful imagination was fired with what I heard from our teacher. I asked him, "Do you think I could read it?" He said, "The mathematics is very difficult." At the end of the session I got hold of the book ("Théorie analytique de la Chaleur") out of the university library, and in the first half of the month of May, 1840, I had, I will not say read through the book, I had turned over all the pages of it. Then we started out from Glasgow for Germany, the joint families of my father, my brothers and sisters, and our friend Dr. Nichol and Mrs. Nichol, and John Nichol and Agnes Jane Nichol. The two families made together a tour in Germany, and during two months or six weeks in Frankfort, Mrs. Nichol and her two children were with my father and his family every day while their father went on tour to the Tyrol. Excuse me for speaking of those old times. I am afraid I have trespassed on your patience. These recollections may be nothing to you, although they are dear to me. They are, indeed, closely connected with the subject of the present meeting.

While we were encamped for a time in Bonn, Dr. Nichol took me and my elder brother on a walking tour in the volcanic region of the Eifel. We had four days of intense enjoyment, and the benefit of what we learned from him, and saw around us, in that interesting region remained with my brother all his life, and remains with me.

I have to thank what I heard in the natural philosophy class for all I did in connection with submarine cables. The knowledge of Fourier was my start in the theory of signalling through submarine cables, which occupied a large part of my after life. The inspiring character of Dr. Nichol's personality and his bright enthusiasm lives still in my mental picture of those old days.

The old astronomical observatory—the Macfarlane Observatory—was situated in the upper part of the old college green, or garden, as we used to call it, behind the college, off the High Street. I do not suppose any person here ever saw the old college green, but you have all read of it in "Rob Roy," and of the duel between Osbaldistone and Rashleigh. I do not remember the details of the duel, but I remember it was appointed to be fought in the upper part (at least I have always assumed, in my mind, it was in the upper part) of the college garden of the University of Glasgow. The garden was in two parts, the lower on the near side of the Molendinar, the upper on the higher ground beyond the stream, which we crossed by a bridge. Has any person here ever seen the Molendinar? There used to be mills on it, I assume, from the name. It is now a drain! Before we left the old college it was covered in. We had still the upper and lower green, but the Molendinar flowed unseen for many years after the university left the old site. I remember in the Macfarlane Observatory beautiful experiments on light shown us in the most delightful way by Dr. Nichol, Grimaldi's fringes by sunlight, and prisms showing us splendid solar spectra, and telescopes, and brilliant colours on a white screen produced by the passage of polarised light through crystals. He gave us firmly the wave theory of light, and introduced us to Fresnel's work. As he appreciated Fourier, so he appreciated Fresnel, two of the greatest geniuses in science, and fired the young imagination with the beautiful discoveries of those men. In that old observatory in the high green, and in the natural philosophy class-room of the old Glasgow college, was given to me the beginning of the fundamental knowledge that I am most thoroughly occupied with to this very day, and I am forcibly obliged to remember where and when my mind was first drawn to that work which is a pleasure to me, and a business to me just now, and will, I hope, be so for as long as I have time to work. You can imagine with how much gratitude I look upon John Pringle Nichol and upon his friendship with my father. His appointment as professor of astronomy conferred benefit, not only upon the University of Glasgow, but also upon the city and upon Edinburgh, and the far wider regions of the world, where his lectures were given and his books read. The benefit we had from coming under his inspiring influence, that creative influence, that creative imagination, that power which makes structures of splendour and beauty out of the material of bare dry knowledge, cannot be overestimated.

FLOW OF STEAM FROM NOZZLES.

It is well known that when a gas is flowing from a vessel by an orifice, if the outside pressure is less than sp_0, p_0 being the pressure in the vessel where the gas is at rest, the pressure in the throat of the orifice is never less than sp_0 if s is

$$\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$$

where γ is the ratio of the specific heats. s is 0·527 for air. It is also known that, with fair accuracy, we

may assume steam which is dry and just saturated to behave as if it were a gas the γ of which is 1.13, and steam with 25 per cent. of moisture as if it were a gas the γ of which is 1.113. It results that the velocity in the throat delivering steam is never greater than the velocity of sound in such steam as exists in the throat, and the pressure in the throat is never less than 58 per cent. of the pressure inside the vessel, however low the pressure of the outside space may be.

Mr. Napier's experiments first directed attention to this phenomenon, and Prof. Osborne Reynolds, in 1885 ("Collected Papers," vol. ii. p. 311), gave the explanation.

Students are still too much influenced by their knowledge of flowing water; they cannot help thinking that the flow of a gas is analogous, whereas in all important particulars the flow of a gas is entirely different from the flow of a liquid. After much unbelief among students of this subject, it is now becoming known that when there is a divergent mouthpiece outside the throat, the velocity of a compressible fluid may become very much greater than the velocity of sound; speeds of 3000 or 4000 feet per second seem to be possible at the ends of the divergent orifices used in the Laval turbine. Some years ago I framed a theory of the injector which seemed reasonable, and yet I found it wrong in its application to experimental results. I now know that it was really a good working theory. It seemed to be wrong really because I could not imagine a velocity of steam greater than that found by Napier, the velocity of sound.

I wish to show that the reasoning of Prof. Osborne Reynolds leads to an explanation of what occurs in an expanding mouthpiece. The motion is steady in the vessel until the narrowest part or throat is reached; in the expanding mouthpiece the motion is turbulent, but perhaps I may be allowed to consider the motion as steady throughout, as this will illustrate what occurs well enough, and turbulent motion mathematics is quite beyond my powers.

If W is the weight of gas passing along a stream tube the cross section of which is A, then at a place where the pressure is p we know from the usual reasoning that

$$W = A\sqrt{\frac{2g\gamma}{\gamma-1} w_0 p_0 \left(\alpha^{2/\gamma} - \alpha^{1+1/\gamma}\right)} = Awv$$

if w is the weight of unit volume of the gas, being w_0 where p is p_0 and if α stands for p/p_0.

Now let us keep W constant, and we are able to calculate the cross section of the stream at any place where p is known.

I sometimes ask the individuals of a class of students to calculate, each of them, a part of such a table as the following:—

Imagine steam in a vessel at $p_0 = 14400$, or 100 lb. per square inch, to flow towards a throat with an expanding orifice outside; at the following pressures I give the corresponding cross sections A of a stream tube and the velocity there. It will be seen that where the tube is narrowest the pressure is 57.85 lb. per square inch; this is near the narrowest part of the orifice. Beyond this in the expanding part A increases, the pressure falls, and the velocity becomes greater and greater.

I take a stream tube in which the flow is 1 lb. per second, or W = 1. These numbers deserve study. It is evident that to get very high speeds the mouthpiece must be much enlarged from the throat, but as rapid enlargement must lead to greater turbulence, velocities much greater than 3000 feet per second ought hardly to be expected.

If we double all the pressures in the table, the values of A and v there given are right for the case of flow of steam from a vessel where p_0 is 200 lb. per square inch; about two pounds of steam per second now flows along the tube.

An expanding mouthpiece increases the flow of water, and velocities are less where cross sections are greater; but in the case of air or steam, the total quantity flowing is not increased, and velocities are greater where cross sections are greater.

p lb. per sq. in.	A sq. ft.	v ft. per sec.	p lb. per sq. in.	A. sq. ft.	v ft. per sec.

JOHN PERRY.

PROGRESS OF GEOLOGICAL SURVEY OF THE UNITED KINGDOM.

IT would be impossible to give on one page an epitome of the work done in a year by the Geological Survey, but it may be possible to explain the arrangement of the official summary of progress and to indicate the character and range of the information contained in it.

By far the greater number of persons who consult it want first of all to learn whether anything new has been published about their own district. We find, therefore, that the information is arranged geographically under the heads England and Wales, Scotland and Ireland, and that subordinate to these there is a reference to districts, not well defined physical or political divisions of permanent importance, but divisions arbitrarily chosen for the purpose of easy reference to the areas over which the work of the year has been carried on.

The descriptions are further classified under the names of the geological formations found in each district.

The most important part of the work deals, of course, with the observations made in the field and recorded on the maps and sections, or described in memoirs and explanations, but the palæontological, petrological and chemical work all receive special notice, as do the products of economic value and the excellent museum connected with, and largely brought together by, the Survey.

All who are engaged in geological teaching or research, or the practical application of the science, must watch the results obtained by the Survey, whether they involve, as proved by Mr. Thomas, a correction of the section across the Towy Valley, or throw light on the relation of the Devonian to the Old Red, as may be seen in Mr. Strahan's work, or furnish material for determining the exact "geological equivalents" of the coal-bearing strata in several distinct and isolated areas, as shown by Mr. Kidston, or data for discussing with Mr. Clement Reid the conditions which prevailed when the deposits were laid down in which man's remains first appear.

The practical man, who has always met with so much courtesy and assistance in the Survey Office, whether he seeks how he may find water or in which direction he might hope to pick up again a lost seam of coal or vein of metal, has always turned to the publications of the Survey for the results of the latest and most careful examination of the district in which he is interested.

It is, however, difficult for a man of small leisure to search through the maps, sections, explanations, and memoirs to see whether there is anything which immediately concerns him. In the annual report of progress such men find a short account of what has been done and often a forecast of what line of research it is proposed to follow next—as, for example, in the description of the coal-bearing strata in the basin of the Amman.

It would, however, be a mistake to suppose that the results achieved are of interest to geologists only. From the summary of progress just issued, it may be seen that the work appeals to a much wider public than would at first appear. It contains a record of accurate observations on the relation to one another of the great masses of which the earth's crust is made up—very different from the *a priori* reasoning as to how they ought to behave with which we have so often had to be content. If we turn to the very first page of the introduction, in which the able director of the Survey gives a sketch of what he and his men have done, we read that they have demonstrated that the arrangement of the different kinds of rock proves that there have been movements by which slices of sedimentary and igneous matter, of heavy basic and lighter acidic rock, have been thrust in, so that they now appear in alternating layers over large areas, and further that these earth movements have crushed and kneaded and drawn out the constituents of the rock so that its structure is quite different from that which they have reason to infer it once had from the changes observed as they trace each mass across the country.

The physicist and astronomer will find in the survey publications the results of observations on earth movements recorded by a man like Mr. Harker, who is not only one of the highest authorities in petrography, but also a mathematician of the first order; while geographers will note with interest the inferences which are forced upon clear-headed and experienced observers like Mr. Strahan, who are trained, as few ordinary travellers are, to watch every indication of change of rock structure, and to trace the guiding influence of systems of displacement upon the rivers and other denuding agents which have moulded the surface of the land.

In the Survey memoirs biologists will find treatises, by men like Woodward, Clement Reid, and Lamplugh, dealing with ancient climatal and physical conditions which have varied, as inferred from the flora and fauna as well as from other indications, with the great geologic changes of the earth's crust.

On the staff of the Survey are many men of world-wide reputation who are approaching these large questions from many different points of view, and fully realise what large superstructures may be built up on the facts which they lay down. Carping critics talk of the "uncertainties of geology"; that is because the public is sometimes told what working hypothesis is suggested by evidence which is known to be incomplete. It is not necessary for pioneers to be always repeating the *certainties*, and the Summary of Progress lets the public follow the work as it is going on.

NOTES.

THE council of the Royal Meteorological Society has awarded the Symons gold medal to Prof. Julius Hann, of Vienna, in recognition of the valuable work which he has done in connection with meteorological science. The medal will be presented at the annual meeting of the Society on January 20, 1904.

A bust of John Dalton, presented to the Manchester Literary and Philosophical Society by Sir Henry E. Roscoe on the occasion of the centenary of the announcement of the atomic theory, was unveiled on October 20. The secretary read the following letter from Sir Henry Roscoe:—"I desire to present to the Literary and Philosophical Society of Manchester a bronze bust of Dr. Dalton, as a memento of the many years of pleasant intercourse which I have in past days spent in converse with its members, and as a recognition of the honour which the Society has done me by electing me as an honorary member, and in bestowing upon me its Dalton Medal. The bust is the work of a distinguished sculptress, Miss Levick, and I believe that all those who have seen it agree with me in esteeming it a powerful and lifelike work of art. It will give me great satisfaction to hear that the Society accept my gift, and that they value the bust as a work of art and as a reminiscence of the donor." The president, in formally unveiling the bust, observed that it was a happy coincidence that this meeting took place on the anniversary of the date when Dalton communicated to the Society his paper on the absorption of gases by water, in which was given the first hint of the atomic theory.

THE zebra stallion Matopo, which has been described and figured by Prof. Cossar Ewart in his book "The Penycuik Experiments," and was the sire of some interesting zebra-horse hybrids, is dead. This zebra was purchased some time ago by Mr. Assheton-Smith, Vaynol Park, Bangor, who was hopeful that he might find it possible to repeat some of Prof. Ewart's experiments, but unfortunately his expectations have not been realised. Whilst retaining the skin, he has presented the skeleton of the zebra to the University College of North Wales, where it will form a handsome addition to the zoological collection. It may also be noted that to this college Prof. W. A. Herdman, F.R.S., of Liverpool, recently made a donation of some fishes from Ceylon and Indo-Malaya which he collected when in the East investigating the pearl fisheries of Ceylon. Prof. D'Arcy Thompson, C.B., Dundee, has also presented a skeleton of the somewhat rare sea otter (Enhydra) from Alaska. By presentation and purchase a valuable zoological collection, which is under the care of Prof. Philip J. White, has gradually been formed at the college.

DR. DAWSON TURNER has been awarded a Keith prize by the Royal Scottish Society of Arts for papers upon improved Röntgen apparatus and other electrical matters.

AT an auction sale of rare, valuable and standard books by Messrs. Hodgson and Co., Chancery Lane, on October 21, a complete set of Curtis's *Botanical Magazine*, from the commencement in 1787 to the present month, realised the sum of 120*l*.

THE opening meeting of the Institution of Electrical Engineers will be held on November 12, when the premiums awarded for papers read or published during the session 1902–1903 will be presented, and the president, Mr. Robert Kaye Gray, will deliver his inaugural address.

MR. MARCONI, in company with Captain H. B. Jackson, has gone to Gibraltar to carry out further experiments for the Admiralty. It is hoped to be able to open communication with Gibraltar before losing touch with Portsmouth.

ACCORDING to the daily papers, the Post Office authorities are about to make experiments with the de Forest system of wireless telegraphy. Dr. Lee de Forest has come over

from America to superintend the experiments; the system, in which an electrolytic conductor is used in place of the ordinary coherer, is in considerable use in America.

A FORTNIGHT ago we were able to record the fact that a speed of 125½ miles an hour had been attained by the Siemens car in the high-speed trials which are being carried on at Berlin. Last Friday this record was beaten, and a speed of 130½ miles an hour attained. It is said that a higher speed than this is not desired. The passing of the car at full speed seems to have created a strong impression on a large crowd of sightseers who witnessed the experiments from Dahlwitz Station.

WE regret to see the announcement of the death of Dr. C. T. Hudson, F.R.S., president of the Royal Microscopical Society from 1888 to 1890, and joint author of Hudson and Gosse's "Rotifera." Dr. Hudson was born in 1828, and was fifteenth wrangler in the mathematical tripos of 1852. From 1855 to 1860 he was headmaster of Bristol Grammar School, and from 1861 to 1881 of Manilla Hall, Clifton. He was elected a fellow of the Royal Society in 1889, chiefly on account of his work on Rotifers, concerning which he was the chief authority. The genus Pedalion, discovered and described by him, was a very remarkable and important contribution to animal morphology; Dr. Hudson was also the discoverer of numerous other new genera and species of Rotifera, described in the publications of various scientific societies.

AN announcement is made in a Government resolution on the annual report of the Survey of India for 1901–2 that the necessity for effectively revising and keeping up to date the maps now in existence, as well as of providing fresh ones, has been forced upon the Government of India. "We can only hope," says the *Pioneer Mail*, "that there may be no half measures, and that the reform may be thorough, for assuredly the need is more crying than most can have any idea of."

ACCORDING to the *Westminster Gazette*, Mr. F. du Cane Godman has recently presented to the British Museum (of which he is a trustee) a collection of nearly 30,000 specimens of beetles, following on a previous donation of 50,000. The present collection consists mainly of representatives of the family Elateridæ, or "ship-jacks," the bulk being from Central America. The collection in the Museum is now the finest in the world, and housing space is a problem. Our contemporary makes a curious mistake in referring to the fact that 150,000 *specimens* of beetles are already described, and that the annual addition to the British Museum collection averages 400 *specimens*; in both cases, of course, *species* are meant.

A REUTER telegram from Wellington, dated October 25, states that the Antarctic relief ship *Morning* has left Lyttelton to join the *Terra Nova*, the relief ship for the *Discovery*, at Hobart. In connection with the relief of the Nordenskiöld Antarctic Expedition, the *Times* reports that the Swedish vessel *Frithjof*, the French steamer *Le Français*, and the Argentine gunboat *Uruguay* will meet at Ushnaia on November 1, and will then proceed to Seymour's Island, and from thence to Snowhill, Dr. Nordenskiöld's proposed base.

A CORRESPONDENT, referring to Prof. W. H. Everett's letter on rocket lightning in our last issue, directs attention to a closely similar phenomenon observed in London between 2 and 3 a.m. on the morning of October 16. From the south-eastern horizon of a clear sky, a "wriggling stream" of bluish-white light shot up in a vertical direction and broke off short without spreading. It would be interesting to know if any other observer witnessed this display, and if a thunderstorm occurred that night anywhere to the south-east of London within twenty or thirty miles.

COMMANDER R. E. PEARY has been granted leave of absence in order to make one more attempt to reach the North Pole. In a letter to the Secretary of the U.S. Navy, published in the *National Geographic Magazine* for this month, Mr. Peary outlines the plan he proposes to adopt. He intends to make his winter camp fully one hundred miles north of his previous winter quarters, so that when he is ready to start in spring he will be a hundred miles nearer his goal. The distance from Peary's proposed winter camp near Cape Joseph Henry to the North Pole and back again is less than the average distance of four sledging trips which he has made. Mr. Peary proposes to start in July, 1904, to reach Cape Joseph Henry with his vessel in the fall of that year, and to make his dash for the Pole in 1905. In case he does not reach the proposed winter camp in 1904, he will spend 1905 in reaching it, and attempt to reach the North Pole in 1906.

THE fourteenth International Congress of Americanists will be held at Stuttgart on August 18–23, 1904, under the presidency of Prof. Karl von den Steinen. The congress is concerned with the history, culture, linguistics, and mythology of the various aboriginal races of America, and generally with the archæology and ethnography of the New World. Correspondence referring to anthropology and ethnography should be addressed to Prof. Karl von den Steinen, Berlin-Charlottenburg, Hardenbergstrasse 24, and that referring to archæology, discovery, and Central America to Prof. Eduard Seler, Steglitz bei Berlin, Kaiser Wilhelmstrasse 3. The general secretary is Prof. K. Lampert, Stuttgart, Archivstrasse 3.

THE volume referred to in the foregoing note affords convincing evidence of the interest shown in scientific subjects in New Zealand, and it is not unnatural to find that men of science in that colony are beginning to ask that scientific principles may influence the national system of education. Mr. Hill, in a paper on technical education, read before the Hawke's Bay Institute, rightly maintained that "the study of natural science should be fostered even beyond the public school course, and this can readily be done by the introduction of botany, geology, agricultural chemistry, and other cognate subjects into the advanced or secondary course. The maintenance by the Government of technical schools and schools of science and agriculture would give prestige to such institutions, and these, with the university colleges, should supply all the academic, scientific, and technical training that is wanted for the professions and the pursuit of every specialised form of industrial work."

THE council of the Royal Society will proceed on November 5 to the election of a Joule student for the period 1903–5. The studentship will be awarded for investigations in those branches of physical science more immediately connected with Joule's work. Applications from candidates will be received by the Assistant Secretary, Royal Society, Burlington House, London, W.

THE first number of vol. ix. of the *Bulletin* issued by the Società Sismologica Italiana gives the rules of that Society, a list of its members, and a continuation,

up to the end of 1901, of the well-known earthquake register compiled at the Central Meteorological Office in Rome. The late appearance of this publication arises from the fact that with the Italian records there are incorporated corresponding records which have been collected from seismological stations throughout the world. In this publication we therefore have not only entries relating to disturbances confined to the Italian peninsula, but also of practically all the large earthquakes of the world.

We have received from the Cambridge Scientific Instrument Company its new catalogue of Duddell oscillographs. These instruments were described in detail in Nature of December 6, 1900 (vol. lxiii. p. 142). Since that time several improvements have been made in their construction which have the effect of making them more trustworthy instruments, and better able to withstand the somewhat rough usage which they are likely to meet with in engineering work. We note also that a double permanent magnet oscillograph is now on the market; this instrument has two sets of strips, and is thus able to show the waveforms of current and P.D. simultaneously; hitherto the portable instrument has only been made with one set of strips. Amongst the illustrations to the catalogue are a number of excellent reproductions of oscillograph records, which serve to show the variety of purposes for which the instrument is suited. One has only to turn to any of the more recent papers dealing with alternate current working to see how important a part the oscillograph is now playing and is destined to play in the future in this branch of electrical engineering.

We have also received from the Cambridge Scientific Instrument Company a pamphlet describing Prof. Callendar's apparatus for measuring the mechanical equivalent of heat, which was recently described before the Physical Society, and a second pamphlet relating to the application of electric resistance thermometry to meteorology. This latter paper sets forth some of the cases in which the use of resistance thermometers is peculiarly suitable, as, for example, the measurement of water temperatures or underground temperatures. The method can be used with much advantage for measuring or recording temperatures at some distance from the observatory, and has the additional recommendation that the thermometer itself need not be disturbed or approached when the reading is taken. We pointed out some of the other uses of these thermometers in these columns a few weeks ago.

In a recent number of the *Bulletin de la Société d'Encouragement pour l'Industrie nationale*, M. Charles Henry has an interesting paper on the luminous efficiency of oil lamps and flames generally. He shows that the efficiency increases with the intensity, at first very rapidly, as the intensity rises from 1 to 2 carcels, and then more slowly, becoming practically constant at 3 carcels. The same has been shown to be true for arc lamps, the law of variation being nearly the same in both cases, only the arc lamp naturally varies over a much wider candle-power range; the efficiency does not become a maximum, in fact, until about 600 carcels. If the efficiencies at their respective maxima are compared, the arc lamp is found to be approximately five times as good as an oil lamp, one carcel-second being obtained for an expenditure of 70 watts in the one case and of 320 in the other; this is allowing for the losses in the boiler, engine and dynamo generating the current, and represents, therefore, the actual superiority of the arc over the oil lamp. If, however, the efficiencies at equal candle-power are compared, the oil lamp is three times as good as an arc—but, of course, an arc of 3 candle-power is never used in practice. The efficiency of the oil lamp may be improved 25 to 40 per cent. by surrounding the lower portion of the flame with a copper ring to prevent loss of heat by convection.

In the *Field* of October 17, Mr. G. Renshaw announces that he has found in the museum of the Royal College of Surgeons a skull of the extinct South African blaauwbok (*Hippotragus leucophaeus*), which is believed to be the only known specimen in existence.

The *Proceedings* of the Royal Irish Academy for May contain an important paper by Dr. G. H. Carpenter on the relationships between the classes of Arthropods. The author considers that group to have been derived from a single stock, and since typical insects, crustaceans, and arachnids possess the same number of segments, the ancestral type must likewise have been definite in this respect. Consequently, millepedes and the like must be aberrant types in which the segmentation has been abnormally increased. Probably the ancestral forms were naupliform (*i.e.* larval) crustaceans, and not, as commonly believed, well-developed annelid worms.

The *Illustrated London News* of last week (October 24) contains a special supplement devoted to the first part of an account, illustrated by reproductions from original photographs, of Major Powell-Cotton's recent hunting expedition in Eastern Equatorial Africa. One of the objects of the expedition was, we believe, to obtain specimens of the okapi, but although the celebrated traveller and big-game hunter has been unsuccessful in this respect, he has succeeded in mapping out an extensive tract of hitherto unexplored country, and has likewise acquired much valuable information with regard to the natives and the fauna. It was during this expedition that the two fine giraffes now mounted in the Natural History Museum were obtained. Special interest attaches to the traveller's discovery of a spot to which elephants resort when about to die, the habit on the part of these animals of having a "dying ground" being paralleled in the case of the South American guanaco. The cave-dwellers of Mount Elgon appear to have made a more favourable impression on Major Powell-Cotton than they did on their discoverer, Sir Harry Johnston. One of the photographs shows a native stalking hartebeests behind an ass on the head of which has been fixed the scalp and horns of one of these antelopes. The conclusion of the account will appear in this week's issue.

At Rossitten, in eastern Prussia, large numbers of crows and rooks are caught alive in nets every year during the two migration seasons. The director of the station of the German Ornithological Society at Rossitten proposes to try a curious experiment with these birds. Small metal rings bearing a number and date will be attached to one foot of each of them, after which they will be liberated and permitted to proceed upon their own paths of migration. Notices have been sent all over Germany requesting that when any of these birds are shot the foot and the ring attached to it may be returned to the director of the "Vogelwarte" at Rossitten. It is quite possible that some of them may stray even as far as the shores of Great Britain, and if this should happen it is hoped that the director's request may be attended to. An accurate record will be kept at Rossitten of the dates of the liberation of every bird and of the locality whence its foot is returned, and it is expected that some interesting deductions will be made from the information thus obtained.

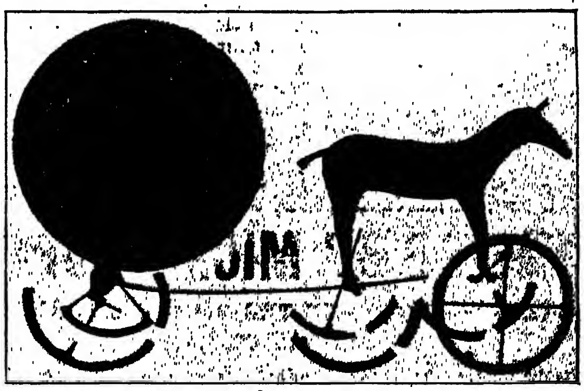
THE small, but well-ordered, zoological garden at Bâle is well worthy of a visit. It is situated in the new quarter of the city beyond the railway station, and has the advantages of a good soil and a clear stream of water running through it. The new lion-house, which will shortly be ready for occupation, is planned on an extended scale, but will not be quite so large as those of London and Berlin. There will be a set of external cages for the animals on the south side, but the interior of the building on the north side will be appropriated to the exhibition of reptiles. There is a fine herd of the American bison, which has frequently bred in this garden, and very good examples of the elk and reindeer, neither of which seem to do well in England. The special pet of the director, Dr. Hagmann, is a young female orang, which has been living at Bâle in good health for more than three years, and is remarkably tame and intelligent. She obeys orders given in German, but has not yet learned to reply to them in that language.

THE geology of the country near Chichester is described in a memoir of the Geological Survey by Mr. Clement Reid, F.R.S., with contributions by Mr. G. W. Lamplugh and Mr. A. J. Jukes-Brown. The memoir, which is accompanied by a colour-printed map (sheet 317), deals with a portion of the South Downs in Sussex, with the picturesque regions of Midhurst, Petworth and Pulborough on the north, and the low-lying fertile tracts of drift gravel and brick-earth on the south. The formations described range from the Wealden to the London Clay, together with Clay-with-flints, certain marine gravels, and other superficial deposits. The price of the memoir is one shilling, and of the map one shilling and sixpence. Both may be obtained from any agent for the sale of Ordnance Survey maps, or through any bookseller from the Ordnance Survey Office, Southampton. For educational purposes this and other memoirs in the same series are invaluable.

THE second part of the general report and statistics for 1902 relating to mines and quarries, edited by Prof. C. Le Neve Foster, F.R.S., and published as a Home Office Bluebook, deals with questions of labour. It gives the facts relating to persons employed and accidents at mines and quarries in the United Kingdom, and to the enforcement of the Mines and Quarries Acts. In 1902, 1061 separate fatal accidents occurred in and about the mines and quarries of the United Kingdom, causing the loss of 1172 lives. Compared with the previous year, there is a decrease of fourteen in the number of fatal accidents and of fifty-seven in the number of lives lost. Three-fourths of the fatal accidents by explosions of fire-damp or coal-dust were due to naked lights, the illegal use of matches, or the illegal opening of a safety-lamp. The worst disaster of the year was the explosion at MacLaren Colliery, Abertysswg, Monmouthshire, where sixteen persons lost their lives and eighteen were injured. In connection with this explosion, Prof. Le Neve Foster remarks, "fortunately the roads were well watered, or otherwise the loss of life would probably have been very much larger"; and in this contention he is supported by Mr. Martin, one of H.M. Inspectors of Mines who reported on the disaster, and concluded his report with the following words:—"This is perhaps the first practical proof of artificial watering limiting the effects of what would otherwise have proved a widespread and much more disastrous affair. It is certainly an object lesson for all colliery managers." Owing to the large number of accidents occurring at quarries from the use of explosives containing nitro-glycerin when in a solid or frozen state, it has been thought desirable to circulate special notices to be posted up on the door of the magazine or store from which the men fetch their explosives. The notice directs that all cartridges made of dynamite, gelignite, blasting gelatin, and other explosives containing nitro-glycerin must always be thawed (in a properly designed warming pan) before use during the months of December, January, February, and March, and also at any other times if the cartridges are not in a soft or pasty condition.

A PECULIAR form of the basidiomycetous fungus *Lentinus lepideus* is described by Mr. W. G. Smith in the *Journal of Botany* (October), in which numerous clavaria-like branches spring from a central club-like portion. Mr. E. G. Baker completes in this number his systematic arrangement of the Indigoferas of tropical Africa.

THE current number (October) of the *Reliquary and Illustrated Archaeologist* contains some notes by Mr. W. R. Prior on an image of the sun found last autumn at Trundholm, in northern Zeeland, and two pictures of the object, one of which is here reproduced on a reduced scale, by permission of the publishers, Messrs. Bemrose and Sons, Ltd. The image is 1 foot 1½ inches broad and 8 inches high, and was found in fragments about six inches under the surface of the ground. It was easily reconstructed by Dr. Sophus Müller, director of the National Museum at Copenhagen, and a full description of the object has appeared in Danish.



Sun Image found at Trundholm, Denmark.

"It has been clearly proved," says Mr. Prior, "an image of the sun being dragged round on a chariot as an object of worship, an idol of the sun-worship dating from about 1000 B.C., and the best of its kind found anywhere, both as regards design and execution. In Egyptian and Oriental mythology, as well as in Grecian, the sun was represented as a round disc, often inlaid with gold. Several pictorial representations of the sun are known from the same period, but none that has any close resemblance to this find. Everything seems to indicate that the find belongs to the older Bronze age, and is of purely Scandinavian origin in its rich ornamental style and artistic workmanship, which appear in northern bronzes of that period."

IN order to obtain flowers out of their natural season, it is possible to retard their growth at an early stage by placing the plants in cold, dry houses, and then to force them later under the influence of heat and moisture, or it is possible to stimulate the young buds into premature development by subjecting them to the effects of ether. M. A. Maumené, a strong advocate of the etherisation system, discusses its scientific and practical aspects in the *Revue scientifique*. He maintains that not only do plants develop more quickly after being etherised, but that development is more regular and complete.

IN Japan the custom prevails of burning down yearly, tri-yearly, or at longer intervals the tracts of ground known as "hara," this name being applied to the bare hillsides which have been denuded of trees. One of the first products on these lands is a grass known as "kaya," *Miscanthus sinensis*, and it is with the idea of increasing this crop that the lands are burnt. This fallacy is combated by Mr. O. Shishido in the *Bulletin* of the College of Agriculture, Tokio, where he points out that the *hara*, although favourably situated, are now practically unproductive areas. In the same journal Mr. H. Shirawasa indicates the development of the oil in the camphor-tree which crystallises out into camphor.

A USEFUL little book has been published by the Royal Geographical Society entitled "Hints on Outfit for Travellers in Tropical Countries," by Dr. Charles F. Harford. The hints are of just the practical kind that intending travellers will find serviceable.

A SIXTH edition of Prof. W. H. Burr's "The Elasticity and Resistance of the Materials of Engineering" has been published by Messrs. John Wiley and Sons, of New York, and Messrs. Chapman and Hall, of London. More than half the book is new, and the advanced matter relating to the general theory of elasticity in amorphous solid bodies, and the theories of torsion and flexure, have been placed at the end of the book as an appendix.

THE Bureau of American Ethnology has published a Natick dictionary compiled by the late Dr. James H. Trumbull. In an introduction Dr. Edward E. Hale explains that the dictionary is published as it was left by Dr. Trumbull, whose widow presented the MS. to the American Antiquarian Society. The manuscript was passed to the late Major Powell, who placed it in the hands of Dr. Gatschet, of the ethnologic staff of the Bureau, who has superintended its publication. It is hoped that the book will form the first volume in a series of vocabularies of the native languages.

IT has been shown recently that the composition of the surface layers of a solution differs to a slight extent from the composition of the solution as a whole. Experiments made by Miss C. C. Benson with very dilute amyl alcohol, which readily gives rise to a durable foam on shaking, show that this foam is also different in composition from the main solution, the proportion of alcohol being slightly greater in the foam than in the rest of the liquid. The composition of the solutions was determined by surface tension measurements by the drop method.

THE problem of turning to practical use the free nitrogen of the atmosphere for the purposes of agriculture and industry is one which has excited attention for many years past. According to a recent communication of Dr. Frank, of Charlottenburg, the fixation of atmospheric nitrogen on a technical scale can be effected through the agency of the carbides of the alkaline earth metals. Barium carbide is especially suitable for the purpose, and by the absorption of atmospheric nitrogen is converted directly into barium cyanide. The reaction with calcium carbide proceeds differently, the product obtained being calcium cyanamide, which, however, by heating with water under high pressure is easily converted into calcium carbonate and ammonia. Experiments have, moreover, shown that the calcium cyanamide can be used directly as a means of supplying nitrogen to the soil.

ALTHOUGH the analogy between asymmetric carbon and nitrogen in regard to optical rotation is assured by the fact that the activity of the nitrogen compounds can be explained by a simple extension of the theory of van 't Hoff and Le Bel, yet previous experiences seem to point to the analogy being very incomplete. The instability and the tendency of the active forms to undergo spontaneous racemisation are conspicuously characteristic of the nitrogen compounds. These properties no doubt depend upon the readiness with which nitrogen passes from the pentavalent into the trivalent form, a transformation which at once destroys the spacial asymmetry. An interesting paper dealing with the subject is published by Dr. Wedekind in the current number of the *Zeitschrift für physikalische Chemie*.

AN investigation of the best conditions for the electrolytic refining of copper has recently been carried out by Messrs. F. J. Schwab and I. Baum, an account of which is given in the October number of the *Journal of Physical Chemistry*. The factors which have been taken into consideration are the cost of the power necessary to precipitate a tank of copper with different current densities and at different temperatures, the cost of heating the tank, the deterioration of the electrolyte, the interest charge on the copper in the tank, and the quality of the copper deposited. As the result of a large number of series of experiments, in which the influence of these factors and their correlation were examined, the authors come to the conclusion that in order to operate a plant most economically and to secure the best financial returns, copper should be refined in covered tanks at a temperature of 70° C., with a current density of 3¼–3½ amperes per square decimetre.

THE additions to the Zoological Society's Gardens during the past week include two Chestnut-breasted Finches (*Donacola castaneothorax*), a Bicheno's Finch (*Estrelda bichenovii*); fourteen Banded Grass Finches (*Poephila cincta*), eight Gouldian Finches (*Poephila gouldiae*) from Queensland, two Modest Grass Finches (*Amadina modesta*), fourteen Chestnut-eared Finches (*Amadina castanotis*); two Undulated Grass Parrakeets (*Melopsittacus undulatus*), a Peaceful Dove (*Geopelia tranquilla*), a Graceful Ground Dove (*Geopelia cuneata*) from Australia, presented by Mrs. Alfred H. Houlder; an American Bittern (*Botaurus lentiginosus*), captured at sea, presented by Mr. Yeo; two Chameleons (*Chamaeleon vulgaris*) from North Africa, presented by Mr. G. T. Coleman; a Hocheur Monkey (*Cercopithecus nictitans*) from West Africa, a Grey Seal (*Halichoerus grypus*) from the West Coast of Ireland, a Red-fronted Lemur (*Lemur rufifrons*) from Madagascar; an Adelaide Parrakeet (*Platycercus adelaidae*) from Australia, deposited; two Great Kangaroos (*Macropus giganteus*) from Australia, a Banded Cotinga (*Cotinga cincta*) from Brazil, purchased; a Hybrid Waterbuck, between (*Cobus unctuosa* ♂ and *Cobus ellipsiprymnus* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN NOVEMBER:—

Nov. 3. 3h. 45m. to 7h. 2m. Transit of Jupiter's Sat. III. (Ganymede).
7. 11h. 23m. Minimum of Algol (β Persei).
9. 8h. 43m. to 9h. 28m. Moon occults λ Geminorum (Mag. 3·6).
10. 7h. 26m. to 10h. 44m. Transit of Jupiter's Sat. III. (Ganymede).
,, 8h. 12m. Minimum of Algol (β Persei).
14–16. Epoch of Leonid Meteors (Radiant 150° + 22°).
15. 1h. Venus in conjunction with the Moon. Venus 0° 55′ N.
,, Venus. Illuminated portion of disc = 0·429.
16. 6h. 11m. to 9h. 53m. Transit of Jupiter's Sat. IV. (Callisto).
17. 11h. 12m. Transit (ingress) of Jupiter's Sat. III. (Ganymede).
27. 23h. Venus at greatest elongation (46° 44′ W.).
30. 9h. 55m. Minimum of Algol (β Persei).

RECENT SPECTROGRAPHIC OBSERVATIONS OF NOVÆ.—Using the slitless spectrograph recently attached to the Crossley reflector, Prof. Perrine has obtained photographs of the recent spectra of various novæ.

A spectrogram of Nova Aurigæ, taken with a total exposure of 5 hours on August 29 and 30, shows that important changes have taken place in the spectrum of this star since 1901, when the spectrum was photographed by Mr. Stebbins. At that time the chief nebular line at λ 501 was equal in intensity to the lines at λ 462, λ 434, and Hδ, but in the recent photographs it is entirely absent; the other lines are relatively the same, but all appear to have decreased in intensity with regard to the continuous spectrum. This Nova is now of the fourteenth magnitude.

In the case of Nova Persei, a spectrum obtained on July 30, with an exposure of 2 hours 3 minutes, shows that striking changes have taken place since March, 1902. Hβ has decreased greatly in brightness during the interval, and the condensation at λ 434 has also become less marked, whilst Hδ has only suffered the normal diminution in brightness. The lines at λ 339 and λ 346 show the greatest changes, the former having entirely disappeared, whilst the latter is barely distinguishable on the latest spectrogram; the chief nebular line does not appear to have changed relatively to the general spectrum. On July 30 the magnitude of Nova Persei was about 11·5 or 12.

Even in the more recent Nova Geminorum important changes are already noticeable; photographs were secured on August 28, 31, and September 2, and when compared with the observations of May 11 it was seen that during the interval of 3½ months the whole spectrum had become much weaker; the chief nebular line had become much stronger, whilst Hβ had greatly decreased in relative intensity. The line at λ 434 is by far the strongest in the whole spectrum, and that at λ 463 is much broadened and probably composite; there are also indications of the higher hydrogen lines on the background of continuous spectrum. On a number of spectrograms obtained between April 2 and 8 a condensation at λ 350 was a remarkable feature, on April 18 no indications of this condensation were present, whilst on April 26 there was a strong condensation at λ 346, but nothing at all at λ 350; later observations confirm this interesting phenomenon.

Visual observations of the spectrum of Nova Geminorum, made by Mr. H. D. Curtis on August 17 and 18 with spectrograph No. 1 attached to the 36-inch refractor, showed the three chief nebular lines well developed, Hβ faint, the line at λ 4959 rather stronger, and the line at λ 5007, into which the greater part of the Nova's light seemed to be concentrated, very much more intense, whilst D and Hα were not visible. The change of this star into one of the nebular type is apparently now complete (Lick Observatory *Bulletin*, No. 48).

OCCULTATION OF A STAR BY JUPITER.—A communication to the Kiel Centralstelle, published in No. 3903 of the *Astronomische Nachrichten*, announced that Mr. T. Banachiewicz, of the Warsaw University, had observed an occultation of the star B.D.−6°.6191 (mag.=6·5) by Jupiter at about 7h. 10m. (Berlin M.T.) on September 19.

Several observers recorded their observations of this phenomenon in No. 3906 of the *Nachrichten*, amongst others Herr Kostinsky, of the Pulkowa Observatory, who gave the times of immersion and emergence as 20h. 10m. 21s. ±1s. and 21h. 52m. 4s ±1s. (Pulkowa S.T.) respectively.

In a letter to the October number of the *Observatory*, Mr. Denning gives the details of his observations of the phenomenon about half an hour after the probable reappearance of the star, when it was situated at about 10″ from the S.S.E. limb of the planet. He states that the same star will be about 20′ south of Jupiter on December 29 at approximately 10h. G.M.T.

ROTATIONAL VELOCITY OF VENUS.—*Bulletin* No. 3 of the Lowell Observatory contains a description, by Mr. V. M. Slipher, of some experiments made at that observatory in order to determine, by the Deslandres spectrographic method, whether Venus has a short rotational period or not.

The instrument used was the new Lowell spectrograph, made by Brashear, which gives an angular dispersion of 46°.5 for one tenth-metre when set for the minimum deviation of λ 4270. The spectrograph is so attached to the adapter that it may be rotated about the optical axis in order to obtain spectrograms with the slit in various relative positions; the plates used were fine-grain Seed's "23" brand, and were exposed for about 8 minutes during the hour immediately succeeding sunset, whilst the air currents were most quiescent. For purposes of measurement an iron spectrum was photographed on the same plate, and twelve of the finest iron lines were used as fiducial lines. The results obtained show very small probable errors, and indicate that Venus does not possess a short period of rotation. A period of twenty-four hours would cause an inclination of the lines amounting to one-third of a degree, and similar experiments performed on the planet Mars, and published in *Bulletin* No. 4, show that a longer period than this would be clearly indicated by the apparatus and method used.

THE STANDARDISATION OF ELECTRICAL PRESSURES AND FREQUENCIES.

WE have received a copy of the resolutions of the Engineering Standards Committee with reference to standard pressures for direct current and standard frequencies. In view of the importance of the subject to the electrical industry at large, the document is reprinted below in full.

Standard Direct Current Pressures and Standard Frequencies.

The standardisation of electrical pressures and frequencies was the first portion of the important work entrusted to the subcommittee on generators, motors and transformers by the electrical plant committee. The subcommittee consists of the following gentlemen:—

Colonel R. E. Crompton, C.B., chairman.

Colonel H. C. Holden, R.A., Captain A. H. Dumaresq, R.E., representing the War Office.

Commander G. L. Sclater, R.N., Mr. L. J. Steele, representing the Admiralty.

Mr. Llewellyn Preece, representing the Crown Agents for the Colonies.

Dr. R. T. Glazebrook, representing the National Physical Laboratory.

Mr. B. H. Antill, Mr. W. B. Esson, nominated by the Electrical Engineers' Plant Manufacturers' Association.

Mr. A. C. Eborall.

Mr. S. Z. de Ferranti.

Mr. Robert Hammond.

Captain H. R. Sankey.

Mr. C. H. Wordingham.

Mr. Leslie S. Robertson, secretary.

Mr. C. le Maistre, electrical assistant secretary.

At an early stage in their deliberations, the subcommittee decided that the most advantageous method of approaching this problem, beset as it is with so many difficulties, would be from the point of view of those most affected, namely the users of lamps and of motors for power purposes. It was therefore agreed that the standard pressures to be suggested should be measured at the consumers' terminals as settled by Act of 1899.

At the present time there exist many different pressures declared by the various lighting and power authorities. In view of the great desirability of obviating this unsatisfactory state of affairs it was deemed advisable to suggest the minimum number of standard pressures which would best meet present commercial requirements and, at the same time, utilise to the fullest extent the consumers' existing appliances.

After careful consideration, it became evident to the subcommittee that the direct current pressures of 110, 220, 440, and 500 volts would best meet the requirements, because carcases built for these standard pressures could be utilised for pressures 10 per cent. above or below the suggested standards, without any alteration whatever in the castings or mechanical components, by merely altering the windings and excitation.

It is to be hoped that now these direct current pressures have been fixed as standards by the committee, they will in future be universally adopted by the engineers advising

corporations and others distributing electrical energy. In course of time the benefits to the electrical industry at large, which will certainly follow the adoption of these standard pressures, must become more and more apparent.

A circular was drafted embodying the suggestions of the subcommittee, and this was submitted, first to the manufacturers for their consideration, and secondly to the leading consulting engineers and users of motors.

The information so courteously placed at the disposal of the subcommittee by the consulting engineers and manufacturers was most carefully weighed and considered by the subcommittee, and certain definite conclusions were arrived at, the circular being sent, in the first instance, to the manufacturers, as they were the people most directly interested. Replies were received from all the leading firms, who expressed themselves unanimously in favour of the recommendations of the subcommittee. The consulting engineers similarly gave their adherence to the proposals of the subcommittee.

Before coming to their final decision the subcommittee on generators, motors and transformers conferred with the subcommittee on electrical tramways, of which Mr. A. P. Trotter is chairman, and a joint meeting took place, with the result that the pressure of 500 volts, which most concerned the latter subcommittee, was agreed to, and in addition to the pressures already agreed to 600 volts was decided upon as the standard pressure for electrical railways.

The question of the adoption of standard frequencies, although of equal importance with that of standard pressures, was not surrounded with the same difficulties. It was, however, deemed advisable to fix upon the standard frequencies at the earliest possible stage of the work, as no progress could be made in the standardisation of prime movers for driving alternate current machinery until such time as the frequencies had been settled upon. On this question there appeared to be a great preponderance in favour of frequencies of 25 and 50. The only point upon which any serious difference of opinion appeared to exist was the advisability of the adoption of a third frequency of 40 or 42, to enable rotary converters to be used to the fullest advantage. All the arguments in favour of this third frequency were fully discussed, but after carefully weighing the *pros* and *cons* the subcommittee decided not to recommend the adoption of more than two frequencies, namely, 25 and 50.

The recommendations of the subcommittee were then submitted to the electrical plant committee, the publication committee, the main committee, and the Board of Trade for their approval.

This having been obtained, it was deemed advisable, in the interests of the electrical industry of the country, that the findings on the questions of direct current pressures and frequencies should be published at an early date, without waiting for the completion of the entire report to be issued at a later date.

The following are the resolutions on standard direct current pressures and standard frequencies:—

(1) That the standard direct current pressures, measured at the consumers' terminals, be:—

110, 220, 440, 500 volts.

(2) That the standard direct current pressures, measured at the terminals of the motors, be:—

For tramways 500 volts.
For railways 600 volts.

(3) That 25 periods per second be the standard frequency for:—

(*a*) Systems involving conversion to direct current by means of rotary converters.
(*b*) Large power schemes over long distances.
(*c*) Three phase railway work, where motor gearing and the inductive drop on the track rail have to be considered.

(4) That 50 periods per second be the standard frequency for:—

(*a*) Mixed power and lighting on town supply mains.
(*b*) Ordinary factory power plant.
(*c*) All medium size power plant where rotary converters are not employed.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

The present transitional phase of geographical thought and activity was faithfully mirrored in the proceedings of Section E. The majority of the papers revealed the wide range of geographical interests rather than any great advance in geographical coordination. In this they are typical; for while there are many workers at geographical problems, few, if any, would put forth the claim of being complete geographers. There are indications of many geographical specialisms being recognised. Their exponents are, however, at one disadvantage when compared with other specialists. An organic chemist usually has had a thorough training in chemistry before he specialises in organic chemistry. Few geographical specialists have had any training as geographers. Each makes his own contribution, but it is often an isolated one, and does not fit into a general plan of the subject. The unity of geography and the relation of its parts are very gradually being elucidated. The want of this coordination is strongly felt by most geographical workers. At the conclusion of the Southport meeting one wished for a summary coordinating the communications discussed. Perhaps this is felt, though to a less extent, in other sections, and it would be useful if the presidential duties were made to conclude by the giving of a brief review of the work done at the section.

The address of the genial president, Captain Creak, was the only one which surveyed the whole world. It was on terrestrial magnetism, and has already been printed. Dr. Vaughan Cornish's researches, summarised in the report of the committee on terrestrial surface waves, are on worldwide phenomena, which he illustrated on this occasion mainly by beautiful views of the wave forms of Niagara, from which he has recently returned, and by pictures of wave forms in snow and on quarry roads caused by heavy sledge traffic.

The section was also privileged to hear an address from Prof. Pettersson, of Stockholm, who spoke for an hour in excellent English, on the effect of ice melting on oceanic circulation. Prof. Pettersson has long insisted that the thermodynamic cycle of latent heat, consisting of ice formation in polar regions and of ice melting in sea-water in lower latitudes, was a potent cause of oceanic currents. He has calculated that the ice melting between Iceland and Jan Mayen generates about 400,000 horse-power annually, which is expended in accelerating the water movements of the east Iceland polar current. The energy set free on ice melting in sea-water maintains a kind of inverted waterfall, an upwelling of bottom water to the surface. Warm currents follow the trend of deepest isobaths, ice currents exist only in shallow seas, where no warm current can melt them. Ice currents and warm currents meet between Iceland and Jan Mayen, west of Spitsbergen, south-east of Newfoundland, and round the margin of the ice-girdled Antarctic. The "outbursts" of Antarctic icebergs which carry them to low latitudes in the Indian Ocean may influence the climate of India and Australia. The latest Antarctic outburst and series of great droughts in India occurred between 1891–98. Prof. Pettersson considered that regular surface observations between 60° and 100° E. and a few series of deep-sea soundings would reveal hydrographical variations with important meteorological bearings. He also pointed out that current measurements at depths of 800–4000 metres in the Atlantic were needed to ascertain the significance of the currents generated by ice attraction. At the conclusion of his paper Prof. Pettersson showed in miniature an experiment to illustrate the effect of melting ice in causing currents in salt water carried out by Mr. J. W. Sandström, assisted by Miss A. Palmquist, who have made a series of useful calculations from the data obtained from this experiment.

Travellers' tales were few, but full of human interest. No one who heard Lieutenant Shackleton will forget the vivid and racy account he gave of the National Antarctic Expedition. Dr. Tempest Anderson's slides and descriptions of the volcanic phenomena of St. Vincent and Martinique were equally effective. Lieut.-Colonel Manifold described his journeying from India across China, and back over different routes through the heart of the Empire. In his paper were many hints of the great activity of other Powers

than Britain in pushing on railway construction and promoting the expansion of their commerce. Dr. H. O. Forbes read a report on the work of his expedition to Sokotra. Dr. J. P. Thompson, the energetic Queensland geographer, contributed a comprehensive account of the geography of the State.

Exploration is now no longer confined to foreign lands, and some of the younger botanists have shown us what can be done when the plant world at home is regarded geographically. From the point of view of pure science they are making an important contribution to the study of the relationship between organisms and environment, and compiling part of the data necessary for the study of macro-organisms—the complex associations of rock, air, water, and organic life considered as a whole, which are the subject-matter of the geographer. From the point of view of applied science they are carrying out an equally valuable work, for a knowledge of the characteristics and distribution of the different plant associations is the best clue to the possibilities and limits of their profitable exploitation for the production of economically important plants and animals. Such botanical surveys might well be subsidised by the Board of Agriculture. The example of the Canadian Geological Survey might be followed, and the work be entrusted to teachers of botany who would carry it out in their vacations.

Dr. Otto Darbishire, of Owens College, discussed the general problem of the relations of botany and geography, and insisted on the necessity for modern travellers having a knowledge of ecology. Dr. W. G. Smith, of the Yorkshire College, who has carried on the work of his deceased brother, who planned a botanical survey of Great Britain, also urged the importance of the observation and mapping of vegetation features in geographical exploration, and illustrated his thesis by reference to the maps already made for Britain. The maps made of the plant associations of the Eden, Tees, Tyne, and Wear basins by Mr. F. J. Lewis, of University College, Liverpool, were shown and described; and Mr. Moss discussed the age and origin of the peat moors of the southern Pennines.

One of the applications of botanical geography to practical affairs was well illustrated in a valuable paper by the chief engineer of the Liverpool Waterworks, Mr. Parry, who has been the pioneer in the afforestation of the catchment areas of water reservoirs, which has been proved to increase the purity of the water supplied to the citizens and to protect their pockets. Mr. E. D. Morel also discussed a problem in applied geography. He pointed out the value of West Africa for the production of raw cotton, and the results that had been obtained by appealing to the commercial instincts of the natives instead of having recourse to coercion. The importance of a study of native land and administrative systems was emphasised.

Mr. E. A. Reeves read a timely paper on the nature of geographical surveying suited to present requirements, when route charts must be replaced by maps based on surveys planned on scientific lines, while not so elaborate or accurate as large trigonometrical surveys. Mr. E. Heawood contributed the one paper on the history of geography. He discussed the newly discovered maps of Henricus Glareanus, who first described a convenient method for constructing the gores of a globe. One of his maps is the earliest known which shows a hemisphere on an equidistant polar projection.

The geography and education sections held a joint sitting to discuss geographical education. Mr. H. J. Mackinder opened with an eloquent exposition of the regional method of teaching geography and of the possibility of weaving into the regional treatment so much as is needed of other sciences by taking these one at a time in the successive stages of the strictly geographical argument. He submitted that geography could be placed in its rightful position only by the simultaneous application of a four-fold policy:—(1) The encouragement of university schools of geography where geographers should be made, of whom many would become secondary teachers; (2) the appointment of trained geographers as teachers in our secondary schools, either for geography alone or for geography and general help in other subjects; (3) the general acceptance of a progression of method in the subject, not expressed in detailed syllabuses issued by the State or other dominant authority which would tend to stereotype teaching, but in a tradition similar to that which at different times has governed the teaching of language and mathematics; (4) the setting of examinations by expert geographical teachers.

Mr. Hugh Richardson gave a valuable account of how he taught his pupils from thirteen to seventeen years of age the use of maps and books, and insisted on the value of laboratory work on which their books gave little help. Mr. Hewlett spoke of aims and difficulties in the teaching of geography, and Mr. Cloudesley Brereton of geography in secondary education.

In the discussion which followed, the main objections urged against Mr. Mackinder's ideas were that sufficient time was not allowed for carrying them out, and that it was impossible to adopt his suggestion that pupils should be grouped in special sets for the geography lessons. The need for teachers who have had a training in geography, and the value of geography as a coordinating subject in the curriculum, seemed to be recognised by all.

A. J. H.

ENGINEERING AT THE BRITISH ASSOCIATION.

THE section had a lengthy programme to work through at Southport, but it must be confessed that there were but few papers of outstanding importance.

On Thursday, September 10, after Mr. Hawksley's presidential address, which naturally dealt mainly with the problem of the supply of water to cities and villages, a paper was read by Mr. C. A. Brereton on the new King Edward VII. bridge over the River Thames, at Kew. The author showed some interesting lantern slides to explain more clearly the method of construction adopted in previous bridges which crossed the river at this site, and also in the case of the new structure. It was not until 1892 that, induced by the increase in the traffic and the inconvenience caused by the narrowness of the old bridge and the steepness of its gradients, the County Councils of Surrey and Middlesex decided to take steps to replace the bridge by a new one; the necessary Act of Parliament was eventually obtained in 1898, the contract was then let to Mr. Gibb, and the work was begun at once.

The bridge consists of three elliptical arches, the centre one being of rather longer span than the two side arches; it has a span of 133 feet, and a headway of 20 feet above Trinity high-water mark, while the two side spans are only 116 feet 6 inches in span, with a headway of 17 feet. The piers from which these three arches spring are carried down into the solid London Clay at a depth of 18 feet below the bed of the river. The width of the carriage way is 36 feet, and there are 9 feet 6 inch footways on either side; the maximum gradient is only 1 in 40. The whole of the arches, and the exterior of the piers, is constructed of solid granite, chiefly Cornwall and Aberdeen, many of the big stones weighing as much as 8 tons each. To provide for the traffic during the construction of the new bridge, a temporary timber bridge was put up alongside the old one; this was completed in the remarkably short time of six months. The cofferdams for the piers of the new bridge were started in December, 1899, and but little difficulty was met with in their construction. All three arches were constructed simultaneously, and therefore it was necessary for all the stones for the arches to be brought on to the ground before the turning of the arches was commenced; every stone was numbered and placed in the receiving yard ready to take its place in the work. The masonry of the arches was commenced in May, 1902, and completed in December of that year—an extremely expeditious piece of work. The total length of the bridge proper is 502 feet, the approaches on the Middlesex and Surrey sides bringing the overall length to 1182 feet. The bridge was opened by His Majesty the King on May 20 last, having taken about three and a half years to construct; one year was occupied in the construction of the temporary bridge and the removal of the old bridge.

The only other paper dealt with on the Thursday was an interesting contribution by Mr. J. Harrison—illustrations of graphical analysis. The author gave an account of a simple graphical method of obtaining equations for the displacement of the valve, and for the sliding of the block in the link in an ordinary Stephenson's link gear. In fact, it

was a graphical method of analysing a Fourier series, the author's methods being exceedingly neat and handy, but requiring very exact and careful draughtsmanship.

The first paper taken on Friday, September 11, was specially written in order to prepare members for the visit of the section on Saturday to the new Manchester Municipal Technical Institute. Principal J. H. Reynolds gave, with the aid of a number of lantern slides, an interesting account of the construction and equipment of this great technical institute. The author's paper was practically a defence of the methods which have been adopted in connection with the equipment of the engineering and other departments of this Institute; the authorities have been attacked for fitting up their laboratories with unnecessarily complicated apparatus, probably beyond the capacity of the class of students they are likely to have, and it must be admitted that there is some justification for this criticism. Members of the section were better able to form their own opinion on this controversy after the visit on Saturday. As regards the strength of materials laboratory, the machines are those ordinarily employed, with the addition of a very powerful appliance for compression purposes, but as it happens to be extremely simple in construction, being nothing more or less than a modified cotton press, it can be used as easily by students (though its capacity runs into hundreds of tons) as if it were a machine of only a few tons capacity. In the steam engine laboratory, however, there is no doubt that the experimental engine, a fine piece of design due to Prof. Nicolson, is on too big a scale for teaching purposes; it may be an admirable instrument for research in the hands of Prof. Nicolson, and therefore the authorities of the college may be justified in the expenditure which must have been incurred both in the original purchase of this engine and in its working expenses, but for the instruction of the students likely to frequent such a technical institute, it would have been far better to have provided half a dozen engines, each, say, of 10 to 15 horse-power, and each of a different type. The changes in essential points in the design of prime movers of all kinds, and in fact of most machinery, come so rapidly, that if a college is to keep its equipment up to date, it should not be of too expensive a character, as it will be necessary pretty frequently to scrap apparatus, and replace it by newer plant more in accordance with the practice and design of the day. Another criticism which might be offered upon the equipment of the whole college is that too much apparatus has been put in at once; it would have been undoubtedly wiser to have arranged for the equipment to be gradually and steadily increased year by year as the number of students increased, and the demand for such increased apparatus arose.

At the conclusion of this paper, and after a brief discussion, the report of the committee on the resistance of road vehicles to traction was taken, and the committee was reappointed for another year. The work of this committee is of such great importance that it will be desirable to direct attention to this report and the work carried out by the committee a little later on in a special article.

Mr. T. Clarkson's paper on improvements in locomobile design was then read. The author is a strong supporter of steam-driven cars; he claimed that there was greater trustworthiness in the case of steam, more certainty in action, more reserve power, that it would to a great extent render unnecessary expensive change speed gears, and that by the use of liquid fuel, burnt in scientifically designed furnaces, there was no smoke and no trouble from the smell produced during the process of combustion. The paper was full of descriptions of exceedingly clever details, such as an ingenious method of automatically controlling the feed when going down or up hill, the pumping of oil under pressure to lubricate every bearing and every moving part, the use of metallic packing, necessary on account of superheated steam being used in the cylinders, and other ingenious devices. If the steam car is ever to be a formidable rival of the oil-driven car, it will certainly be due to the labours of such indefatigable scientific workers as Mr. Clarkson.

The remainder of the day was devoted to a discussion, opened by Lieut.-Colonel Crompton, on the problem of modern street traffic. Unfortunately the discussion came on so late that many had gone away for the day who might otherwise have taken part in it, and no very practical suggestions were made by any of the speakers except that further attention should be paid to the regulation of slow, heavy traffic. It is, however, after all a moot question whether there is so much street obstruction or so much difficulty with the control of modern street traffic as the daily Press would make us believe. Apart from a few of the main thoroughfares in London itself, there is very little delay in our cities caused by congestion of traffic, except in exceptional circumstances and on exceptional days. Colonel Crompton alleged that electric trams were as slow as the old horse omnibuses; if so, his experience of such trams must be very unfortunate; certainly this is not the experience of most people, and in towns like Glasgow, Manchester, and Liverpool, the introduction of electric traction has certainly much increased the speed at which one can pass from one part of the town to another, and in these cities the problem of street traffic is not complicated as it is in a few of the leading thoroughfares in London by the crawling cab nuisance. Probably without inconvenience to the general public many of the cabs in London might be withdrawn, and certainly by a judicious arrangement of underground tube railways, and by the extension of the electric tramway service, the greater part of the cumbersome, slow-moving, obstructive omnibuses might be driven from the streets, and it is in this direction, rather than in expensive widenings and overhead bridges, that the problem of congestion in the central streets of London will have to be met.

Monday, September 14, was devoted almost entirely to electrical papers. The first of these was one by Mr. W. B. Woodhouse on protective devices for high tension electrical systems. The author, who has had considerable experience in work of this nature, briefly described the necessary protective appliances, such as circuit breakers and the devices for preventing or relieving excessive rises of pressure, which are required in high tension electrical power systems. He described several fuses and switches and overload relays which had been found effective in actual practical operation; as regards switches, he was of opinion that the oil-break switch did break circuit at the moment of zero current, and that for this reason it was the one which should be generally adopted. This paper led to an interesting discussion, in which Mr. G. Kapp and Prof. Ayrton were the chief speakers.

Then followed two papers on aluminium as an electrical conductor, one by Mr. J. B. C. Kershaw and the other by Prof. Wilson. Both authors have been experimenting on the effects produced by exposure of aluminium wires and rods to atmospheric influence. Mr. Kershaw's experiments have been conducted on the Lancashire coast, just south of Southport, and Prof. Wilson's in London, on the roof of King's College. Both experimenters found that the aluminium had suffered considerably; Mr. Kershaw found serious corrosion due to the sea air, especially on the under side of the wires, where drops of water had hung for a long time. Prof. Wilson's experiments were a continuation of an earlier series of tests which were described at a previous meeting, and dealt with the effect of atmospheric corrosion on the conductivity of the metal; the later experiments confirm the results obtained in the earlier ones, namely, that an alloy of aluminium with copper alone was inadvisable for electrical purposes when exposed to the atmosphere, as its conductivity diminished steadily, though more slowly after a time.

Of the other papers taken, the most important was that by Mr. B. Hopkinson on the parallel working of alternators; the paper—a highly technical one—it is impossible to summarise. The author dealt with the practical problem of keeping the oscillations, with their accompanying fluctuations in the flow of energy to or from the main or 'bus bars, within moderate limits, and he treated the matter both from the mathematical point of view and in its practical applications.

On Tuesday, September 15, a lengthy programme was dealt with, and we can only refer to a few of the papers. Mr. W. F. Goodrich, in a paper on twenty-five years' progress in final and sanitary refuse disposal, gave some valuable figures as to the progress which has been made in this branch of sanitary engineering. No less than 180 towns are now using destructors; in 63 of these the steam generated is used in electricity works, and in 40 in connection with the pumping plants of the town sewage works, while in 3 cases the power available is utilised by water-

works pumping engines. As a result of numerous tests it might be roughly estimated that every ton of refuse burnt generated about one ton of high pressure steam, and that with the modern high temperature destructor cells the smell and dust nuisances were practically banished.

Liquid fuel was the subject of Mr. A. M. Bell's communication; much information was given as to the various sources of supply and also as to the best types of oil-burning apparatus, and the author quoted some striking figures obtained in recent tests. In a test at Messrs. John Brown and Co.'s works, 16.09 lb. of water were evaporated per pound of Texan oil burnt, the boiler having an efficiency of 84 per cent.; of course a certain proportion, the author says never more than 3 per cent., of the steam is needed for spraying the oil; with a Stirling boiler, which had an evaporation at standard conditions of 10·55 lb. of water per pound of Welsh coal burnt, the evaporation had been increased to 15·42 lb. per pound of Texan oil, when the furnace was suitably modified for oil consumption. It was pointed out in the discussion that still more economical results could be obtained when this oil was used in internal combustion engines.

Dr. H. R. Mill gave the section some interesting data as to the rate of fall of rain at Seathwaite, and pointed out that in these west coast regions of heavy annual fall the maximum rate of fall was nothing like so great as may occur during heavy summer thunderstorms in drier parts of the country, where it may equal at times 3 inches in the hour.

The last paper of the day was one by Mr. R. Pearson on natural gas in Sussex, and it will astonish most persons to learn what a large amount of gas is now obtained in this district. At Heathfield some eighty houses are using it for lighting and heating purposes, and gas engines utilising it develop a horse-power on a consumption of about fifteen cubic feet of the natural gas per hour. With the development of the Kentish coal-fields and the Sussex gas and oil-fields, both by no means improbable in the early future, there is no doubt that the south-eastern corner of England would undergo an industrial revolution; much as one might regret to see its lovely rural and pastoral character disappear, everyone would welcome the advent of manufacturing industry into this somewhat sleepy corner of the kingdom.

The section had, in consequence of its lengthy programme, to sit on the morning of Wednesday, September 16, when a number of very interesting communications were dealt with. Members of the staff of Messrs. Willans and Robinson contributed two papers—Mr. C. H. Wingfield described experiments on the permanent set in cast-iron as bearing on the design of piston-ring springs, and Mr. Izod a piece of apparatus for testing the brittleness of steel. Both papers are the outcome of the constant experimental research going on in the modern up-to-date engineering workshop, and are a sufficient answer to the reproaches of those who, knowing little or nothing of what they write about, are constantly declaring that trade is leaving the country owing to the apathy and stupid conservatism of our manufacturers. Both communications should be carefully studied by those engaged in the study of the strength of materials.

Mr. W. Odell described some experiments he had carried out to determine the power wasted by the windage of fly-wheel and dynamo armatures, and he stated that a 9-foot disc running at 500 revolutions a minute would absorb about 10 H.P. Mr. W. Cramp read a paper on single phase repulsion motors, a matter of great practical importance in electric tramway work; he claimed that the problem had been solved, and that a single phase alternating current motor had been designed quite equal to a direct current motor.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE anthropological section met in the Town Hall, Southport, under the presidency of Prof. Johnson Symington, F.R.S., of Queen's College, Belfast, and, as usual, attracted large audiences. The programme was a full one, and the principal communications were in the department of Egyptian, Mediterranean, and British archæology, a fact which is partly attributable to the widespread feeling—very clearly expressed by the President of the Association in the course of one of the discussions—that the human sciences, in the older and more academic sense, fall properly within the scope of the Association's work, and merit scientific recognition.

Most important, perhaps, among these new accessions to the section's programme was the group of papers on work in Roman Britain, an area where a subject, which elsewhere can be treated in the full light of written history, has to be explored almost wholly by the methods of prehistoric archæology; and the appointment, with a small grant, of a committee of the Association "to cooperate with local effort on Roman sites in Britain" cannot fail to strengthen both the subject and the section at large.

The president's address, which dealt with the relations between brain and skull, and with the problems which result, has been already printed in full (October 1, p. 539), and gave a broad and philosophic tone to the opening discussion; but the subsequent papers on points of anthropography dealt almost wholly with detailed work of a somewhat specialist kind. Dr. Wm. Wright's account of the skulls from round barrows in east Yorkshire, now in the Mortimer Museum at Driffield, led to the conclusion that the old dictum enunciated by Thurnam—"round barrow, round skull"—is not even approximately accurate for this area, for the cephalic index ranges from 69 to 92, and almost all the European varieties of cranial shape are represented. A marked resemblance, however, was frequently noted between the skulls from any one barrow.

Mr. W. L. H. Duckworth's investigation of the physical anthropology of Crete and Greece, though still incomplete, has brought together a large mass of new material of many periods for the reconsideration of the ethnology of the Ægean area. The bones from the pre-Mycenæan ossuaries of Palæokastro, in eastern Crete, show a purely Mediterranean type, which is shared by those from Mycenæan interments on the Greek mainland; whereas even in Crete, and universally on the mainland, the modern population betrays by its brachycephaly a large admixture of Albanian, Venetic, or Slav intruders. Eastern Crete, however, is more brachycephalic now than the central districts, and this Mr. Duckworth is inclined to attribute to intrusions from Asia Minor. A further grant made by the Association will, it is hoped, enable Mr. Duckworth to continue this very promising inquiry.

Dr. E. J. Evatt's observations on the pads and papillary ridges on the palm of the hand showed that the fœtal disposition of these pads resembles that in the mouse and some other lower animals, which is probably morphologically equivalent. In the adult the pads are to be regarded as vestigial. The papillary ridges are produced by the invasion of the corium by the underlying layer; the interlocking of the two probably serves to connect them more strongly; and the patterns are due to the stresses of prehension acting on ridges which originally lay transversely.

Mr. N. Annandale, in describing a collection of skulls from the Malay Peninsula, noted the great development of the cerebellar part of the occiput, and a widespread abnormality of growth of the third molar.

The committees on a pigmentation survey of the school children of Scotland, and on anthropometric investigations among the native troops of the Egyptian Army, presented interim reports of a formal character. In the latter case the 17,000 measurements already taken cannot apparently be worked up for publication without expert clerical assistance, and it is much to be hoped either that this may be provided without undue delay, or that the committee may see its way to hand over its data to one or other of the biometrical centres which have such assistance at their disposal.

The committee appointed to organise anthropometric research presented a short but very useful report. A single year's work has sufficed to collect and collate the experience of practically all the centres at which anthropometric work is being carried on, as to objects of research, methods, instruments, schedules, and the like, and it is next proposed to inquire under what conditions of maintenance and administration a collection of anthropometric statistics could be established as the nucleus of more systematic investigations. The preface to the report, by Prof. Cleland,

the chairman of the committee, is a valuable summary of the objects and methods of anthropometric work.

The president's brief account of Grattan's craniometric methods illustrates well the need for some such coordination of inquiry as the above-named committee proposes to supply. Grattan's work in radial craniometry, and his very ingenious craniometer, which is now in Prof. Symington's keeping, remained unpublished and unknown until long after similar methods had been rediscovered independently by other workers.

In general ethnography the papers were also few and of various quality. Dr. W. H. R. Rivers's researches on the psychology and sociology of the Todas formed the subject of a committee report, which was supplemented by two papers on special points by the investigator. By the same genealogical method as he employed in Torres Straits, Dr. Rivers has succeeded in unravelling the complicated scheme of kinship and marriage restrictions. This system is of the kind known as "classificatory," every male of an individual's clan being either his grandfather, father, brother, son, or grandson, and so forth. Marriage is regulated by kinship, being prohibited between the children of brothers and between the children of sisters, but being customary between children of brother and sister, and when a girl becomes the wife of a boy she is understood to become also the wife of his brothers. Infanticide certainly was practised formerly, but it is strenuously denied now.

In a separate paper Dr. Rivers described the elaborate ritual of the Toda dairy, in which the dairyman is the priest, and the whole industry endued with a religious character.

The account of the ancient monuments of northern Honduras, &c., presented by Dr. T. W. Gann, described a large number of temples, pyramids, fortifications, underground buildings, monoliths, and ancient enclosures for various purposes, and also the pottery, implements, and ornaments attributable to their builders; with notes on the burial customs and general civilisation of the ancient inhabitants, and observations on the modern ethnography and of the influence of European civilisation on the aborigines.

Dr. J. E. Duerden communicated a note on a type of wooden image which is widely distributed in cave deposits in the West Indian islands.

Miss Pullen Burry's account of the rapid evolution of the Jamaica black gave a favourable picture of the social condition of the negro population. Obeah-worship is practically extinct, peasant-proprietorship has inspired a taste for agriculture, and life and property are safe even in the remoter districts.

Mr. C. Hill Tout and Mr. David Boyle sent papers on the ethnology of the Siciutl Indians of British Columbia and on the Canadian Indians of to-day, but the committee on an ethnographical survey of Canada, of which they are members, presented no report this year.

An account of the legends of the Dieri and kindred tribes of Australia, by Messrs. A. W. Howitt and Otto Siebert, contained much new and valuable matter, but did not lend itself to presentation in full. It will be published shortly in the *Journal* of the Anthropological Institute.

Other papers, of a more or less ethnographical character, raised questions of general importance, and provoked useful discussion.

Mr. W. Crooke's examination of the progress of Islam in India and its causes laid stress on the successful Mohammedan propaganda, which, together with the higher social status of the caste-free Mohammedan, has resulted in considerable conversion of Hindus to Islam, and also on the circumstance that hereditary vigour, maturer marriage, and more varied and invigorating diet tend to make the Mohammedan individual more fertile and more long-lived than the Hindu.

Prof. R. S. Conway, in discussing the ethnology of early Italy and its linguistic relations with that of Britain, dealt almost wholly with the linguistic evidence of early Italian place- and tribe-names, recurring thus, after a considerable interval, to a department of anthropological inquiry which has been overmuch neglected in this section. He distinguished two main sets of ethnics, one ending in -CO the other in -NO. The occurrence of ethnics in -CINO (*i.e.* -NO superimposed upon -CO) shows that the -NO stratum is the later, and its geographical distribution leads Prof. Conway to connect it with the irruption of the northern group of peoples into Peninsular Italy, who had knowledge of iron and buried their dead. To these, contrary to the view of Mommsen and his school, Prof. Conway holds that the *Romani*, or at all events their aristocracy, belonged, and he explains the peculiar geographical distribution of the Italic dialects of Umbria and the Volscian area by the probable effects of this northern invasion, coinciding, as he supposes, in point of time with the Tyrrhenian colonisation of Etruria. He compares the linguistic contrasts which separate the -CO and -NO folk in Italy with those which distinguish Goidels and Brythons in north-western Europe, and suggests that the westward and the southward movements which can be traced are to be referred to the same centre of disturbance.

Mr. D. MacRitchie argued, from the survival of the use of skin-covered canoes in N.W. Europe, to the existence of a racial type of Mongoloid Europeans. It should be noted, however, that one might sit in a skin-covered canoe without having Mongoloid physique.

In contrast with the somewhat meagre output in ethnography, the archæological communications were unusually numerous and attractive.

Mr. Llewellyn Treacher's paper on the occurrence of stone implements in the Thames Valley between Reading and Maidenhead (read also in Section C), and Mrs. Stopes's account of her late husband's collections from implementiferous gravels at Swanscombe, in Kent, summarised much useful work on limited areas. Mrs. Stopes's other paper, on saw-edged palæoliths, submitted a wide induction from copious data; so copious and varied, indeed, that the preliminary question intruded itself whether nature, as well as man, had not some hand in their preparation.

Mr. Annandale was on safer ground in his collection of survivals of primitive implements in the Faroes and Iceland, and exhibited a great variety of types. Their distribution is by no means uniform, those found in the Faroes being generally absent from Iceland, and *vice versâ*. Mr. Annandale suggests that this may be due to differences in the history of the original settlers in the two areas.

A paper by Mr. G. Clinch described the megalithic monument of Coldrum, in Kent, which comprise a central cromlech, without capstone, but with a double chamber, and an irregular line of large blocks of stone on the western side, with traces of a tumulus. No excavation has been attempted as yet, and the monument is partly destroyed by a cart-way, but the author compares it with a larger megalithic structure, of Neolithic date, at Sievern, in Hanover, and concludes in favour of a late Neolithic date for Coldrum. He lays stress on points of similarity which he detects between Coldrum and Stonehenge. Discussion and criticism were impaired in this, as in some other cases, by the absence of the author.

Mr. H. Balfour gave an account of a model of the Arbor Low stone circle, which had been prepared by Mr. H. St. G. Gray as the outcome of the recent excavation of this monument by a committee of the Association. It would be well if every such excavation were so conducted as to permit a similar reproduction for convenient reference hereafter.

Prof. W. Ridgeway offered a suggestive theory of the origin of jewellery, namely, that mankind was led to wear such objects by magic rather than by æsthetic considerations.

All peoples value for magical purposes small stones of peculiar form or colour long before they can wear them as ornaments; *e.g.* Australians and tribes of New Guinea use crystals for rain-making, although they cannot bore them. So, in Greece, the crystal was used to light sacrificial fire, and was so employed in the Church down to the fifteenth century. The Egyptians under the twelfth dynasty used it largely, piercing it along its axis. From this bead came the artificial cylindrical beads made later by the Egyptian, from which modern cylindrical glass beads are descended. The beryl, a natural hexagonal prism, lent itself still more readily to the same form, and the cylinders found without any engraving on the wrists of the dead in early Babylonian graves had a similar origin. The Orphic Lithica gives a clear account of the special virtue of each stone, and it is plain that they acted chiefly by sympathetic magic. The Greeks and Asiatics used stones primarily as amulets, and to enhance the natural power of the stone a device was cut on it. The use of the stone for sealing was simply secondary, and may have arisen first for sacred purposes.

Shells are worn as amulets by modern savages, *e.g.* cowries in Africa; red coral is a potent amulet worn by travellers by sea; pearls are a potent medicine in modern China; seeds of plants are medicine everywhere; and the claws of lions are worn as amulets all through Africa, and are "great medicine," and imitations of them are made.

When gold becomes first known it is regarded exactly like the stones mentioned. Thus the Debæ, an Arab tribe, who did not work gold, but had abundance in their land, used only the nuggets, stringing them for necklaces alternately with perforated stones.

Magnetic iron and hæmatite were especially prized, the power of attraction in magnetic iron, as in the case of amber, causing a belief that there was a living spirit within. Hence iron in general was regarded with peculiar veneration, and not because it was a newer metal, as is commonly stated.

In a paper on the origin of the brooch, and the probable use of certain rings at present called "armlets," Mr. E. Lovett suggested, as the prototype of the ring-and-pin contrivance for fastening a cloak, the use, by a hunting people, of the mammalian *Os innominatum* and *Os calcis*. He noted, further, that very many rings of early date, usually described as "armlets," are too small to allow the entrance of a hand. As such rings are frequently found associated with pins of similar materials, commonly regarded as "hair-pins," and as ring and pin are sometimes found *in situ* on the breast of a skeleton, he infers that they represent a simple ring-and-pin fastening of the kind described above. An apron-fastener of this type, composed of an iron ring and a horse-shoe nail, is still worn in some of the blacksmith's shops in Scotland. The next step of development follows when the pin is perforated at the thick end and attached to the ring by a fibre to prevent it from being lost. This stage is actually represented in China. A further step is taken when the pin itself is hinged upon the ring, for security, by bending its flattened head round the ring, a form which is abundant in Celtic times. The inconvenience which accompanies the ring-and-pin brooch, that the fabric must be drawn so far through the ring, was remedied by leaving a gap in the ring; the "penannular" brooch results.

Miss Bulley exhibited a number of examples of crosses, chiefly Celtic, and traversed familiar ground in inferring from them the existence of a distinct type of symbol in which a circumscribed circle is of equal importance with the cross itself. Coptic and Syrian crosses show the same type as the Celtic, though not so markedly. The subject, if treated at all, needs much more thorough examination.

Mr. John Garstang's account of Egyptian burial customs summarised the results of his discovery of a necropolis of the Middle Empire (about 2200 B.C.) at Beni-Hasan, in Upper Egypt, which contained burying places of minor officials and distinguished women, and illustrated the funeral ritual of the middle classes of the locality. These tombs are not large enough for mural decoration, but they are furnished with numerous wooden models—boats, granaries, and men and women engaged in field-work and household duties—which explain many points connected with the burial of the dead. The objects seem to have borne no relation to the profession of the deceased, but are simply of religious motive—the elaborate provision for a future journey.

Dr. C. S. Myers described the antiquities of Kharga in the Great Oasis, which include a well-preserved temple of Hibis, which is one of the most important monuments of the Persian dynasty in Egypt, and an early Nestorian necropolis, with streets of tombs and funeral chapels of unburnt brick, plastered and frescoed with symbolic ornament and Biblical scenes.

Prof. Flinders Petrie summarised the principal results of his recent excavations at Abydos in two demonstrations entitled "The Beginning of the Egyptian Kingdom" and "The Temples of Abydos." The discovery of the prehistoric age of Egypt, and its division into regular sequences of remains, fills up a period of more than 2000 years before the establishment of the dynastic *régime*, and reveals a wealthy and elaborate civilisation which was already decadent when it was overthrown by the dynastic conquerors. Five different types of man can be distinguished in pre-dynastic times, one of which Prof. Petrie is inclined to identify as Libyan, and akin to a characteristic type in early Greece. The connection of the close of the prehistoric scale of sequences with the early kings has been closely settled by the pottery, and its history shown in the stratified ruins of the earliest town of Abydos; four of the ten kings' names have been found of the dynasty which preceded that of Menes, and also the names of all the eight kings of the dynasty of Menes himself. The growth of the use of writing can be traced on the seals, and the æsthetic revolution which accompanied the establishment of the dynastic kingdom is seen to lead directly to the fixed artistic types which dominate Egypt thenceforward. The Royal tombs likewise are traced in sequence of elaboration from the prehistoric pit grave, first to the brick *mustaba*, and then to the stone-built pyramid of the third dynasty.

At Abydos, on the site of the Osiris temple, ten successive shrines of earlier dates have been unearthed through a depth of 20 feet of soil; the latest is that of Amasis, of the twenty-sixth dynasty, and the earliest that of the first. The principal results were of the last-named period, and included a remarkable school of fine ivory carving, and striking examples of two-colour glazing.

The liberal support which the Association has given throughout to British exploration in Crete was more than justified by the reports of the last season's work. Mr. Duckworth's anthropographic inquiry has been noted already; Dr. Arthur Evans gave a full account of his latest discoveries in the Palace of Knossos, and Messrs. Bosanquet and Myres described the excavation of a pre-Mycenæan town and sanctuary at Palaikastro, in eastern Crete, conducted by the British School of Archæology in Athens, and supported, like the work at Knossos, by the Cretan Exploration Fund.

At Knossos the year's campaign, which was expected to conclude the excavation, took a wholly unlooked-for development, in the discovery, first, of a north-west wing of the palace, including a rudimentary theatre formed by converging staircases, not unlike that found already in the Palace of Phæstos; second, of a detached house to the north-east, with much fine pottery, and a remarkable columnar hall with a *tribuna* and apse at one end, which appears to anticipate the features of the later *basilica*; third, of many scattered deposits between and below the floor levels of the palace, which serve to elaborate and explain the detailed chronology of the whole mass of buildings. One of these deposits, found near the east pillar-room, contained a quite unparalleled accumulation of native-made figurines in a kind of Egyptian glaze-ware, the débris of a sanctuary dedicated to a snake-goddess. In the same deposit occurred also a remarkable marble cross, which seems to have been the central aniconic object of the shrine, and examples of a fresh form of linear script. In view of these important results, it becomes necessary to complete the investigation of the ground below the later floors throughout the palace, as well as to continue the search for the Royal tombs, which has hitherto only led to the discovery of a late and much plundered necropolis to the northward.

At Palaikastro the settlement discovered in 1902 proves to be a considerable town of regular plan, dating from the later Minoan period, with extensive Mycenæan rebuildings. The detailed finds indicate widespread commerce from Egypt to Lipari, and considerable prosperity and comfort at home. The preponderance of submarine subjects in the decorative art suggests that the persistent Cretan sponge industry was already of importance, and a visit paid by Mr. Bosanquet to the island of Kouphonisi, off the south-east coast of Crete, proved the existence of an extensive and clearly pre-Phœnician purple fishery, going back into Minoan times. The pre-Mycenæan sanctuary explored by Mr. Myres on the hill overlooking Palaikastro yielded a remarkable series of votive terra-cottas, and much new evidence as to pre-Mycenæan costume.

The papers on Roman Britain, already mentioned, were as follows:—

Mr. T. Ashby, jun., gave a retrospect of excavations at Caerwent, in Monmouthshire (1899–1903), on the site of the Romano-British city of Venta Silurum, which a recently discovered inscription shows to have been the administrative centre of the Silures in Roman times. The external walls are clearly traceable, with three gates partially preserved, and an inner earthwork which seems to have been the original fortification. The buildings within are chiefly private houses, sometimes wholly enclosing a rectangular

courtyard, an arrangement which is unique in England. Some interesting mosaics have been found, and near the north gate the remains of an amphitheatre *within* the city walls.

Mr. John Garstang described the Roman fortress Bremettenacum (Ribchester), to which an excursion was made in the course of the meeting. Excavations made in 1898–9 have shown that this station was one of a series of fortresses which, with the wall of Hadrian, formed the northern frontier defences of Roman Britain. It is entirely of the earlier character, severely rectangular, with internal buttresses, mural towers, and double-arched gates, and filled within with rows and streets of stone-built barracks and stables.

Mr. Garstang also gave a preliminary account of the Roman fort at Brough, where exploratory excavations have been made quite recently. Like Ribchester, it belongs to the earlier type of fort, and was situated in the favourite position at the junction of two streams. In clearing a deep enclosure within the walls, two inscribed altars were found, and portions of a large inscribed tablet set up by a Præfect of the First Cohort of Aquitani under Julius Verus, Governor of Britain in the time of Antoninus Pius.

The committee on excavations on the Roman site at Gellygaer, near Cardiff, reported that the work was now completed, the results published, and the movable finds installed in the Cardiff Museum.

The committee appointed to report on the excavations at Silchester summarised the last season's work, and strongly urged that, in the small part of the site which remains to be explored, special care should be taken to secure accurate registration of the stratification (if any exists) of the smaller finds, and to investigate the relation in which the rectangular street plan stands to the irregular trapezium of the town wall.

As a result of this and similar recommendations, the Silchester committee of the Association has been reconstituted as a committee "to cooperate with local effort on Roman sites in Britain," and starts work anew with a small grant, to be expended in facilitating special researches of the kind suggested at Silchester, on sites where local or other subscriptions are already providing the funds for a general exploration. The opportunities for work already offered at Silchester on the plant-remains, the frequent occurrence on Roman sites of animal or human bones which need special precautions and expert examination, and the necessity for more detailed and accurate registration of the smaller finds than has been customary hitherto, even in the best conducted excavations, are examples of classes of observation which are only too liable to be neglected by local explorers, and the committee will be doing good service if it can secure for them the attention which they deserve.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—An examination in mathematics and physics will be held at St. John's College on March 16, 1904, for the purpose of electing a fellow in those subjects. Candidates will be given an opportunity of showing their knowledge of experimental physics. All persons are eligible who shall have passed all the examinations required for the degree of Bachelor of Arts on the day of election (April 20).

CAMBRIDGE.—The general board of studies has issued a report proposing a more comprehensive organisation of geographical studies and examinations in the university. The proposals include the establishment of a board of geographical studies, a geographical education fund, to which the university and the Royal Geographical Society each contribute 200*l*. a year, a special examination in geography for the ordinary B.A. degree, and a diploma in geography for advanced work in the subject. The stipend of the reader in geography is fixed at 200*l*., and his lectures and those of the other teachers to be employed will be under the direction of the board, on which the council of the Royal Geographical Society will be represented.

A memorial urging the desirability of some similar organisation of anthropological study has been presented by thirty members of the senate, and is at present under the consideration of the council.

Twenty-two candidates have passed the half-yearly examination in sanitary science, and have thus become entitled to the university diploma in public health.

On October 21, 886 freshmen, including 13 "advanced students," were matriculated. The corresponding number for last year was 868.

Mr. F. F. Blackman, St. John's, has been appointed deputy for the reader in botany, Mr. F. Darwin, F.R.S.

The Ven. E. H. Gifford, D.D., senior classic and fifteenth wrangler in 1843, has been elected an honorary fellow of St. John's College.

The grace for the establishment of the Stokes lectureship and the Cayley lectureship in mathematics, for which a temporary endowment was recently offered to the university by certain anonymous donors, will be offered to the senate to-day (October 29).

MR. R. J. T. BRYANT, Leyton Technical Institute, has been appointed organiser of higher education to the Borough of Lowestoft.

IT is stated in the *Petit Journal* that Harvard University has come into possession of a legacy of about 5,000,000*l*., the whole of the estate of the late Mr. Gordon Mackay.

ON the invitation of Yale University, Prof. Sherrington, F.R.S., of Liverpool University, has undertaken to deliver the second series of Silliman memorial lectures next year.

PROF. H. S. HELE-SHAW, F.R.S., has been appointed, through the Colonial Office, to organise technical education in the Transvaal and the Orange River Colony, and to consider the future university scheme of these colonies. The appointment is not a permanent one, and Prof. Hele-Shaw has been granted leave of absence by the council of the University of Liverpool until September next.

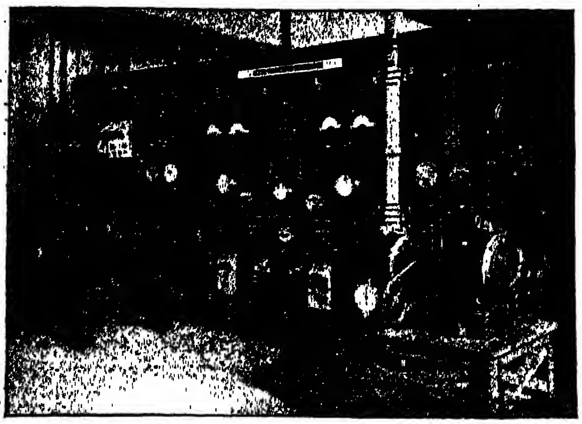
THE County of Essex Education Committee announces that an elementary course of instruction in dairy bacteriology will be given in its biological laboratories at Chelmsford. The course will commence on Thursday, November 5, and will be continued on the ten succeeding Thursdays. The course seems to be a comprehensive one, and should be of considerable value. Normal classes for the training of teachers in natural and experimental science have also been instituted by the committee at Chelmsford. These classes are intended for the practical instruction and training of persons resident in Essex who desire to qualify themselves to teach under the County Council. The classes meet on Saturdays from 10 to 5 o'clock during the winter months.

THE inaugural address to the students of the medical department of University College, Sheffield, was delivered by Sir Michael Foster, K.C.B., on October 15. He directed attention to the variety and complexity of the studies considered necessary for medical students; and he remarked that the question whether the burden was becoming too great for the student, and what things in the curriculum could with advantage be thrown on one side, must be considered, for the least important subjects would have to give way in the future.

THE Home Counties Nature-Study Exhibition will be opened in the offices of the Civil Service Commission, Burlington Gardens, W., to-morrow, October 30, at 3 p.m. Lord Avebury will preside. Admission tickets at special rates can be obtained by teachers and pupils by application to the honorary secretary, Mr. W. M. Webb, 20 Hanover Square, W. The programme includes conferences for teachers on practical methods of nature-study in elementary and secondary schools. The latest scientific developments of the Urban-Duncan microbioscope will be shown on the evenings of Friday and Saturday, and well-known lecturers on natural history subjects, such as Mr. Douglas English, Mr. Richard Kearton, Mr. R. B. Lodge, and Mr. Oliver Pike will give addresses from time to time, and exhibit their slides during the exhibition. Special meetings of the Middlesex Field Club and Nature-Study Society and of the Selborne Society will be held at the exhibition on Monday and Tuesday.

WE have received an admirably illustrated booklet describing the Montefiore Electrotechnical Institute of the University of Liége, and containing a programme of the courses of instruction. In glancing through the illustra-

tions, one is struck by the excellence of the equipment of the laboratories and workshops. We reproduce on a reduced scale an illustration showing the installation for the study of synchronous motors and problems connected with the paralleling of alternators. The character of the wiring is a noticeable feature; the switchboard looks more like a diagram than an actual board, having all the leads plainly visible and easily accessible, which must prove a considerable advantage in teaching and experimental work. The apparatus and machinery installed cover practically the whole field of electrotechnical measurements, a separate



One of the laboratories at the Montefiore Institute.

installation, complete in itself, being provided for the study of each branch. In addition to these "industrial laboratories" there are well-equipped standardising laboratories, chemical and photometric laboratories, drawing offices, and lecture theatres. Altogether the institution appears to be thoroughly equipped for teaching electrical technology.

SOCIETIES AND ACADEMIES.

Manchester.

Literary and Philosophical Society, October 6.—Prof. W. Boyd Dawkins, president, in the chair.—Dr. Henry **Wilde**, F.R.S., read a paper on the resolution of elementary substances into their ultimates and on the spontaneous molecular activity of radium. The author referred to several of his papers published by the Society on the genesis of elementary substances and on the multiple proportions of their atomic weights, wherein certain gaps appeared in the several series in his tables, which have since been filled up by scandium, germanium, helium, argon, neon, krypton and xenon. The remarkable properties of radium were held to represent further realisations of the predictions made in the author's earlier papers. The author had previously indicated the interruption in the regularity of his multiple series $H2n$ through the absence of elements of atomic weights 160 and 184 respectively. As there is only one place vacant higher in this series for an analogue of calcium, strontium and barium, radium was identified by the author as the tenth elementary condensation of $H2n$, with an atomic weight of 184, and a specific gravity of 4·8, as shown in his tables. The author had shown in former papers that helium was the unknown typical molecule of the same series, with an atomic weight of 2, and had previously indicated the probability of the resolution of the higher members of each series into their elementary typical molecules. The production of helium from radium by Profs. Rutherford, Soddy and Ramsay confirmed the author's prevision in the case of the series $H2n$, and this result may lead to the resolution of the higher members of other series into their ultimates.—Fossil plants from the Ardwick series of Manchester, by Mr. E. A. Neville **Arber**. The author has carefully reinvestigated the fossil plants from the Ardwick series of rocks collected by the late Mr. Binney, and which are now in the University Museum of Cambridge. He has also examined the numerous fossil plants from this series in the Manchester Museum, and has come to the conclusion that the Ardwick series of rock does not belong, as stated, to the Upper Coal-measures, but forms a definite transition series between the Upper and Middle Coal-measures of Lancashire. Such a transition series has been already recognised in the Coal-measures of South Wales, Somerset, and Staffordshire.

October 20.—Prof. W. Boyd Dawkins, president, in the chair.—Mr. Henry **Sidebottom** read a paper on recent Foraminifera from the coast of the island of Delos, in which he enumerated some seventy species of Miliolidæ, including four new species and several interesting variations. The new species and variations were fully described, and drawings both of the specimens and their sections exhibited. Mr. Sidebottom stated that the dredgings from this locality were extraordinarily rich in Foraminifera.

Paris.

Academy of Sciences, October 19.—M. Albert Gaudry in the chair.—On the state of vaporised carbon, by M. **Berthelot**. At a temperature of 1200°–1500°, carbon possesses an appreciable vapour pressure, which is so small that, even after several hundred hours in a vacuum, the amount vaporised amounts only to a few milligrams. This carbon is amorphous, and contains no trace either of diamond or graphite.—On the periods of double integrals and their relations with the theory of double integrals of the second species, by M. Émile **Picard**.—On the estimation of argon in atmospheric air, by M. Henri **Moissan**. Pure metallic calcium, prepared by a method previously described by the author, is used to absorb the nitrogen; this metal also absorbs the traces of hydrogen which are always present if a mixture of lime and magnesium powder has been used in the preliminary treatment. Samples of air from various sources gave, with one exception, very concordant figures between 0·931 and 0·938 per cent. by volume, the exception being a sample of air taken on the Atlantic, which gave 0·949 per cent.—On the products of condensation of tetramethyldiamidophenyloxanthranol with benzene, toluene, and dimethylaniline, by MM. A. **Haller** and A. **Guyot**.—On the acclimatisation and culture of pintadines, or true pearl oysters, on the coasts of France, and on the forced production of fine pearls, by M. Raphaël **Dubois**. Successful experiments have been carried out with *Margaritifera vulgaris*, which has been acclimatised and made to yield pearls which, although small, are of good quality.—On linear equations of finite differences, by M. Alf. **Guldberg**.—On a reflection refractometer, by M. Th. **Vautier**. An interference refractometer composed of three mirrors is described, allowing of the complete separation of the two interfering light bundles.—On the composition of zinc peroxide, by M. **Kuriloff**. The only definite peroxide of zinc appears to be $ZnO_2.Zn(OH)_2$.—The phagocyte organ of the crustacean decapods, by M. L. **Cuénot**.—On the phases of folding in the French intra-alpine zones, by M. W. **Kilian**.—The part played by compression in the localisation of the tendons, by M. R. **Anthony**.—On the relations existing between the Surra and the Nagana, according to an experiment of Nocard, by MM. **Vallée** and **Carré**. The authors confirm the views of MM. Laveran and Mesnil as to the non-identity of Surra and Nagana.—Parthenogenesis and treatment of rheumatism, by M. L. **Pénières**.—Experimental researches on the sense of smell in the old, by M. **Vaschide**. In old people the sense of smell is better preserved in women than in men, but in all cases there is a marked diminution in olfactory sensibility due to age.

New South Wales.

Royal Society, August 5.—Mr. F. B. Guthrie, president, in the chair.—The economic effects of sanitary works, by Mr. J. Haydon **Cardew**. The principal object of the paper was to give municipal and health authorities some basis to work upon in devising sanitary services and forecasting their economic effects.—On the protection of iron and other metal-work, by Mr. William M. **Hamlet**. The author dealt with an investigation of the causes of the rapid rusting away of the iron casing at one of the Australian artesian bores, where abundance of carbonic acid gas was evolved at 100° F.; the water also contained alkaline carbonates and bicarbonates with sodium chlorides, silica, &c., amounting to between thirty and forty grains of total solid matter to the gallon. Probably a specially hard and resistant alloy

will be required to stand the prolonged and severe action of the water in question.—On the elastic radial deformations in the rims and arms of flywheels, and their measurement by an optical method, by Mr. A. **Boyd.** In this paper actual measurements of the deflections of the rims during rotation were given, so that the shape of the rim at any speed within the elastic limit of the material could be seen. The flywheels tested were of different design. The curves for a curved armed wheel showed a large inflection between the arms, the maximum deflection being close to the arms. The tests on four armed wheels showed very clearly the great advantage of having the joint along the arms, the effect of the joint in a four-armed wheel, jointed along the arms, being in fact almost negligible.—The aboriginal fisheries at Brewarrina, by Mr. R. H. **Mathews.**

September 2.—Mr. F. B. Guthrie, president, in the chair.—The following papers were read:—The separation of iron from nickel and cobalt by lead oxide (Field's method), by Mr. T. H. **Laby.** An inquiry into the accuracy of Field's method, as it has distinct advantages over methods commonly in use, viz. a *single* precipitation of the iron, and the absence, after the removal of added lead, of all reagents, such as sodium or ammonium salts. Combined with the electrolytic determination of nickel or cobalt, the method becomes rapid. Standard solutions of carefully purified iron, nickel, and cobalt nitrates were prepared. With these solutions twenty-two analyses were made, showing a recovery of more than 99 per cent. of nickel and cobalt.—Pot experiments to determine the limits of endurance of different farm-crops for certain injurious substances, part ii., maize, by Messrs. F. B. **Guthrie** and R. **Helms.** The authors communicated the results of experiments having for their object the determination of the tolerance of maize for sodium chloride, sodium carbonate, ammonium sulphocyanide, sodium chlorate, and arsenious acid.—Bibliography of Australian lichens, by Mr. E. **Cheel.**—On the Narraburra meteorite, by Prof. **Liversidge,** F.R.S. A general account of the characteristics of this metallic meteorite, weighing more than 70 lb., which was discovered in 1855 on the Yeo Yeo Creek, twelve miles east of Temora, N.S. Wales.

Linnean Society, August 26.—Dr. T. Storie Dixson, president, in the chair.—Studies in Australian entomology. No. xii. New Carabidæ (Panageini, Bembidiini, Platysmatini, Platynini, Lebiini, with revisional lists of genera and species, some notes on synonymy, &c.), by Mr. T. G. **Sloane.**—Revision of the Australian Curculionidæ belonging to the subfamily Cryptorhynchides, part vi., by Mr. A. M. **Lea.**—Notes on *Byblis gigantea*, Lindl. [N.O. Droseraceæ], by Mr. Alex. G. **Hamilton.**

DIARY OF SOCIETIES.

SATURDAY, OCTOBER 31.

ESSEX FIELD CLUB, at 6.30.—Exhibition of a Series of Photographs of Fungi, by means of the Lantern: Mr. Somerville Hastings.—Seed Dispersal: Prof. G. S. Boulger.

MONDAY, NOVEMBER 2.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—On the Application of the X-Rays to the Examination of "Safety Fuses": C. Napier Hake.—Scarlet Phosphorus—A New Chemically Active Variety of Red Phosphorus, and its Use in the Manufacture of Matches: Drs. Marquart and Schulz.—New Compound of Phosphorus for the Production of Matches: F. Bale.—Densities of Concentrated Nitric Acid at different Temperatures: Prof. V. H. Veley, F.R.S., and J. J. Manley.—On a Comparison of Different Types of Calorimeters: J. S. S. Brame and Wallace A. Cowan.

TUESDAY, NOVEMBER 3.

ZOOLOGICAL SOCIETY, at 8.30.—On some New Species of Aquatic Oligochæta from New Zealand: Prof. W. B. Benham.—List of the Mammals collected by Mr. A Robert at Chapadá, Matto Grosso. (The Percy Sladen Expedition to Central Brazil): Oldfield Thomas, F.R.S.—List of the Coleoptera collected by Mr. A. Robert at Chapadá, Matto Grosso. (The Percy Sladen Expedition to Central Brazil): C. J. Gahan and G. J. Arrow.

WEDNESDAY, NOVEMBER 4.

GEOLOGICAL SOCIETY, at 8.—Metamorphism in the Loch Lomond District: E. H. Cunningham-Craig.—On a New Cave on the Eastern Side of Gibraltar: Henry Dyke Acland.

ENTOMOLOGICAL SOCIETY, at 8.—On some Aberrations of Lepidoptera: Percy I. Lathy.

SOCIETY OF PUBLIC ANALYSTS, at 8.—On the Salinity of Waters from the Oolites: W. W. Fisher.—Notes on (1) Some Indian Oils; (2) Differentiation of Linseed Oil from Boiled Oils: Dr. J. Lewkowitsch.—Note on the Purification of Hydrochloric Acid and Zinc from Arsenic: Dr. L. T. Thorne and E. H. Jeffers.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Northern Nigeria: Sir Frederick D. Lugard, K.C.M.G.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 5.

CHEMICAL SOCIETY, at 8.—Conductivity of Substances Dissolved in Certain Liquefied Gases. Preliminary Notice: B. D. Steele and D. McIntosh.—The Reduction of Hydrazoic Acid: W. T. Cooke.—The Behaviour of Metallic Oxides towards Fused Boric Anhydride: C. H. Burgess and A. Holt, Jun.—Some Reactions of Vanadium Tetrachloride: B. D. Steele.—Studies on Comparative Cryoscopy. Part I.: The Fatty Acids and their Derivatives in Phenol Solution: P. W. Robertson.—The Vapour Pressures of Sulphuric Acid Solutions. Preliminary Note: B. C. Burt.—The Viscosity of Liquid Mixtures. Preliminary Note: A. E. Dunstan and W. H. C. Jemmett.—Additive Compounds of s Trinitrobenzene and Alkylated Arylamines: H. Hibbert and J. J. Sudborough.—A Contribution to the Study of the Reactions of Hydrogen Peroxide: J. McLachlan.—The Constitution of Certain Silicates: C. Simmonds.—Constitution of Ethyl Cyanacetate. Condensation of Ethyl Cyanacetate with its Enolic Form: P. Remfry and J. F. Thorpe.—Interaction between Chloric and Hydriodic Acids: J. McCrae.—3:5:-Dichloro-1:1:2-Trimethyldihydrobenzene. A Correction: A. W. Crossley.—The Estimation of Hydroxylamine: H. O. Jones and F. W. Carpenter.—A Study of the Isomerism and Optical Activity of Quinquevalent Nitrogen Compounds: H. O. Jones.—The Action of Water and Dilute Caustic Soda Solutions on Crystalline and Amorphous Arsenic: W. T. Cooke.—The Union of Carbon Monoxide and Oxygen, and the Drying of Gases by Cooling: A. F. Girvan.

RONTGEN SOCIETY, at 8.30.—President's Address.

LINNEAN SOCIETY, at 8.—On the Structure of the Leaves of the Bracken, *Pteris aquilina*, in relation to environment: L. A. Boodle.—On the Life-history of a New Monophlebus from India, with a Note on that of a Vedalia predaceous upon it; with Remarks on the Monophlebinæ of the Indian Region: E. P. Stebbing.

FRIDAY, NOVEMBER 6.

GEOLOGISTS' ASSOCIATION, at 8.—Conversazione at University College.
